Major Rehabilitation Evaluation Report

Columbia River at the Mouth, Oregon and Washington

Major Rehabilitation of the Jetty System at the Mouth of the Columbia River

Brubaker Aerial Survey, *Mouth of the Columbia River from Pacific Ocean* (1929).
Collection: National Archives, Pacific Alaska Region.

June 2012 Final

(This Page Intentionally Left Blank)

Executive Summary

The mouth of the Columbia River (MCR) jetty system is in a state of structural decay. Continued deterioration, ongoing storm activity and the continued loss of sand shoal material—the foundation of each of the three MCR jetties—has positioned the jetty system for a series of frequent, costly emergency repairs. Consequently, significant modifications and repairs to the MCR jetties are necessary for the continued safe entry of ships into the Columbia River navigation channel.

Functioning jetties at the MCR support the following:

- $20 billion in international trade
- 42 million tons of cargo
- 3,500 Cargo Vessel crossings per year
- 1,400 crossings requiring more 30-foot draft or greater
- More than 40,000 jobs dependent on this trade

According to the Center for Economic Development and Research, the Columbia/Snake River navigation system is the number one export gateway for the Nation's wheat and barley exports. It is also the number one export gateway for west coast wood and mineral bulk exports and number one for automobile imports. Marine traffic passing the entrance of the Columbia River has increased by 34% from 32 million tons in 2003 to 42 million tons in 2010. All of this translates into significant benefits for not only the Pacific Northwest, but also for the national economy. The Columbia River comprises the M-84 Corridor for the Marine Highway Program. It is noted by the US Department of Transportation as a truck bottleneck resulting in up to 750,000 truck delay hours and an area of major rail congestion. The marine highway serves to reduce the congestion

The primary function of the MCR project is to maintain the navigation channel for deep draft shipping. The secondary function evaluated in the structure rehabilitation effort is to significantly extend the life and reliability of the jetties in order to ensure the primary function.

The MCR jetty system consists of three rubble-mound jetties, with a total originally authorized length of 10.2 miles, constructed from 1885-1939 on massive tidal shoals to secure consistent navigation through the coastal inlet. The inlet morphology has been changing ever since. After decades of storm activity, the tidal shoals of each jetty's foundation have been modified due to erosion.

An analysis was completed that evaluated the causes and problems associated with the current structural instability of the MCR jetty system. This analysis resulted in a recommendation to improve structural reliability, to extend functional life, and most significantly, to maintain deep-draft navigation. Each of the three jetties was analyzed independently in order to define the scope of this major rehabilitation effort. The evaluation report outlines the coastal processes affecting jetty reliability, summarizes the sequence of events leading to the present condition of the jetties, and describes their structural condition. A risk-based, life-cycle analysis was used to examine jetty performance (past and future) and develop jetty modification alternatives through a phased strategy for jetty repair.

Beaches on the ocean sides of the North and South jetties, formed originally as a result of jetty construction, have been receding and thus exposing previously protected jetty sections to storm waves at the beach line. In the absence of specific and immediate repair actions, the jetties and sand shoals upon which they rest will further deteriorate, increasing the likelihood of a jetty breach and immediate impact to the navigation channel and commercial deep draft access to the Columbia River port facilities. Recent interim jetty repairs have addressed some of the immediate critical needs. For example, in 2007 approximately $19M was expended on repairs to the South Jetty. Additional jetty repairs will be necessary to address critical near- and long-term maintenance needs and to reduce the potential need for emergency repairs and/or emergency dredging and the impacts that result to navigation.

Development of this report applied the recent *Lessons Learned* resulting from Hurricanes Katrina and Rita. They are as follows:

Point 1 – Employ Integrated, Comprehensive and Systems-Based Approach
Point 2 – Employ Risk-Based Concepts in Planning, Design, Construction, Operations and Maintenance
Point 3 – Continuously Reassess and Update Policy for Program Development, Planning Guidance, Design and Construction Standards
Point 4 – Dynamic Independent Review
Point 5 – Employ Adaptive Planning and Engineering Systems
Point 6 – Focus on Sustainability
Point 7 – Review and Inspect Completed Works
Point 8 – Assess and Modify Organizational Behavior
Point 9 – Effectively Communicate Risk
Point 10 – Establish Public Involvement Risk Reduction Strategies
Point 11 – Manage and Enhance Technical Expertise and Professionalism
Point 12 – Invest in Research

The major rehabilitation approach for the MCR jetty system is focused on defining the larger processes affecting the jetty system and then describing the jetty system degradation and reliability over time. Frequency and consequences of future jetty repairs, as well as potential impacts to dredging and navigation, were evaluated using a planning model.

Initially, the base condition involved a "fix-as-fails" approach where each jetty was allowed to degrade to as low as 20 percent of the originally authorized cross section and therefore breaches were forecasted. An Independent External Peer Review (IEPR) comment stated that this was an unrealistic assumption. Upon further consideration, the Portland District changed the base condition to reflect the most likely future jetty maintenance strategy of interim repair.

Due to the level of construction and the high mobilization costs, the revised base condition described in this report does not include any jetty head re-construction. Only the trunk and the root of the jetty are maintained, and the jetty head is allowed to recede landward. The base condition is identified as an interim repair approach because the upper portion of the cross section is allowed to be damaged to approximately 35 percent of the remaining cross-section above -5 MLLW prior to repair actions being taken. In this way, the jetty is maintained close to the margin of functional loss without breaching.

The South Jetty dune augmentation at the root of the South Jetty is part of the base condition and will be implemented regardless of the outcome of the MCR Jetties Major Rehabilitation project. Within a broad assessment it was determined that consequences of a breach would be high enough to warrant preventive measures now, independent of any jetty repair activity. In addition, the FY 11 *Major Maintenance Report* (MMR) actions are part of the *Major Rehabilitation Report* (MRR) base condition: North Jetty lagoon fill between stations (STA) 20 to 60; and North Jetty critical repairs between STA 86 to 99.

In this report, the MRR, three basic with-project implementation alternatives were developed and considered for the MCR jetties: scheduled repair, immediate rehabilitation, and scheduled rehabilitation. Alternatives for each jetty were considered to occur either through scheduled, predetermined time and place, or on a monitor-and-repair basis for locations where a stochastic model predicted jetty repair or breach locations or both.

For the North and South jetties, the repair alternative included repair combined with and without engineering features (head capping and spur groins). For the repair alternative, stone placement is generally limited to the above-water jetty sections and remains within the limits of the existing jetty and relic stone structures.

Rehabilitation alternatives generally incorporated engineering components necessary to increase the reliability of the current structure and jetty system, and could include features that extend beyond the current footprint of existing jetty and relic stone structures and include both above- and below-water fill. Engineering features were incorporated as common components in all rehabilitation alternatives and included head capping, and adding spur groins. Rehabilitation strategies were evaluated as both immediate and scheduled. Scheduled rehabilitation included construction at specific locations along a jetty during specific times in order to optimize the federal investment. For example, based on modeling results, construction on Jetty A will be completed years before work concludes on the South Jetty.

A common set of descriptive life-cycle statistics were used to assess the performance for each jetty within a historical and future context. The statistics used to assess historical performance included jetty repair aspects, life-cycle repair cost, jetty geometry (crest profile, cross-section, head location), and jetty reliability. The statistics used to assess future jetty performance and compare alternatives included:

- Average annual cost (AAC)
    - Initial construction cost
    - Repair costs and their timing
- Reliability or the probability of a project feature to perform satisfactorily
- Constructability and access
- Potential impacts to larger inlet system
- Environmental effects of jetty rehabilitation, repair, or function loss
- Jetty lengths were evaluated based on AAC and functional reliability of their performance, the jetties will not be re-constructed to their authorized length at this time.

Alternatives were formulated based on jetty cross-section resilience, maintenance options, and construction scheduling. Estimates of future life-cycle outcomes were made for a range of maintenance strategies and rehabilitation alternatives. Selection of a least cost plan to manage the future life-cycle of each jetty was based on the optimization of the above metric considerations.

The metric used to portray future life-cycle cost is expressed in terms of average annual cost, which is based on a 50-year period beginning with the on-line year of alternative implementation.

Based on the tonnages produced by the Stochastic Risk-Based life-cycle simulation (SRB) model, head capping and spur groins are not part of the least cost—National Economic Development

(NED)—plan for any of the three jetties. However, this does not preclude the addition of either of these engineering features in the future. If biennial photogrammetric surveys and best adaptive management practices indicate the necessity of head stabilization or spur groins or both, such actions will be reconsidered. Furthermore, during the detailed design report (DDR) phase alternatives to optimize head stabilization will be assessed.

Beyond the initial rehabilitation period, the jetties will be aggressively monitored and maintained. The future costs have been estimated as a series of predicted repairs continuing for the next 50 years. Although the predicted repairs for the entire 50 year life-cycle was utilized to select the most economical plan, only the initial rehabilitation period consisting of the first seven years are itemized below.

For all three jetties, the NED plan was selected and their benefit to cost ratios (BCR) are listed below:

- **North Jetty** (BCR: 1.09) – Scheduled repair with head stabilization at or near STA 101, (less extensive than the previously proposed capping). These repairs will be conducted after the base condition maintenance repairs to stations 86-99 and lagoon fill to stop erosion of the jetty root. It does not include spur groin construction.

- **South Jetty** (BCR: 1.00) – Base condition (interim repairs) allowing head recession. It does not include spur groin construction. Dune augmentation near the jetty root will be implemented in FY 13 as a separate action and not included in the cost estimate. Although the base condition is the NED plan, the interim repair, hold head alternative is very close in AAC, differing by 0.9 percent. When conditions are appropriate (i.e., repairs of the South Jetty allow for a haul road to be established to the end of the jetty approximately FY 2019), head stabilization could be re-evaluated—using parameters such as least cost, environmental acceptability and engineering feasibility.

- **Jetty A** (BCR: 1.42) – scheduled repair and head stabilization at approximately STA 89. It does not include spur groin construction. The modeling performed to assess the project alternatives assumes that Jetty A is in place and fully functioning. This is because Jetty A, as originally constructed, protects the North Jetty and helps to train the Columbia River main stem. In addition, Jetty A is believed to play an important function for the Columbia River plume. The plume is an important food source for the 13 Columbia River salmonid evolutionarily significant units (ESUs) listed under the Endangered Species Act (ESA).

The project has a combined BCR of 1.1 for the system (all three jetties).

The initial construction schedule is projected to be from 2014 through 2020. Based on the 100% federally fully funded, feasibility level design in 2012 dollars, project first cost at an effective price level of 01 October 2012 is $238,547,000 and a total project cost fully funded of $257,201,000**.** Total project costs fully funded are estimated as follows per jetty: North Jetty at $79,797,000; South Jetty at $146,884,000; and Jetty A at $30,520,000.

The scheduled jetty repairs plan will reduce ongoing erosion to the surrounding shoals. Stabilizing the North Jetty and Jetty A lengths will have positive effects on the adjacent shorelines as well as the configuration and evolution of the ebb tidal shoal. Scheduled repairs will also help to stabilize both the above and below water morphology at the project.

Chapter 1 of this report provides a general introduction to the MCR jetties system and surrounding area, including:

- The purpose and importance of the jetty system;
- A detailed history of the construction, past repairs, and morphologic changes;
- The technical, as well as budget challenges; and
- A description of the current conditions.

Chapter 2 provides the economic rationale for the federal interest, a summary of how costs are calculated, and the benefit-to-cost ratios of the various repair/rehabilitation alternatives.

Chapter 3 provides the engineering basis for the development and analysis of the alternatives. This chapter includes:

- A characterization of the wave climate and morphologic processes at the MCR;
- The current issues/risks of deterioration or failure for each of the jetties and associated consequences;
- A characterization of the design of each jetty and the relevant performance modes;
- The description of the methodology and model used for assessing the reliability and life-cycle performance of the jetties, including alternatives;
- A summary of how the model was calibrated using historical and hindcast data; and
- A description of each of the repair/rehabilitation alternatives, including the model analysis results related to projected future long-term maintenance actions and reliability.

Chapter 4 builds upon the previous two chapters to provide a comparison of the alternatives based on initial and life-cycle costs, reliability, and environmental considerations. Based on these comparisons, a recommended plan for each jetty is given.

Chapter 5 summarizes the anticipated environmental effects of the proposed rehabilitation of the MCR jetty system, and the coordination undertaken related to environmental compliance issues. The associated EA provides a full evaluation of the project and associated environmental compliance considerations. Additional discussion and pertinent correspondence is included in Appendix D, *Environmental Documentation.* Any citations in this chapter can be found in the References section of the EA. The discussion is pulled directly from the EA which evaluates the effects of the Major Rehabilitation actions, the Major Maintenance Report actions, and South Jetty dune augmentation actions.

Chapter 6 provides an overview of the construction methods (both land-based and water-based) and estimated production rates and schedule for the recommended plan. The associated cost estimates are provided.

Chapter 7 is the recommendation signed by the USACE District Commander.

The first six appendices provide further technical details of the information summarized in Chapters 3 and 4 of the report. Appendices C, D, E, F, and G provide detailed information related to the economic, environmental, and programmatic discussions of Chapters 2, 5, and 6. Appendix H is a summary of key project events and provides an audit trail for all report reviews.

1. INTRODUCTION

1.1. GENERAL

This chapter of the report provides a general introduction to the MCR jetties system and surrounding area, including:

- The purpose and importance of the jetty system;
- A detailed history of the construction, past repairs, and morphologic changes;
- The technical, as well as budget challenges; and
- A description of the current conditions

1.2. PROJECT AUTHORIZATION - MCR PROJECT FEATURES

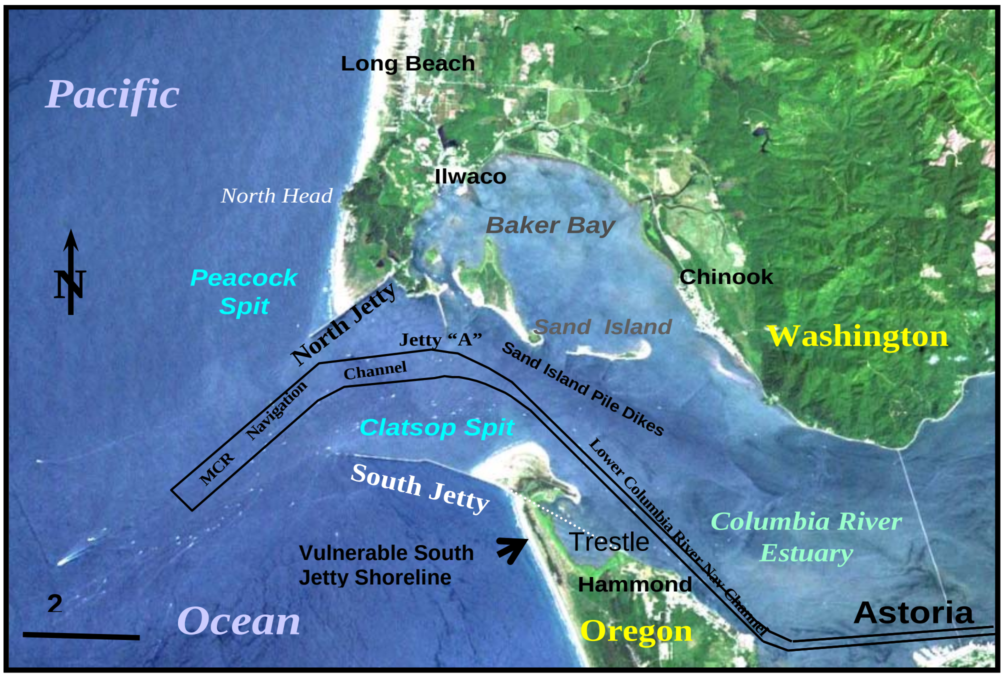
At the mouth of the Columbia River (MCR), three rubble-mound jetties with a total authorized length of 10.2 miles were constructed by the U.S. Army Corps of Engineers (USACE) to secure consistent navigation through the coastal inlet. The Rivers and Harbor Act of 5 July 1884 authorized construction of the South Jetty (first 4.5 miles) to attain a 30-foot channel across the MCR bar. The Rivers and Harbor Act of 3 March 1905 authorized the extension of the South Jetty to 6.6 miles and construction of the North Jetty (2.5-miles long) to attain a 40-foot bar channel (0.5-mile wide)—including spur groins. The Rivers and Harbor Act of 3 September 1954 authorized a bar channel at a depth of 48 feet below mean lower low water (MLLW; all elevations are in this datum unless otherwise noted) and Spur Jetty B on the north shore of the inlet; however, funds for Spur Jetty B were not appropriated. Public Law 98-63, 30 July 1983, authorized deepening the northern most 2,000 feet of the MCR channel to 55 feet below MLLW. Jetty A was authorized and constructed to 1.1 miles in length in connection with rehabilitation of the North Jetty for the purpose of channel stabilization. Its purpose was to assist in controlling the location and direction of the ebb tidal flow through the navigation entrance.

1.3. LOCATION AND PROJECT AREA DESCRIPTION

The MCR navigation project is located at the confluence of the Columbia River with the Pacific Ocean on the border between Washington and Oregon. Figure 1-1 illustrates the navigation project and the three primary navigation structures, the North Jetty, South Jetty, and Jetty A. Those structures are shown in more detail in Figure 1-2. The North Jetty and Jetty A are located in Pacific County, Washington, near Ilwaco and Long Beach on the Long Beach Peninsula. The North Jetty was completed in 1917. Jetty A, positioned on the south side of the North Jetty, was constructed in 1939 to a length of 1.1 miles. Jetty A was constructed to direct river and tidal currents away from the North Jetty foundation. The South Jetty is located in Clatsop County, Oregon near Warrenton/Hammond and Astoria. The initial 4.5-mile section of the South Jetty was completed in 1895, with a 2.5-mile extension completed in 1913. Jetty construction realigned the ocean entrance to the Columbia River, established a consistent navigation channel that was 40 feet below MLLW across the bar, and significantly improved navigation through the MCR. Improvements made from 1930 to 1942 (including addition of Jetty A and Sand Island pile dikes) produced the present entrance configuration. Figure 1-3 illustrates the MCR inlet and bathymetry changes from 1866 to 2003. Plates 1 through 3, located at the end of this chapter, show the layout and stationing of each of the MCR jetties.

Prior to improvement in 1885, the tidal channels through the MCR shifted north and south between Fort Stevens and Cape Disappointment, a distance of about 5.5 miles. The controlling depth of dominant channel through the ebb tidal delta varied between 18 to 25 feet deep below MLLW. The ebb and flood tidal deltas at MCR entrance were distributed over a large area immediately seaward and upstream of the river mouth. Ships often had trouble traversing the Columbia River bar, the area in which the flow of the estuary rushes headlong into towering ocean waves. On many occasions, outbound ships had to wait a month or more until bar conditions were favorable for crossing. To make navigating through the MCR even worse, sailing ships had to approach either of the two natural channels abeam to the wind and waves. The natural channels often shifted widely within the course of several tidal cycles. At best, crossing the bar was dangerous. At worst, it was not possible.

Figure 1-1. MCR Jetty Locations



Offshore of the MCR lays the vast expanse of the northeast Pacific Ocean. Inshore of the MCR lies the Columbia River and estuary, the coastal outlet for a drainage basin of 250,000 square miles where the headwaters emanate from the western slope of the Rocky Mountains. The course of the Columbia River is 1,210 miles long, dropping over 2,600 feet from its Canadian headwaters to the sea. The Columbia River accounts for 60% (winter) to 90% (summer) of the total fresh water that discharges into the Pacific Ocean from the Canadian border to San Francisco, California. The Columbia River estuary is the largest fluvially dominated estuary in the Pacific Northwest. Its upriver limit, defined in terms of salt water intrusion, varies from river mile (RM) 28 to 38 and is a function of fluvial flow and sequencing of the tidal cycle. Current reversal due to tide can occur as far inland as RM 70. Tidal effects (fluctuation of water surface elevation) extend upriver to Bonneville Dam (RM 145).

The 6-mile long deep-draft navigation channel at the MCR has become the ocean gateway for navigation access to and from the 500-mile long Columbia/Snake River inland navigation system. It is a critical regional and national gateway linking agricultural, mineral and goods production across the Northwest, Mountain, Midwest, and East Coast states to growing markets in the Pacific Rim. The economies of many states rely on the trade and commerce that flows up and down the system. Each year, ocean-going vessels on the Columbia River carry about 42 million tons of cargo with an estimated value of $20 billion on an annual basis (more than 40,000 local jobs are dependent on this trade).

Figure 1-2 shows the rubble-mound structures that make up the MCR jetty system. Top left photo shows the South Jetty looking east. The remnant feature shown disconnected from the primary structure is the concrete monolith that was constructed in 1941. The top right photo shows Jetty A. The bottom photo illustrates the North Jetty and the shoreline north of the MCR. The North Jetty also realized significant head recession shown in the photo. As each of the three jetties deteriorates, the MCR entrance and navigation channel is exposed to increased wave energy and sediment movement.

According to the Center for Economic Development and Research, the Columbia/Snake River navigation system is the number one export gateway for the Nation's wheat and barley exports. It is also the number one export gateway for west coast wood and mineral bulk exports and number two for automobile imports. Marine traffic passing the entrance of the Columbia River has increased by 34% from 32 million tons in 2003 to 42 million tons in 2010. Additional economic information about the Columbia/Snake River navigation system can be found in Appendix C, *Economic Analysis*.

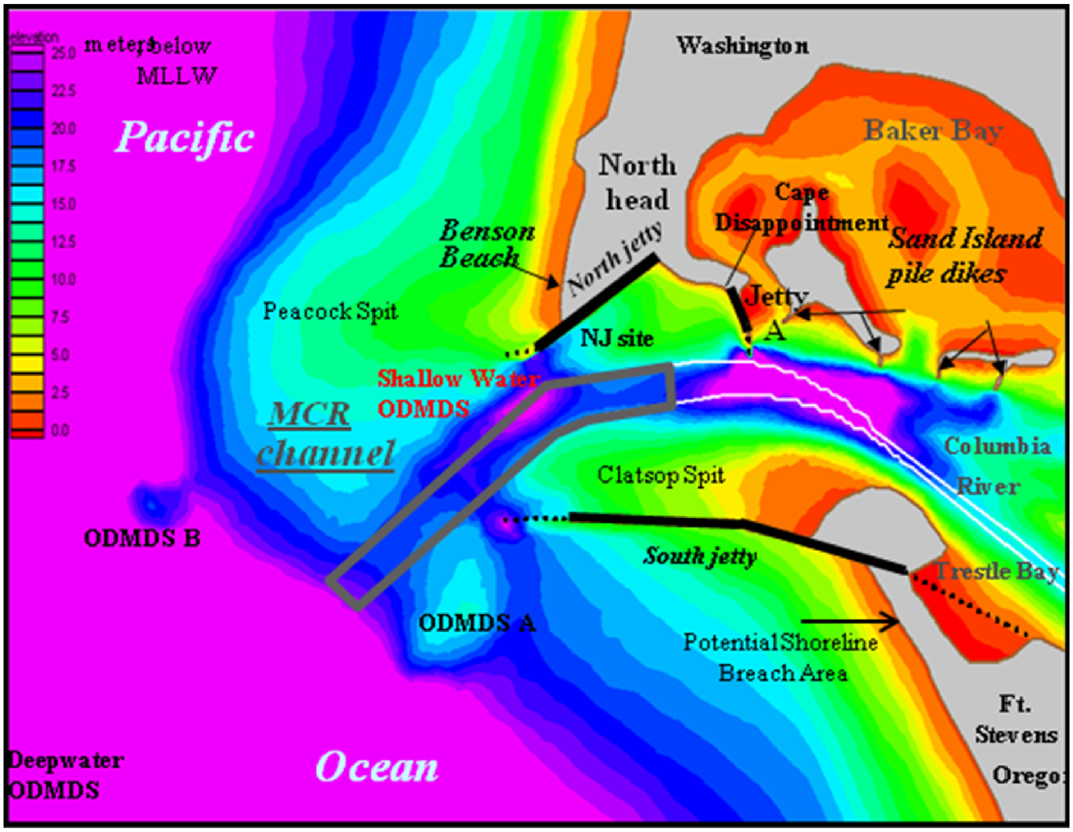
1.4. IDENTIFICATION OF PROBLEMS AND OPPORTUNITIES

Budget guidance [Budget Engineer Circular (EC) 11-2-201, dated 3 March 12] defines major rehabilitation based on these thresholds: "The work will extend over at least two full construction seasons and will require at least $6.6 million in outlays. For inland waterways projects, the reliability threshold will be $14 million." The work on all three of the MCR jetties fits the definition of major rehabilitation and therefore, this report is prepared using that guidance.

This evaluation was undertaken to address problems related to the structural stability of the MCR Jetties to extend their functional life to maintain deep-draft navigation. The jetties are integral to maintaining a reliable deep-draft channel at the mouth of Columbia River due to the inherent relationship between the channel and the jetties. The purpose of this report is to assess the most efficient means of maintaining deep-draft navigation in a least-cost manner. The jetties were constructed on massive tidal shoals and these shoals have been changing since initial jetty construction. The longevity of the jetties is tied to the stability of the shoals on which the jetties were built, and the stability of the shoals is now a function of the jetties. The jetties and shoals act as integrated units to confine tidally driven circulation through the MCR and maintain the present channel configuration. Figure 1-4 illustrates the extensive underwater shoaling at the MCR.

Figure 1-4. Bathymetry and Underwater Shoaling at the MCR

(the color scale indicates depth from shallow to deep, 0.0 meters in red to 25.0 meters in magenta)



Through phased jetty construction (1885-1939) and the associated response of MCR morphology, each project feature at the MCR now is dependent on the other, both in terms of structural integrity and project feature functional performance. Severe deterioration of any of these features can jeopardize the MCR federal navigation channel and adversely affect the other structures. Should the North Jetty experience substantial deterioration from its present condition, the navigation channel, South Jetty, Jetty A, and ultimately the Sand Island pile dikes would be negatively affected. A similar scenario would likely occur if the South Jetty experienced substantial deterioration from its present condition. In this regard, the project features at the MCR are interrelated and perform as a system.

Structural degradation of the jetties has accelerated in recent years because of increased storm activity and loss of sand shoal material upon which the jetties are constructed (Figure 1-5 shows waves attacking the South Jetty). Both the frequency and intensity of extreme cyclones in the Pacific Northwest have increased markedly (Graham and Diaz 2001, Moritz and Moritz 2006). In addition, extremal analyses of Pacific Northwest buoy data from the National Data Buoy Center have shown a gradual increase of the predicted 100-year wave height (Komar and Allan 2000; Moritz 2001; Moritz and Moritz 2006; Ruggiero et al., 2010).

Figure 1-5. Wave Attack on the South Jetty

Beaches on the ocean sides of the North and South jetties, which formed as a result of jetty construction, have been receding gradually over the years, exposing previously protected jetty sections at the beach line to storm waves (Figure 1-6 shows Benson Beach recession at the North Jetty). This recession is in direct proportion with jetty length. As jetty length is shortened, beach front is lost.

The orientation of the shoals/spits at the MCR has arisen due to waves and currents; the morphology and coastal processes at the MCR are linked. Eddies that form within the MCR arise due to the interaction of flow with the jetties and the morphology greatly influences flow and shoaling within the federal navigation channel. The littoral dynamics north and south of the MCR are drastically different from “open coast” areas away from the entrance. Depending on the regional wind field, the “coastal current” up-drift and down-drift from the MCR can attain speeds of 3 feet/second. As the tidal shoals continue to recede (erode), the MCR jetties will be exposed to larger waves and more vigorous currents.

Figure 1-7 illustrates the Ocean Dredged Material Disposal Sites (ODMDS) located at the MCR that are a key element to the project’s channel maintenance program used by ocean dredges that operate there.

Figure 1-6. Shoreline Response North of the North Jetty

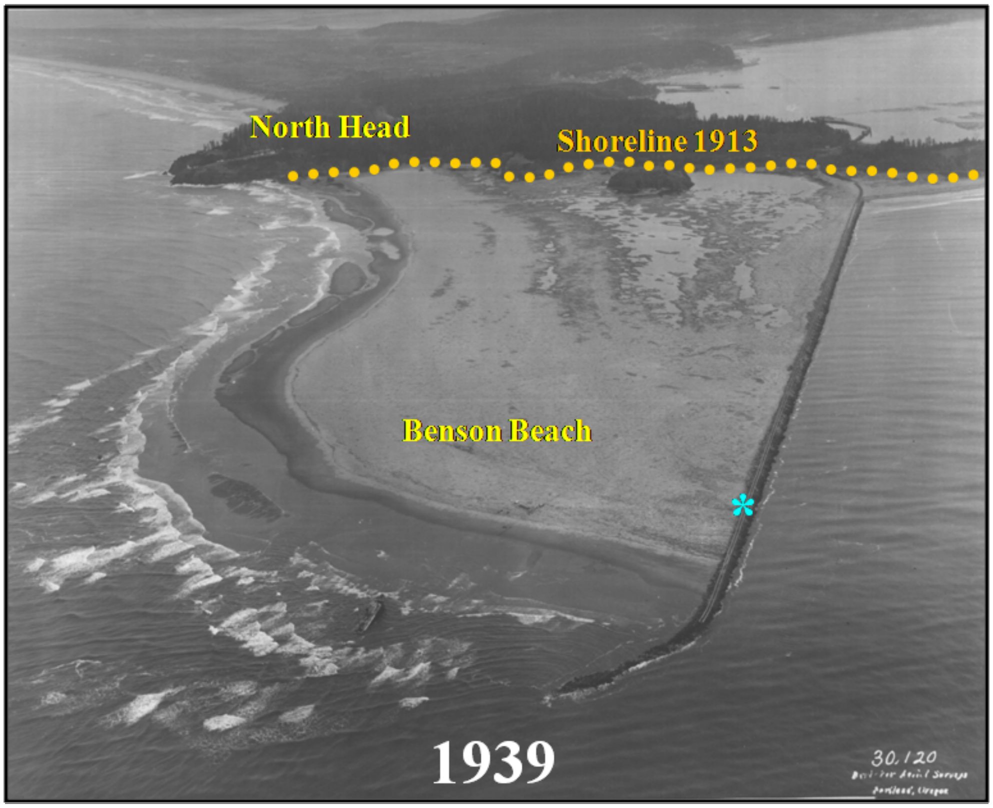


Figure 1-7. Ocean Dredged Material Disposal Sites

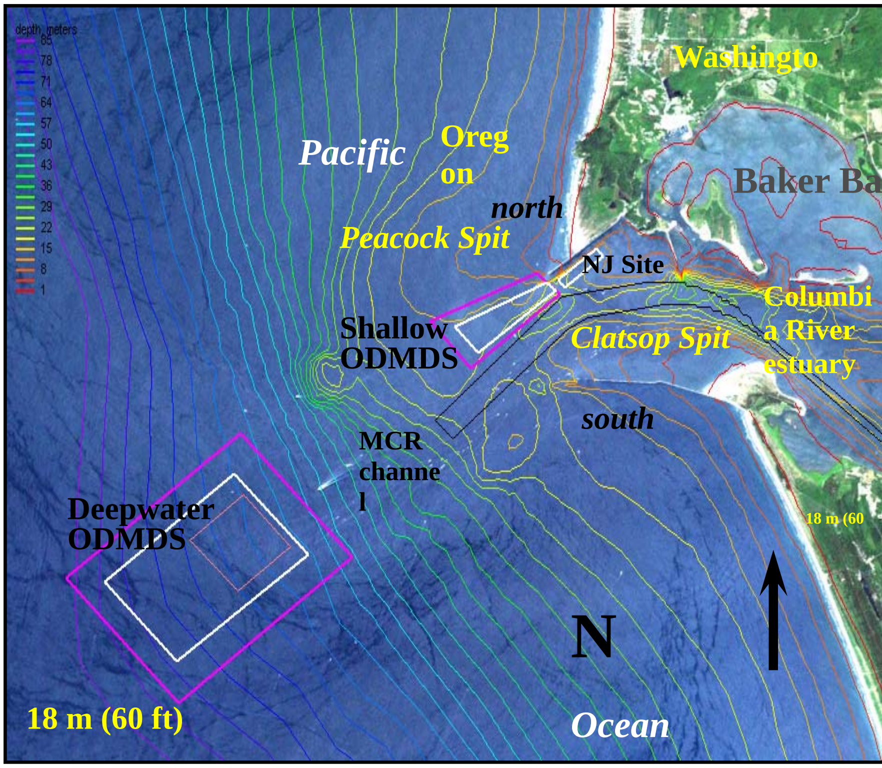


Despite intermittent repair and partial rehabilitation efforts, all of the MCR jetties are currently in a significantly deteriorated condition (Figure 1-8 and Figure 1-9). Intermittent repairs were conducted in 2005 on the North Jetty and in 2006 and 2007 on the South Jetty. The last partial rehabilitation on the North Jetty was conducted in 1964 and addressed 17% of its length, on the South Jetty was conducted in 1982 and addressed 25% of its length, and on Jetty A was conducted in 1961 and addressed 56% of its length. The jetty heads of the North and South jetties have not been repaired since their original construction and are severely deteriorated. The South Jetty head is no longer connected to the trunk by a continuous above water jetty reach. The jetty heads continue to recede landward from their original locations. The above water lengths for the South and North jetties and Jetty A are currently shorter than their authorized lengths by 6,200 feet, 2,120 feet, and 900 feet, respectively. Due to the interaction of wave patterns and currents with the jetty configuration, the shorter jetty lengths can increase underwater shoal erosion, influence shoreline position adjacent to the jetties, and can increase the loading on the structures landward of the jetty head.

Progressive damage to one of the jetties could result in a significant breach which can trigger an emergency repair to the jetty, rapid infill into the navigation channel, and emergency dredging activities. The current rehabilitation approach for the MCR Jetties focuses on adequately defining the larger processes affecting the jetties, and then describing their reliability over time. Some of the larger physical processes have been already mentioned including erosion and re-orientation of the ebb tidal shoal, shoreline erosion adjacent to the structures, increased depths along the jetties due to inlet and channel changes and increasing wave height trends. Consequences evaluated include frequency and consequences of future jetty repairs, as well as potential impacts to dredging and navigation. Each alternative adds additional elements of either process stabilization or above or below water cross section stabilization, as well as varying degrees of cross section reliability improvement.

Figure 1-8. South Jetty Damage Areas

Figure 1-9. North Jetty Damage Areas

In summary, taking no action to rehabilitate the MCR jetties to extend the functional life would result in further deterioration of the structures and would result in a jetty breach. A jetty breach results in accelerated jetty damages adjacent to the breach area, sediment infill through the hole in the jetty, and increased jetty repair and dredging costs. Recent interim jetty repairs have addressed immediate critical needs. However, additional modifications and repairs to the jetties are necessary to address critical near- and long-term needs and to reduce the potential for emergency repairs, emergency dredging, and impacts to the Columbia-Snake River inland navigation system. Further discussion concerning the problems and opportunities of the MCR Jetties can be found in Appendix A1, *Coastal Engineering*.

1.5. PROJECT HISTORY

1.5.1. Construction and Repair History

Table 1-1 provides a description of the construction and repair history for the MCR jetties. The function of the MCR jetties has evolved since initial construction. Improvement of the MCR navigation entrance was conducted incrementally with subsequent stages being initiated as a physical need was recognized. The South Jetty was constructed first as a mid-tide jetty to a moderate length (1885-1895). Instability of the South Jetty and continued migration of the navigation channel led to recommendations to extend the South Jetty and raise it to a high tide jetty. During improvement of the South Jetty (1905-1913), it became apparent that a North Jetty would be needed to maintain a stable navigation channel.

Table 1-1. Construction and Repair History for the MCR Jetties

1881: Proposed project to build a strong pile-dike, 3 feet high about at low tide, 8,000 feet long and 20 feet wide along a line previously established on the south side. The structure to start near the northeast corner of Fort Stevens, following the 12-foot curve, dike will be directed a little westward of the outer part of headland of Cape Hancock. It was stated that work commence soon (during summer and autumn) because channel maintenance is dependent upon building up Clatsop Spit.

1883: A jetty plan approved by the Board of Engineers from the south cape of the entrance on the spit. A survey was conducted in October-November of the south cape, Point Adams, to extreme low water. The jetty extends from Point Adams and makes the distance between the outer end of the jetty and Cape Disappointment the same as the distance between Chinook Point and Point Adams. The Board stated that any structures placed in-river should not harm the river and should keep the channel open using the tide; therefore, the jetty should not obstruct the entry of the flood tide. The jetty design called for a crest elevation at low water level. Estimated depths of various jetty sections from the landward end are: 5,000 feet - less than +6 feet; 7,500 feet – +6 to +11 feet; 4,000 feet – +11 to +16 feet; and 7,500 feet – +16 to +21 feet. Jetty crest elevation was designed to be at low water level because of wave violence that could harm a higher jetty. The logic was that a higher jetty could be built, if needed later, by placing more stone on the existing jetty. A jetty height to mid-tide level was suggested but not recommended because the lower jetty would be quite effective in directing the ebb tide and would interfere less with the flood tide. A higher jetty would result in higher maintenance costs due to the jetty being more exposed to wave action.

1884: The improvement plan for MCR was approved by the Rivers and Harbors Act of July 5, 1884 to maintain a channel 30 feet deep at mean low tide by constructing a low-tide jetty, about 4.5 miles long, from near Fort Stevens on the South Cape to a point about 3 miles south of Cape Disappointment.

1886-1896: Original construction South Jetty from Fort Stevens (station 25+80) across Trestle Bay and Clatsop Spit to station 250+20. Rock placed with a natural slope to an elevation from 4 to 12 feet, crest width roughly 10 feet. "The jetty, of a brush-mattress and stone ballast, was built for 1,020 feet from ordinary highest tide-line, and minor constructions added." Material has filled along the jetty's south side, moving the shoreline seaward. Highest tide-line is located at tramway station 30+50. A 115 feet long spur was built landward of the jetty for shore protection. A 510 feet long sand-catch, consisting of heavy beach drift and loose brush, was built on the south side of landward end of the jetty to continue filling the old outlet of a lagoon at extreme end of Point Adams. Jetty stone was originally dumped in ridges, but waves flattened and compacted the rocks to a width of 50 feet. The report indicated urgency to extend the jetty to prevent further deterioration of the bar channel.

1889: The South Jetty now under construction for 1.5 miles. Clatsop Spit has more material visible at low water and the river channel has a tendency towards a straight course out to sea. Tillamook Chute being closed. Sand building up south of the jetty adjacent to and in front of the mattresses as they are constructed.

1890: South Jetty construction is 3.25 miles underway. Jetty elevation at MLLW for about 3 miles. 1.25 miles of tramway to be constructed. Clatsop Spit building up, the outflowing waters being concentrated over the channel bar. Station 25+80 considered the beginning of the jetty. The jetty mattress has advanced from stations 99+04 to 194+08. The jetty elevation is at MLLW to station 170+00. From Station 170+00 to the end of mattress work, there is about 9 feet of rock on top of the mattress. At station 65+00, there were signs of sinking and a large amount of rock was dumped in place.

1903-1913: Extension of South Jetty. Crest elevation of jetty raised to 10 feet MLLW from stations 210+35 to 250+20, and rock placed from stations 250+20 to 375+52, elevation increasing in steps to 24 feet MLLW. Crest width is 25 feet and side slopes are natural slope of rock. Seaward bend in the jetty is added and called the "knuckle."

1913-1917: Original construction of North Jetty from stations 0+00 to 122+00. Side slopes are 1 vertical by 1.5 horizontal (1:1.5) and crest width is 25 feet. Crest elevation varies from 15 to 32 feet.

1931-1932: Repair South Jetty from stations 175+00 to 257+68.7 (shoreline to knuckle), side slopes 1:1.5, crest elevation 24 feet MLLW, and crest width 24 feet. This is first maintenance for South Jetty. The jetty had been flattened to about low water level. 2.2 million tons of stone placed in super-structure. The work completed in 1936. The end of jetty would unravel 300 feet or more, so a solid concrete terminal was constructed above low water level. The terminal was located 3,900 feet shoreward of the original jetty end that was completed in 1913.

1933-1934: Repair of South Jetty from stations 257+68.7 to 305+05 (knuckle to middle of outer segment). Two level cross section with crest elevations of 17 and 26 feet. Crest width of each level is 24 feet. Side slopes are 1:1.5 on channel side and vary from 1:1 to 1:1.75 to 1:2 on ocean side.

1935-1936: Repair South Jetty from stations 305+05 to 353+05 (middle of outer segment to existing end). Similar design to 1933-1934 repair.

Table 1-1 (continued). Construction and Repair History for the MCR Jetties

1936: Stone/asphalt cone-shaped terminal constructed on South Jetty from stations 340+30 to 344+30. Crest width of approximately 50 feet and elevation varied from 23 to 26 feet. Side slopes are 1:2.

1937-1939: Repair of North Jetty from stations 68+35 to 110+35. Crest elevation 26 feet and crest width 30 feet. Side slope 1:1.25 on ocean side and 1:1.5 on channel side.

1939: Original construction of Jetty A from stations 40+93.89 to 96+83. Crest width is 10 feet from beginning to station 53+00, 30 feet in width, and elevation at 20 feet from this point on. Four pile dikes completed at Sand Island.

1940: Repair of South Jetty with replacement rock in locations as needed.

1940-1942: South Jetty repair from stations 332+00 to 343+30. Concrete terminal/stone foundation added. Crest elevation from 8-20 feet and crest width from 50-75 feet, 10 inches. Side slopes determined by concrete terminal shape.

1945-1947: Repair Jetty A from stations 78+00 to 96+00. Crest elevation to 20 feet with crest width of 40 feet.

1948-1949: Repair 300 feet of Jetty A from stations 92+35 to 95+35 with a crest elevation of 20 feet, a crest width of 30 feet, and side slopes of 1:1.25.

1951: Repair Jetty A from stations 91+50 to 93+00 with a crest elevation of 20 feet MLLW, a crest width of 30 feet, and side slopes of 1:1.5.

1952: Repair of Jetty A from stations 90+00 to 94+00 with a crest elevation of 20 feet, a crest width of 30 feet, and side slopes of 1:1.5.

1958: Repair of Jetty A from Stations 41+00 to 79+00. Crest elevation raised to 20 feet and a crest width of 20 feet from Stations 41+00 to 56+00. Crest width is 30 feet from Stations 61+00 to 79+00.

1961-1962: Repair Jetty A from stations 50+00 to 90+50, with no repairs from Stations 68+00 to 76+50. Crest elevation built with a 10% grade from 20 feet to 24 feet from stations 50+00 to 68+00. The crest elevation was raised to 24 feet from stations 76+50 to 90+50.

1961: South Jetty repair from stations 194+00 to 249+00 (before knuckle, current stationing). Crest elevation varies from 24 to 28 feet and crest width is 30 feet. Channel side slope 1:1.25 and ocean side slope 1:1.5. Repairs from stations 38+00 to 93+00 (old stationing). Elevation at station 38+00 is +24 feet and then increased with a 0.5% grade up to +28 feet for the remainder of repair section. The repair centerline is located 13 feet north of the centerline of the original jetty design. The design crest width 30 feet. North slope 1:1.25 and south slope 1:1.5.

1962-1965: South Jetty repair from stations 249+00 to 314+05 (beyond knuckle). Crest elevation begins at 28 feet and transitions to 25 feet for most of section. Side slopes vary from 1:1.5 to 1:2 and crest width is 40 feet (this appears to be the furthest seaward intact portion of current jetty). Repairs made from stations 93+00 to 157+50 (old stationing). The crest elevation is +28 feet at station 93+00, then decreases to +25 feet at station 95+00, and then continues with this elevation to end of the repairs. The crest width is 40 feet and has a slope of 1:1.5 from stations 93+00 to 152+00. Slope then transitions to 1:2 from stations 152+00 to 154+00. The centerline of the repair is 15 feet south of the trestle centerline.

1965: Repair North Jetty from stations 89+47 to 109+67 with a crest elevation of 24 feet and crest width is 30 feet. Side slopes vary from 1:1.5 to 1:2.

1982: Repair South Jetty from stations 194+00 to 249+00 (segment before knuckle). Crest elevation varies from 22 to 25 feet MLLW. Crest width varies from 25-30 feet and side slopes 1:1.5. Crest elevation varies from +22 feet at station 38+00 to +25 feet at station 80+35 (old stationing). From stations 44+50 to 80+35, crest width is 30 feet and slope is 1:1.5. Centerline of repairs has 10 feet maximum variance to the north for the South Jetty control line. From stations 80+35 to 93+00, centerline of repairs is the same as South Jetty control. Crest elevation +25 feet, width varies from 25-30 feet, side slope is 1:1.5.

2005: Interim repair of North Jetty (stations 55+00 to 86+00). Crest elevation +25 feet with side slope of 1:1.5.

2006: Interim repair of South Jetty (stations 223+00 to 245+00). Crest elevation +25 feet with side slope of 1:2.

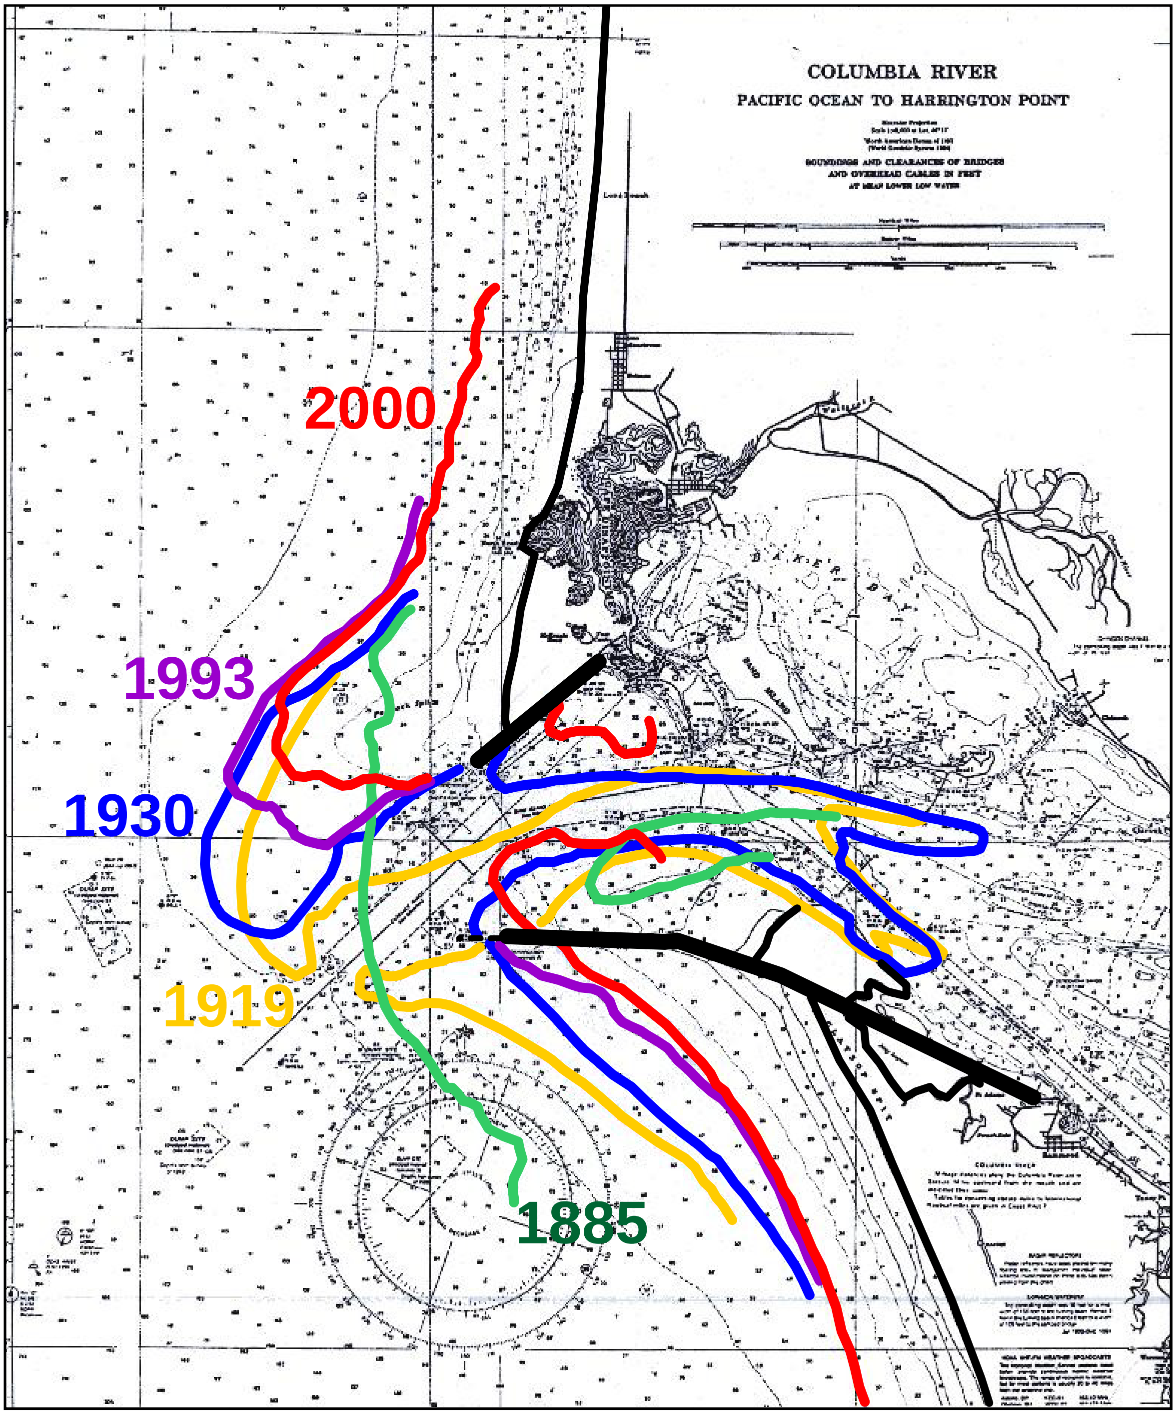
2007: Interim repair of South Jetty (stations 255+00 to 285+00). Crest elevation +25 feet with side slope of 1:2.

The sequential improvements were conducted during 1885 to 1917. During the early 1930s (after both North and South jetties had been in place and significant modification of the inlet's morphology had occurred), the North Jetty became threatened by high velocity ebb tide flow that threatened to undermine the structure's channel side foundation. Concurrently, the south side of Sand Island was being eroded by increased current action. Loss of either the North Jetty or Sand Island would have rendered the inlet unsuitable for navigation. The adverse circulation affecting the North Jetty and Sand Island was motivated by the northward migration of the estuary thalweg toward Cape Disappointment. In the late 1930s, the Sand Island pile dikes and Jetty A were constructed by the USACE to stabilize the evolving inlet. The pile dikes stabilized Sand Island, preventing detrimental effects on Baker Bay and inlet navigation. Jetty A prevented the northward migration of the inlet's thalweg while deflecting ebb away from the North Jetty and flood current away from Sand Island. Collectively, all three jetties and the Sand Island pile dikes now function in concert to balance the large scale ocean processes affecting the entrance. Through the evolution of the inlet and its morphology, Jetty A now also serves as a breakwater to protect Sand Island and the Ilwaco entrance into Baker Bay from large ocean waves.

Since the original jetty construction, several large-scale physical process changes have altered the current and projected future reliability of the jetties. These large-scale process changes gradually impact the stability of the structures and their reliability. It has been shown that as increased depths are secured in the improved navigation channel, larger waves are able to enter the channel and attack the jetties, in addition to undermining the sandy foundation upon which they rest. These increased depths primarily affect the channel-side of the jetties, particularly the North Jetty which is closer to the navigation channel. Along the landward half of the North Jetty, another de-stabilizing flow path has developed through the structure as tidal flow moves through the structure to the eroded lagoon behind the structure.

Another apparent large-scale process change has been a gradual increase in the wave climate both in terms of storm wave height as well as number of large storms occurring in a given year. Concurrent with the increase in storm climate and the larger interior waves and currents, foundation erosion has accelerated both seaward and adjacent to the jetties. During 1993 to 2000, the 40-foot contour on the ebb tidal shoal receded landward at a rate seven times faster than during 1930 to 1993, as shown in Figure 1-10. As the ebb tidal shoal recedes, the wave and current regime at the entrance and along the jetties changes.

Figure 1-10. Map of 40-foot Contours near the MCR Over Time, 1885 to 2000

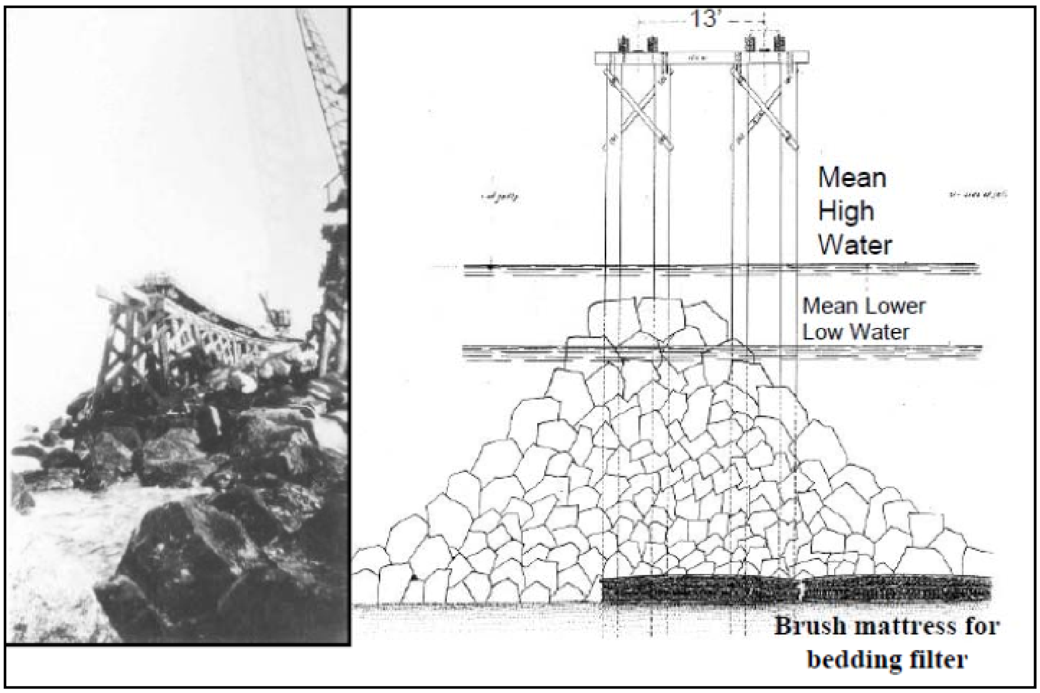


1.5.1.1. South Jetty

In 1884, Congress authorized the USACE to construct a 4.5-mile-long South Jetty for the purpose of attaining a 30-foot-deep channel across the MCR bar. The jetty was to extend northwesterly from Fort Stevens (on Point Adams) in a slightly convex manner along Clatsop Spit to a point about 3 miles south of Cape Disappointment. A jetty with a crest elevation at mid-tide was originally considered due to the assumption that it would control currents, as well as a high-tide jetty, but would cost less and contain sand better than a low-tide jetty. Table 1-2 summarizes the construction and repair efforts for the South Jetty over the project life.

The original crest elevation of the South Jetty was constructed to a mid-tide elevation (3 to 5 feet above M LLW) and a crest width of 10 feet. Figure 1-11 shows the design cross-section and construction method used to construct the South Jetty. Emphasis was given to ensure a proper "bedding" layer underneath the jetty to establish a stable foundation. The maximum size of armor stone was 7 tons, based on professional judgment and limitation of the tramway equipment. The finished side slope of the jetty was approximately 1 vertical by 1.5 horizontal (natural slope).

Figure 1-11. Design Section for Original South Jetty Construction



Improvements during South Jetty construction included the addition of four rock spur-groins (100-1,000 feet long) on the jetty's north side (at stations 52, 88, 156, and 228) to prevent scour and undermining, and increasing the jetty crest elevation. From shore to station 120, the jetty crest elevation was increased to 12 feet to reduce wave overtopping, prevent shoal migration, and protect the tramway. The crest elevation was sloped down from +12 feet (station 120) to +4 feet at station 250+20. Construction of the 4.5-mile-long South Jetty started in 1885 (station 25+80) and was completed in 1895 (station 250+20, known as the "knuckle").

A rock revetment was constructed east of the South Jetty root (along stations 0-25) to prevent erosion flanking of the jetty by waves and currents. Construction of the original jetty required 946,000 tons of stone, which was placed using a trestle-supported tramway with locomotives, side-casting cars, and crane. Stone was delivered to the tramway by barge. Before construction of the South Jetty, there was no dominant channel though the MCR and controlling depth was about -20 feet below MLLW.

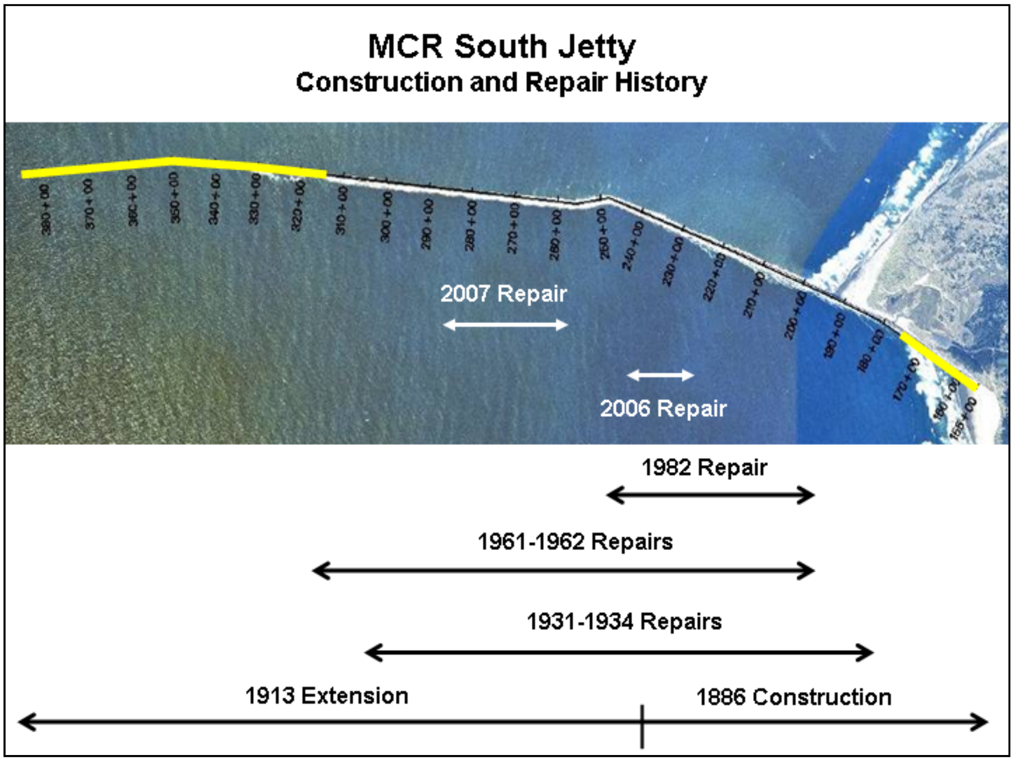
Upon completion of the original South Jetty, a well-defined channel had developed through the MCR with controlling depth of 30 feet below MLLW. The jetty length was still insufficient to continue funneling sediment into deep water and by 1902 all traces of a channel had disappeared and the governing depth reverted to 20-22 feet below MLLW. In 1903, the Board of Engineers recommended that Congress authorize the USACE to enact the following: (1) the South Jetty be extended 2.5 miles in length toward the west and the jetty crest raised to 10 feet MLLW or higher; (2) a 2.5-mile-long North Jetty be constructed on Peacock Spit (after completion of South Jetty extension); and (3) commence dredging at the bar, if needed. It was specified that the North and South jetties be 2 miles apart at their ends. The purpose of the recommended improvements was to obtain a 0.5-mile-wide channel through the MCR with controlling depth of -40 feet below MLLW.

In 1905, Congress authorized the implementation of the 1903 recommendations for the purpose of attaining a channel 40 feet below MLLW and 0.5-miles wide across the bar. Repairs were made to the original 4.5-mile-long South Jetty (stations 175-250) using 410,000 tons of stone. Construction of the 2.1-mile-long extension (stations 250-375) required 4.48 million tons of stone. Work on the South Jetty was completed in 1913. The alignment of the extension was intended to extend the seaward location of the channel by following the shallow waters of Clatsop Spit as far as possible without making significant changes in the direction of the structure. It was thought that if the 2.1-mile-long extension were constructed in continuation of the straight-line direction of the original jetty, the velocities of the ebb and flood tides would be significant enough to undermine the jetty foundation, unless groins were incorporated. The extension was expected to prevent the ebb flow from losing energy and dissipating over Clatsop Spit, but instead to be guided toward the existing channel and help maintain its depth. It was expected that the extension would hold Clatsop Spit in position and allow it to build up by impeding the entrance of sand into the channel. The curvature of the jetty at the "knuckle" was intended to encourage deposition of sand along the channel side of the jetty, so that the installation of groins would not be necessary.

As completed in 1913, the South Jetty had an average crest width of 10 feet and an elevation of +10 feet along the inner 2.65 miles (stations 25-165) of the jetty. The outer 4 miles of the jetty (stations 165-375) had an average crest width of 25 feet and elevation of +24 feet. The finished side slope was approximately 1 vertical by 1.5 horizontal (natural slope). An increased jetty crest elevation was needed to prevent wave overtopping damage to the lee side of the jetty, reduce sediment transport over the jetty, and protect the construction tramway from wave action. Stone size was the same as used for the original jetty (maximum size 7 tons). Two submerged rock groins (extending northward 200 feet from the jetty centerline) were constructed at the outer area at stations 309 and 333 to prevent scour along the north side of the jetty toe. These two rock groins have been instrumental in stabilizing the outer end of the jetty toe since time of construction. Figure 1-12 shows the construction and repair history for the South Jetty over the project life. The yellow line on the figure indicates the area along the jetty that has never been repaired since original construction.

Figure 1-12. South Jetty Construction and Repair History

(yellow represents portions of the jetty that have never been repaired)



1931-1942 South Jetty Rehabilitation

Due to the high cost of tramway construction and maintenance, jetty repair work was deferred during 1917-1931. By 1920, the outer 2.5 miles of the South Jetty crest had been beaten down by wave action and scour to an elevation of 4 feet. By 1931, the elevation of the crest was at approximately MLLW from Clatsop Spit (station 170) seaward to the jetty head (station 375). The degradation of the South Jetty allowed significant re-distribution of Clatsop Spit along the north side of the South Jetty. Much of the sediment emanating from Clatsop Spit was transported northward and eventually deposited within the southern flank of the navigation channel. By 1931, the outer 1,500 feet of the North Jetty had been beaten down to an elevation of about 3 feet and some settlement had occurred along its entire length. Except at the outer end, the North Jetty had stood up rather well due to the accretion of sand along its northern side, which by 1932 had extended to the head of the jetty (see Figure 1-6).

The first and most significant effort to rehabilitate the South Jetty was undertaken by three separate contract actions during 1931-1936. The total length of reconstructed jetty was 3.4 miles, beginning at station 175 and ending at station 353. As rehabilitated in 1936, the above-waterline part of the South Jetty extended to within 3,300 feet of the end of the jetty as completed in 1913. During 1931-1936, a total of 2.21 million tons of stone was placed. The stone was placed using tramway, dump cars, and a 25-ton crane. Stone was delivered to the tramway by barge. Average production of stone placement was 75,000 to 100,000 tons/month. To prevent future wave damage, the larger armor stone that was placed on the south jetty during the 1931-1936 rehabilitation ranged between 6 and 25 tons. Average armor stone size was 9 tons. The armor stone size was chosen based on professional judgment and equipment limitations. Rehab crest width ranged between 24 to 70 feet and crest elevation was 26 feet. Even before repairs could be completed, it was realized that the outer 3,000 feet of the South Jetty could not be maintained due to continual stone loss from the jetty. In 1937, station 350-353 was rebuilt using 10,600 tons of armor stone infused with 12,800 ton of asphalt-sand mix. The asphalt-bound jetty head performed poorly.

By 1941, the end of the rehabilitated South Jetty (station 338-353) had been reduced to 0 feet elevation by wave action and toe scour/undermining. In an effort to form a stable jetty head, a massive concrete terminal was constructed during 1941-1942. The terminal was 50-75 feet wide by 300 feet long with an elevation of 8 to 20 feet, requiring 14,000 cubic yards (cy) of concrete and 76,000 tons of stone, and was constructed at station 331 to form an armored cap. At present, most of the concrete terminal has been displaced by scour and wave action. Only the outer 100 feet of the concrete terminal remains today, secured by relic stone (from previous repairs) and the rock groins along the north side of the jetty. The 1931-1942 rehabilitation sequence was the last time that the tramway method of repairs was used on the South Jetty. A remnant of the concrete terminal presently forms the seaward-most extent (above water line) of the South Jetty at station 331, which is 4,400 feet shoreward of the 1913 maximum offshore extent (station 375). This feature can be seen in Figure 1-13.

Figure 1-13. Remnant of Concrete Terminal at End of South Jetty

1960-1982 South Jetty Rehabilitation

The South Jetty was repaired during 1961-1965 and in 1982. During 1961-1965, approximately 521,000 tons of stone were used for repair between stations 194-314. This was the first time that an empirical design approach (Hudson equation) was used to define armor stone size for the South Jetty in terms of incident wave height and jetty side slope. In 1961, jetty repairs occurred along stations 194-249 and addressed the most severe damage, which had been sustained along stations 232-242 where the South Jetty crest had been reduced to 3-10 feet above MLLW. Within this area, the jetty had been damaged by wave action to a degree such that the north side of the jetty had sustained damage by wave overtopping. Other areas along stations 194-249 had experienced a general damage trend due to wave action and scour/undermining along the south side of the jetty. Between stations 194-249, the jetty was rebuilt with a crest width of 24 feet and elevation of 24 feet. Jetty side slope for the repair was 1.5 horizontal by 1 vertical on south side and 1:25 horizontal by 1 vertical on the north side. During 1961, a total of 213,461 tons of stone was placed. During 1962, repairs occurred along stations 249-314 using a crest width of 40 feet and elevation of 25 feet MLLW using 308,000 tons of stone. Most of the stone was placed along the southern side of the jetty. Stone was placed using land-based crane and jetty haul road. The size of armor stone averaged 25 tons.

In 1982, the South Jetty was repaired and 77,000 tons of stone was placed along stations 194-249 (same as in the 1962 repair). Most of the stone was placed along the southern side of the jetty to address wave damage. The amount of stone placed per unit length of jetty in 1982 (at 14 tons/feet) was less than one-third of any repair effort previously conducted on the jetties. Armor stone size averaged 13 tons (maximum 25 tons/minimum 8 tons). The repair cross-section had a crest elevation of 25 feet, crest width of 30 feet, and side slope of 1.5 horizontal to 1 vertical. Stone placement was by land-based crane and jetty haul road. Stone was delivered to the job site by barge.

2006-2007 South Jetty Interim Repairs

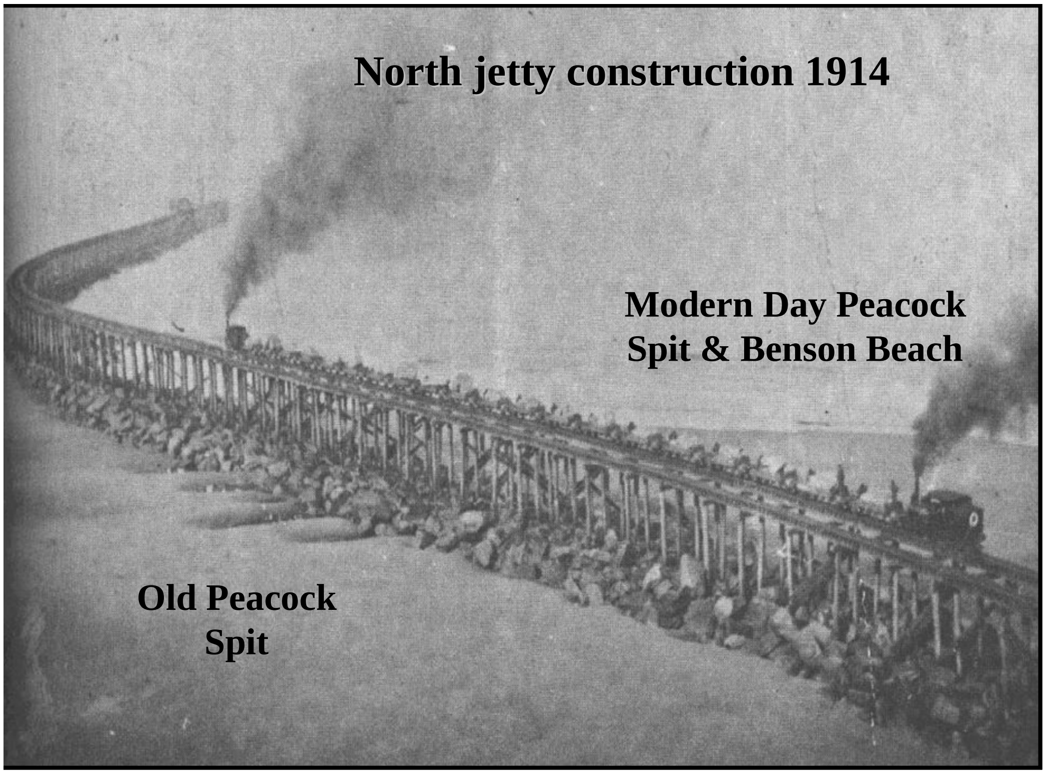
During 2006 and 2007, interim repairs were conducted along the South Jetty. These repairs were short-term efforts intended to stabilize the jetty until a longer term action could be taken. In 2006, interim repairs were conducted from stations 223 to 245. Crest elevation used was 25 feet with a side slope of 1 vertical to 2 horizontal. The stone sized ranged from 15 tons to 22 tons. In 2007, interim repairs were conducted from stations 255 to 285. Crest elevation used was 25 feet with a side slope of 1 vertical to 2 horizontal.

1.5.1.2. North Jetty

Congress authorized construction of the North Jetty through the Rivers and Harbors Act of 1905. Construction of the jetty was needed to limit the northward migration of the navigation channel, in response to South Jetty construction during 1885-1913. The direction of the jetty was to follow approximately the shallow waters southwesterly across Peacock Spit without a sudden change in direction to a point roughly 2 miles north of the end of the South Jetty. Heavy scour along the jetty toe was expected and taken into account during design by incorporating additional bedding stone.

North Jetty construction began in 1913 after completion of the South Jetty, and was completed in 1917. The North Jetty extended southwest from Cape Disappointment (station 0+00) along Peacock Spit for about 2 miles (station 107), then turned westward for about 1,700 feet and terminated at station 122. The 2.35-mile-long North Jetty required 2.95 million tons of stone. The stone was placed using a trestle-supported tramway with locomotives, side-casting cars, and crane. Stone was delivered to the tramway by barge. The same cross-section as shown in Figure 1-11 was used for original North Jetty construction, except that crest elevation was at 28 to 32 feet MLLW. Crest elevation along the landward 3,000 feet of the jetty was 15 feet MLLW. Jetty crest width was 25 feet. Maximum armor stone size was 7 tons. The finished side slope was approximately 1 vertical by 1.5 horizontal (natural slope). Figure 1-14 illustrates the trestle-based original construction of the North Jetty.

Figure 1-14. Trestle-based Original Construction of the North Jetty



Upon completion of the North Jetty in 1917, the two MCR jetties would work together to: (1) constrict the width of the MCR entrance to 2 miles at the terminal ends of the jetties, at which point the velocity of tidal flow would minimize the formation of shoals in the MCR entrance channel; and (2) "hold" and prevent channel-ward encroachment of existing entrance shoals - Peacock Spit along the north side of the MCR entrance channel and Clatsop Spit along the south side of the channel. By 1917, the navigation channel had attained a controlling depth of 40 feet and channel width was 1,000 feet. By 1937, the controlling depth was 46 feet and the distance between 40-foot depth contours along the channel centerline was 8,000 feet. The two jetties stabilized the inlet and enabled maintenance of an engineered entrance with nominal dredging. Figure 1-15 and Table 1-3 summarize the construction and repair efforts for the North Jetty over the project life. The yellow line on the figure indicates the area along the jetty that has never been repaired since original construction.

Figure 1-15. North Jetty Construction and Repair History (yellow represents portions of the jetty that have never been repaired)

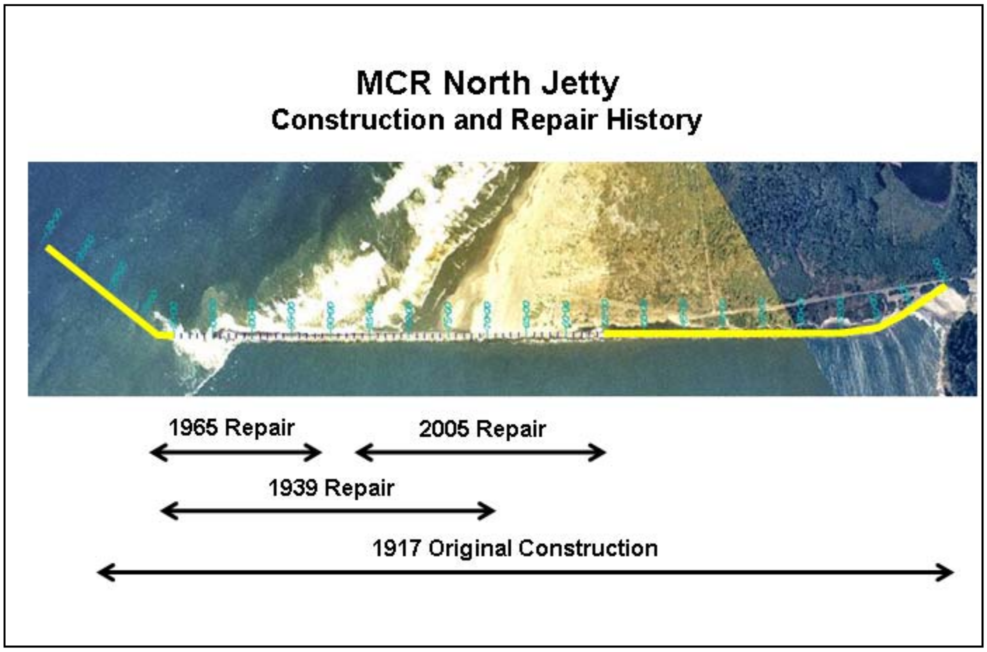


Table 1-3. Construction and Maintenance Activities for the MCR North Jetty

Design Parameter	1917	1939	1965	2005
Stone Density (pcf)	167	167	167	167-180

Ending Station	122+00	110+35	109+67	86+00

The first effort to rehabilitate the North Jetty was undertaken during 1938-1940. The total length of jetty reconstruction was 4,200 feet from stations 68-110 using 243,833 tons of stone. Along most of this reach, the north side of the jetty had resisted wave action due to the accumulation of sand (Benson Beach, see Figure 1-6). However, the south side of the jetty was damaged due to undermining from current action and direct exposure to waves. All of the stone placed on the jetty trunk during the 1938-1940 rehabilitation was along the northern side to maximize the effectiveness of establishing a rebuilt cross-section by placing stone on the more stable slope as opposed to the undermined slope on the south side of the jetty. Each side of the jetty head received equal amounts of stone (stations 108-110). The stone was placed using tramway, dump cars, and a 25-ton crane. Stone was delivered to the tramway by barge. Armor stone size ranged between 6-25 tons. Average armor stone size was 9 tons. The armor stone size was chosen based on professional judgment and equipment limitations. Rehabilitated crest width was 30 feet and crest elevation was 26 feet above MLLW.A concrete terminal (width of 70 feet and elevation 17 feet using 3,280 cy of concrete) was constructed from about stations 118-120 to establish a secure jetty head. The seaward-most 1,400 feet of the North Jetty (stations 120-124) was not rehabilitated. By 1964, the North Jetty concrete terminal had been reduced to 0 feet MLLW or less. The 1938-1940 rehabilitation sequence was the last time that the tramway method of repairs was used on the North Jetty. By 1964, the concrete terminal had broken into several pieces and settled to – 6 feet. At present, the remnants of the concrete terminal have been beaten down to below –10 feet.

The North Jetty was repaired in 1965 and 132,000 tons of stone was placed along stations 89-110. In 1964, the head of the North Jetty had been beaten back by wave action and undermining to station 103 from the original jetty head location at station 124. Along much of the southern side of the jetty, the outer armor stone had sloughed into the river exposing smaller core stone. The 1965 repair was needed to address damage along the southern side of the jetty caused by undermining of the jetty toe and to re-establish a stable jetty head. This was the first time that an empirical design approach (Hudson equation) was used to define armor stone size for the North Jetty in terms of incident wave height and jetty side slope. Model studies conducted by the Waterways Experiment Station in 1963 indicated that rehabilitation of the North Jetty to its outer end would improve flow patterns around the jetty, such that less shoal material would deposit in the MCR navigation channel. Much of the repair effort was dedicated to re-establishing a secure jetty head.

Most of the stone placed along the jetty trunk was placed along the northern side to efficiently re-establish a jetty cross-section. The exposed core stone along the south side was not believed to be vulnerable to wave attack, and significant water depth along the southern side of the jetty precluded an efficient cross-section renewal. Armor stone size ranged between 15-25 tons. The repair cross-section had a crest elevation of 24 feet and crest width of 30 feet. Stone placement was by land-based crane and jetty haul road. Stone was delivered to Ilwaco by barge and transported 2 miles by truck to the job site.

Early in this investigation, it was determined that portions of the North Jetty were close to failure. Interim repairs of the North Jetty in 2005 addressed only the upper part of the cross-section damage (stations 55 to 85) and were expected to last 10 to 15 years. The intent of this interim repair was to address the loss of jetty cross section above elevation -10 feet due to slope failure and direct wave action, in order to address short term stability problems.

1.5.1.3. Jetty A

During the early 1930s, after both the North and South jetties had been in place and significant modification of the inlet's morphology had occurred, the North Jetty became threatened by high velocity ebb tide flow, which threatened to undermine the structure's channel side foundation. Concurrently, the south side of Sand Island was being eroded by increased current action. In the late 1930s, the Sand Island pile dikes and Jetty A were constructed to stabilize the evolving inlet. Original construction was conducted with diorite rock from stations 40+93.89 to 97+36. From the beginning of the structure to station 53, the jetty was just a small armament feature with a crest width of 10 feet. The jetty from stations 53 to 92+86 was 30-feet wide at an elevation of 20 feet. The centerline of the jetty was centered along the railroad trestle. At station 92+86, the railroad trestle diverges into two trestles. The centerline of the jetty appears to be the center of the two trestles. Figure 1-16 and Table 1-4 summarize the construction and repair efforts for Jetty A.

Multiple partial repairs to Jetty A were made during the 1940s to 1960s. In 1958, approximately 3,800 feet of the inner end was repaired (stations 41 to 79). The structure had degraded to an elevation of 15 to 20 feet and was rebuilt to 20 feet (stations 41 to 56) with the baseline on the centerline of the old trestle. From stations 56 to 61 a transition occurs where the centerline of the repair changes from 25 feet to the right of the baseline to 10 feet left. From stations 61 to 79, the crest width was 30 feet.

*Change order increased average weight of Class A to 8 tons.
**No repairs from sta. 68+00 to sta. 76+50.

In 1960, approximately 3,150 feet of the outer end of Jetty A was repaired. The section was rebuilt to +24 feet in elevation from degraded elevations of +10 to 15 feet. A memorandum established a cap stone weight of 17.6 tons based on a wave height of 15.5 feet and a specific gravity of 2.4. The stone size considered for the 1960-1961 repair was a 6-ton minimum and at least an average weight of 10 tons. The armor layer was designed to have class A stone placed along the westerly/ocean slope and over the crest of the jetty. Class A and class B stone would then be placed along the easterly/Baker Bay slope. Select class A stone, weighing more than 15 tons, was placed between jetty stations 90+00 and 90+50.

A 1960 Design Memorandum stated that the history of repairs at Jetty A, "suggests major deficiencies in past construction." This design report stated that since the jetty, "is principally serving as directional current training and not as wave protection, the structure would adequately fulfill all requirements if the repairs were to end at station 91+00 rather than 95+50. For the same reason, the height of jetty repair between stations 78+00 and 91+00 should be held to elevation +20." Rock in the armor layer was individually placed with a crane, as opposed to being dumped onto the jetty from the trestle and tramway. Stations 41 to 79, repaired in 1958, received considerable damage due to overtopping waves. Breaks in the jetty exposed the jetty to further damage. The design report stated that it was believed that the first damage to the jetty was due to subsidence caused by scouring of sand from around the jetty base resulting in armor stone displacement. Smaller rock was then exposed to waves, which resulted in further displacement.

A small armament was built from stations 49+93.89 to 53+00 on Jetty A according to plan drawings and the 1960 Design Memorandum. The jetty was then built to an elevation of 20 feet MLLW out to station 92+86. From stations 92+86 to 97+36, a second trestle was built and the jetty crest width was built wider, with a crest width at the end of 90 feet. There have been six repairs since original construction. The centerline of the jetty has not remained the same throughout the repairs.

Jetty A, as originally constructed, protects the North Jetty and helps to train the Columbia River mainstem. In addition, Jetty A is believed to play an important function for the Columbia River plume. The plume is an important food source for the 13 Columbia River salmonid evolutionarily significant units (ESUs) listed under the Endangered Species Act (ESA).

1.5.1.4. Forensic Analysis of Historical Jetty Stability

A forensic analysis of historical construction and repair efforts at the MCR project incorporates both the capacity of the structure to resist damage as well as the degree of loading the structure undergoes. Both of these categories have evolved over time for all of the jetties being analyzed. The location and capacity of the historical construction efforts are shown in Figure 1-2 through Figure 1-16 and Tables 1-2 to 1-4. For the purposes of defining the failure history, the jetty lengths can be divided into general zones of exposure. Table 1-5 summarizes the primary loading factors for the range of zones of each jetty. Zone 1 is closest to shore and typically has the lowest loading forces while zones 3 and 4 are the furthest offshore and have the highest and most complex loading. Additional information on construction history can be found in Appendix A1, Section 5. The last column summarizes the identified failure modes associated with that construction effort and point in time.

The key capacity features that influence the performance of the MCR structures include stone size, sideslope, stability coefficient, and crest elevation. All of these factors have been influenced somewhat by construction method. Pacific Northwest jetties have historically been constructed from the top of the jetty downward with limited reach length equipment. In the case of the initial construction, this involved the construction of a railroad trestle that extended the length of the structure from which the rock was dumped. The initial construction and subsequent repairs evolved over time from the initial low crest, small stone size construction of the South Jetty first construction to the more substantial cross sections of the later efforts. For subsequent repair efforts, minimum crest width and crest elevation were often associated with providing a safe and viable construction platform for the equipment. A rigorous and analytical approach to sizing the stone for the construction and expected wave loading did not occur until the 1950’s and 1960’s.

At the MCR and for most Pacific Northwest coastal projects, wave attack is the primary loading factor, both front slope attack as well as backslope instability due to overtopping. Other related damaging forces are related to the scour and morphology change around the project. In some cases morphology/shoreline change can have a positive effect on the stability of the structure, e.g. the shoreline accretion along the north side of the North Jetty has functioned to protect the landward half of that structure from oceanside loading. However, in other cases, toe scour or shoreline recession has the combined effect of destabilizing the structure toe as well as allowing larger waves to impact the structure. Increasing wave heights over time at the entrance can also be attributed to sequential channel deepening actions. While the original authorized depth was 30 ft in 1882, the actual depth over time achieved was variable during the construction of the three jetties. Once all three jetties were constructed, more stability was achievable in the maintained channel. The gradual increase in channel depths occurred in 1895 (30 ft), 1918 (40 ft), 1957 (48 ft), and 1984 (55 ft).

Shortly after the construction of the North Jetty, it became threatened by high velocity ebb tide flow which threatened to undermine the structure's channelside foundation. In contrast to the South Jetty original construction, the North Jetty construction plan did not include any channelside spur groins to assist in controlling the flow along the foundation of the structure. Concurrently, the south side of Sand Island was being eroded by increased current action. Loss of either the North Jetty or Sand Island would have rendered the inlet unsuitable for navigation. The adverse circulation affecting the North Jetty and Sand Island was motivated by the northward migration of the estuary thalweg toward Cape Disappointment. In the late 1930s, the Sand Island Pile Dikes and Jetty A were constructed by USACE to stabilize the evolving inlet. At the same time the scour was occurring on the channelside of the North Jetty, the ocean side of the structure was being protected by a large accretion fillet. Along the landward half of the North Jetty, another de-stabilizing flow path had developed through the structure as tidal flow moved through the structure to the eroded lagoon behind the structure.

By 1919, the 40 foot contour had been displaced more than 6560 feet seaward in response to the phased jetty construction and the morphology had been thrown out of equilibrium due to increased tidal flow velocity in and around MCR. On the south side of MCR, there was no seaward displacement of the 40-foot contour. Rather, the 40-foot contour south of MCR had been receding landward since jetty construction in 1885. By 1930, waves and currents were acting on the displaced morphology to bring the region to equilibrium. The displaced tidal shoals on the north side of MCR were being eroded and the 40-foot contour was receding landward. The offshore extent of the 40-foot contour on the south side of MCR has been receding landward of its 1885 position, toward the South Jetty, since jetty construction.

Appendix A1, Figures A1-19 to A1-24 and Appendix A5 show morphological change to the inlet over time since original construction. Specific changes to be noted which relate to project loading include shoreline or underwater shoal accretion or erosion, reorientation of the ebb tidal flow path through the mouth, and deepening of the contours which allows greater wave penetration into the inlet. Continued jetty length loss preceded additional erosion of the underwater shoals and greater wave loading of the landward portions of those structures as well as adjacent structures. All of these loading and stability processes have been simulated in the life cycle performance model for this project through the hindcast mode of the event tree simulation.

Table 1-5. Historical Failure Modes for the MCR Jetties

Failure Mode (STA (zone))	Channel-side Wave Height	Oceanside Wave Height	Channel-side Scour	Oceanside/ Backside Scour	Overtopping Forces	Deficient Design Section

80 to 97 (3)		X	X	X	X	X

1.5.2. Historical Morphology Change at the MCR Inlet

An extensive bathymetric analysis was conducted of the MCR by Applied Coastal Research and Engineering in 2006 in order to document evolution of the morphology spanning the time frame prior to jetty construction to the present day. (Byrne and Griffee, 2006) The report built on a preliminary study completed for the Portland District in 1998 (Byrnes and Li, 1998). The study was designed to compile and analyze existing surveys over shorter time intervals to address dredged-material management issues and regional sediment management at and adjacent to the MCR. Detailed bathymetric change maps from this study can be found in Appendix A5.

Between 1868/77 and 1926, massive adjustments in sediment volume occurred at the entrance where the ebb-tidal shoal moved seaward about 2 mi, depositing approximately 252 million cubic yards (MCY) of sediment in 90-ft water depth. Approximately 70% of this deposition occurred between 1899 and 1926, after the entrance jetties were constructed. The ebb-shoal that formed is strongly skewed to the north, even though the channel exits the coast to the south-southwest. Deposition of northward directed sand from the ebb-shoal created Peacock Beach, just north of the north jetty and south of Cape Disappointment. Clatsop Spit evolved in association with construction of the south jetty, creating a 3.5 mi long beach and filling the 1868 entrance channel as the new channel shifted north and displaced Sand Island. Sediment deposition north of the channel and in Bakers Bay (158 MCY), east of Cape Disappointment, appears to be the result of decreased flow in the area resulting from jetty placement and channel realignment. Conversely, seafloor erosion south of the south jetty is the result of decreased sediment supply to the area when the entrance channel shifted to the north, jetting much of its sediment load seaward to the ebb shoal. Sediment erosion associated with channel realignment and erosion south of the south jetty (543 MCY) controlled the sediment budget in the entrance area.

Bathymetric changes recorded for the period 1926 to 1958 illustrate similar depositional trends as the previous surface comparison, but many differences are documented as well. A number of trends emerge from the comparison. First, net northward transport of sediment is illustrated by the north-oriented ebb shoal. The center of the shoal has again moved seaward in response to flow from the increasingly-deeper channel (-40 to -48 ft during this time period); sediment deposition on the ebb shoal during this time was 181.8 MCY. A substantial zone of erosion exists just landward of the ebb shoal, marking the position of the 1926 ebb-tidal delta. The magnitude of erosion for this feature (81.4 MCY) is a little less than half of the deposition recorded for the ebb shoal. Another indication of northward sand transport is the apparent streaming of sand north from the ebb-tidal delta to the beaches along the coast of Long Beach Peninsula. During this time, beaches were accreting along this entire stretch of coast. Approximately 94.1 MCY of sand deposited along the coast during this period.

The interior entrance area illustrates zones of erosion and deposition associated with channel migration, dredging, and deposition at the north end of Clatsop Spit. Overall, erosion (155.2 MCY) is greater than deposition (67.4 MCY) in the entrance area, creating a net sediment loss of 87.8 MCY. To the south of the south jetty, sediment erosion is occurring along the beach (12.4 MCY) and on the shelf (38.4 MCY). The sediment deficit is related to jetty placement and blocking of sand from the entrance that used to supply sediment to the northern Oregon coast. Shoreline change data from Byrnes and Li (1998) suggest that this is a local phenomenon (with 3.5 mi of the jetty), with net shoreline advance indicated south of this point. Komar and Li (1986) discuss this spatial variability in shoreline response and state that in recent years, shoreline retreat south of the jetty has diminished and stabilized.

A number of bathymetric surveys conducted by the USACE – Portland District were employed to evaluate geomorphic changes at the Columbia River mouth up to 2003. Surface comparisons were made for two time periods: 1958 to 2003 and 1994 to 2003. The 1958 to 2003 seafloor change map illustrates the same general trends as those presented for the 1926 to 1958 comparison, except the magnitude of accretion and erosion has increased. The centroid of deposition on the ebb shoal (minus the impact of dredged material placement at Site B) has shifted to the north. Sediment accretion north of the entrance along Long Beach Peninsula continues to occur as the shoreline moves seaward. In addition, erosion associated with the 1926 ebb-tidal delta has increased, and the magnitude of sediment deficit south of the south jetty has been enhanced. One major difference for the 1958 to 2003 surface comparison is the presence of two well-developed mound areas representing dredged material disposal Sites A and B. These areas have been accumulating dredged material since 1956.

The final surface comparison is for the 1994 and 2003 survey dates. Largest changes are associated with offshore dredged material placement, erosion on the ebb shoal, and nearshore and beach erosion just north of the north jetty. Erosion on the ebb shoal and the nearshore area north of the north jetty is consistent with the 1958 to 2003 bathymetric comparison. These two areas indicate net losses of 20.1 MCY and 23.7 MCY, respectively. At ocean disposal sites A and B, erosion on the disposal mound is prevalent; however, sediment deposition occurs to the north of each mound as well, indicating the dominant direction of net drift for dispersed sediment. Site A has had no new material deposited since 1995 and Site B has been inactive since 1998. This information provides direct evidence of net transport pathways at and adjacent to these disposal sites, and throughout the study area. The general trend of deposition north of the entrance is still evident, but the magnitude of change is relatively small due to the short period of time between surveys. A net deficit of about 21 MCY of sediment is calculated for the entire surface. (Byrne and Griffee, 2006)

1.5.3. Service Disruptions, Repairs, and History of Project Costs

A discussion of the construction and repair history for the MCR jetties is provided in Section 1.4.1. Construction of the North and South jetties significantly altered the natural inlet at MCR and secured a stable deep draft navigation channel, although there is risk of jetty destabilization due to scour. A more detailed discussion is provided in Appendix A1. Historically, breaches have occurred in the MCR jetties.

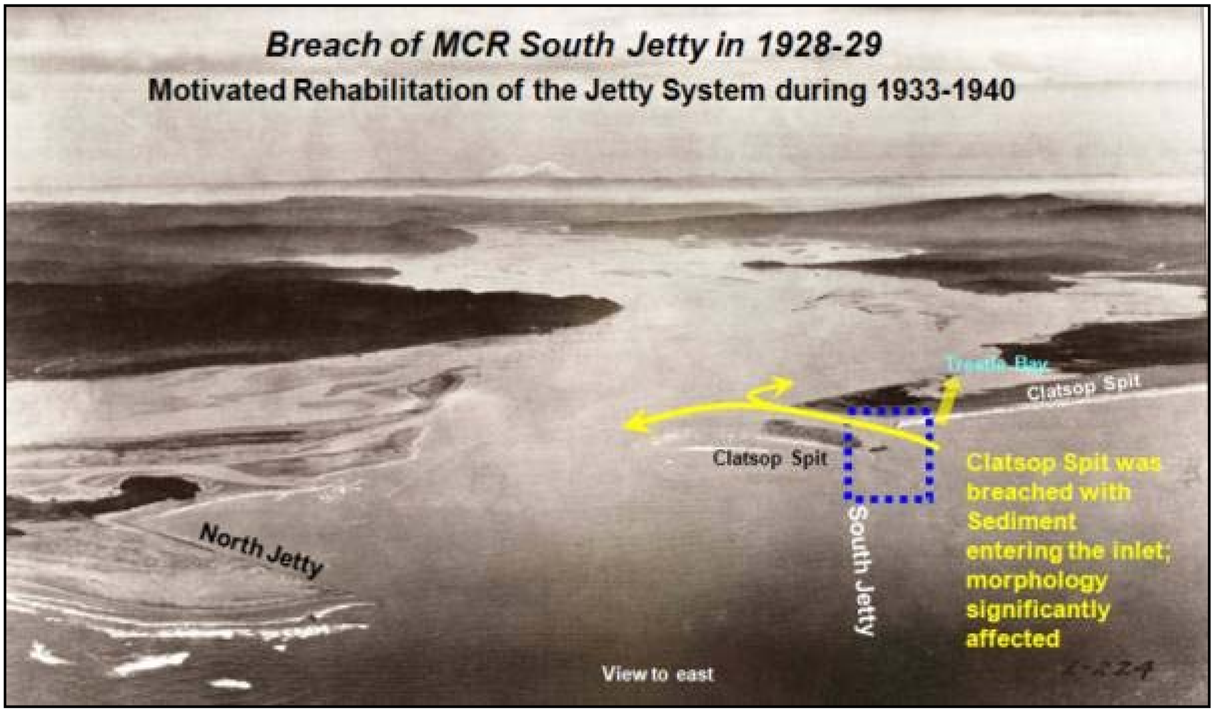
In a historical context, the South Jetty root breached extensively during the late 1920s. This event modified the configuration of the MCR inlet and affected navigation, motivating a significant rehabilitation campaign of the South and North jetties during the 1930s. Figure 1-17 illustrates this event. In 1928, a breach through the jetty cross section occurred near the shore connection (jetty root). The consequences of the breached jetty were significant. A large volume of sediment passed through the breach (from south to north) and deposited in the inlet, which changed the inlet's morphology. Much of the sediment along the ocean shore south of the inlet was transported by flow through the breached jetty (narrowing the margin between the ocean and Trestle Bay). Storm surge overtopped the shore and passed into Trestle Bay, threatening the stability of the entire inlet. Tidal circulation through the breach promoted the northward migration of Clatsop Spit, which adversely impacted navigation through the MCR. The breach event motivated a 9-year jetty rehabilitation program for the North and South jetties and included the construction of Jetty A.

The outer end of the North Jetty was rehabilitated from 1938-1940; however, by 1958 the jetty was again in need of rehabilitation because a 300-foot breach had developed immediately shoreward of the terminal block, and the river side of the outer half of the jetty had been damaged by undercutting. During the late 1950s, Jetty A had become breached, resulting in a concerted effort to rehabilitate the structure. Jetty A has not been repaired since 1962. Figure 1-18 shows the Jetty A breach, as well as an imminent breach developing along the North Jetty in 2002.

During 1999-2004, reaches of the North and South jetty became partially breached, motivating "interim repairs" to both jetties, performed "just-in-time" during 2005-2007. Before completion of the North Jetty interim repairs in 2005, approximately 300,000 cy of sand (from Benson Beach) had passed through the damaged section of the North Jetty. This volume was estimated based on bathymetric surveys conducted during 1999 and 2006. The sand deposited along the channel side of the North Jetty, not being transported toward the navigation channel due to lack of hydraulic forcing. Interim repairs addressed the most critical areas of the North and South jetties in a cost-effective manner. The interim repairs were intended to last 10 to 15 years (from 2006), until the jetties could be rehabilitated.

Major disruptions to the MCR navigation channel have been avoided through several large rehabilitation efforts throughout the extended project life of the MCR structures. Figure 1-19 and Figure 1-20 illustrate damage to the South Jetty and the attempt to stabilize the structure. Each of those efforts served to re-establish the robustness and reliability of the structures.

Figure 1-17. Historical Breaching of the South Jetty



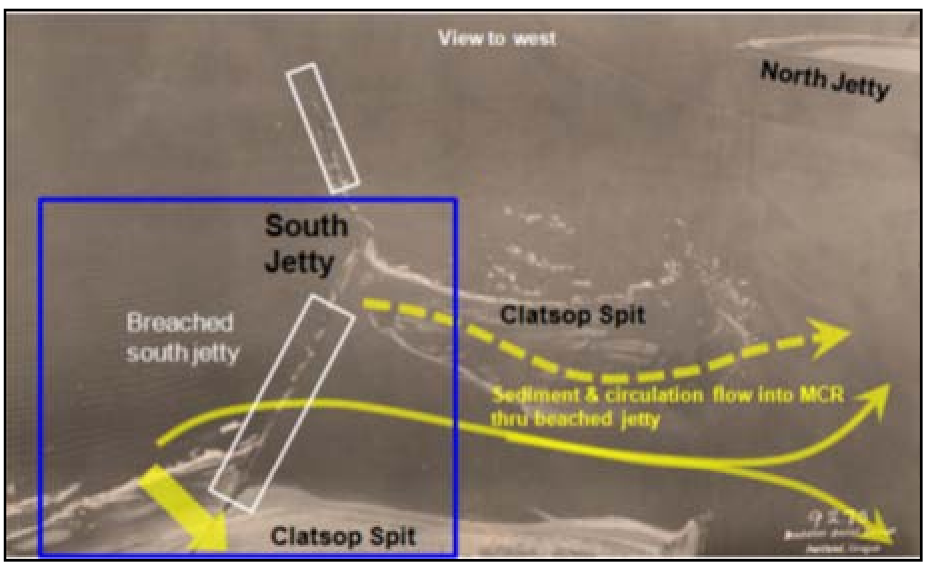


Figure 1-18. Historical Breaching of the North Jetty and Jetty A

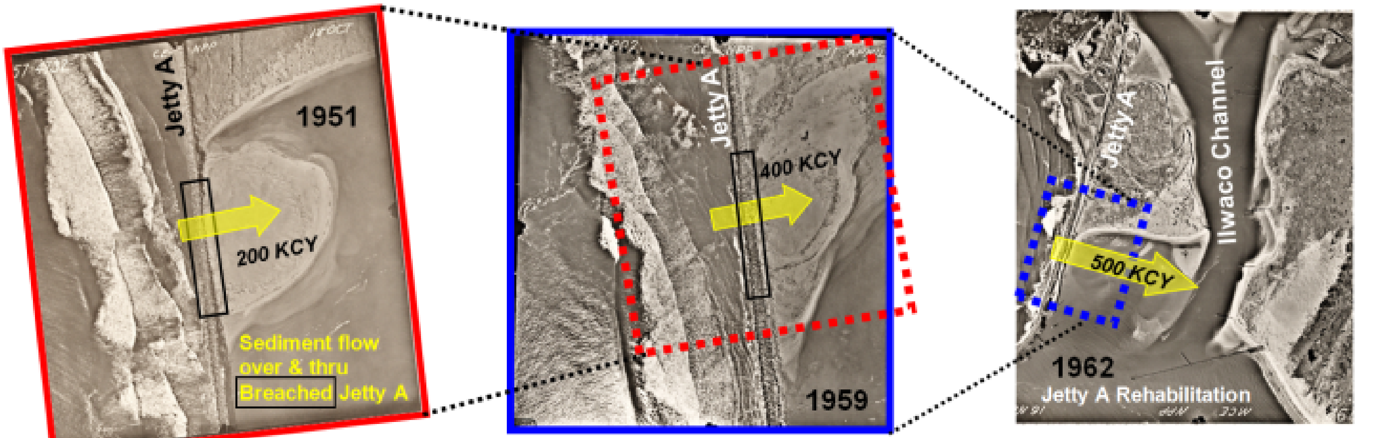
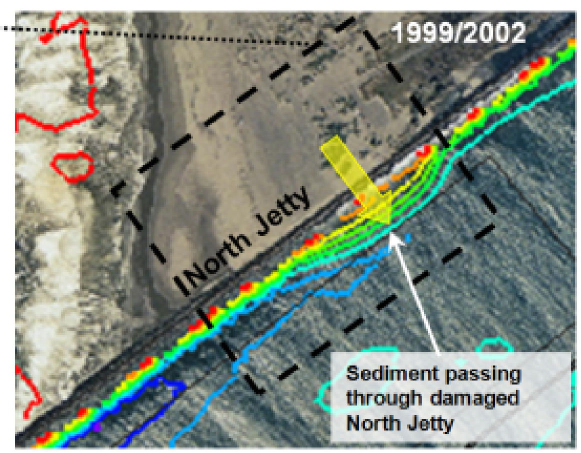


Historical breaching of Jetty A. Jetty A was constructed in 1939 to halt northward migration of the inlet and re-direct currents away from the north jetty, In 1950, a 300-ft long breach developed at the mid-span of Jetty A allowing ~200 KCY to be transported (eastward) over the jetty and toward Ilwaco channel. Jetty A was rehabilitated in 1961-62 to restore function and prevent further sediment encroachment (closure) of the Ilwaco navigation channel. During 1951-61, approximately 500 KCY passed thru the Jetty A breach.

Had the NJ not been repaired "just-in –time" in 2005, it would have breached soon after allowing a very large volume of sediment to pass into the MCR inlet and the navigation channel.



Recent breaching of North Jetty. The North Jetty (NJ) was constructed in 1914-17 to stabilize the north side of the MCR inlet, and was repaired in 1939 & 1964. By 2002, several areas of the NJ were on the verge of breaching. The jetty cross-section between Sta 57-70 was degraded such that sediment was being transported through the jetty during high-tide storm wave conditions.

1.5.4. **Expected Future Changes in Jetty Structures over time**

1.5.4.1. North Jetty

The North Jetty has receded about 2,100 feet in length since original construction (Figure 1-24 and Figure 1-25). The location of the jetty head is typically referred to as the last full jetty cross section at the design crest elevation. Based on historical recession rates, the jetty head will continue to deteriorate at a rate of about 20 to 50 feet per year. At this rate at the end of a 50-year period, it is expected to reach stations 76 to 90 (or about 1,800 feet of additional loss from its current position) in very close proximity to where the existing shoreline is today. Peacock Spit and Benson Beach are expected to continue to erode shoreward at a similar rate to the jetty length deterioration. Much of the sediment loss associated with shoreline retreat would migrate into the federal navigation channel and routine maintenance dredging of the MCR entrance would increase over time.

The North Jetty trunk will degrade by three distinct processes: direct wave impact, wave overtopping (affecting above-water portion of jetty), and scour at the jetty base (affecting below-water portion until it fails and destabilizes the above-water portion). The present channel side toe of the jetty is severely compromised due to foundation scour, while the landward half of the ocean side of the jetty is protected by high elevation bathymetry. Both sides of the seaward half of the jetty are exposed to large waves. The North Jetty acts as a wing dam to prevent Peacock Spit and Benson Beach from entering the inlet.

Figure 1-24. North Jetty Head Recession

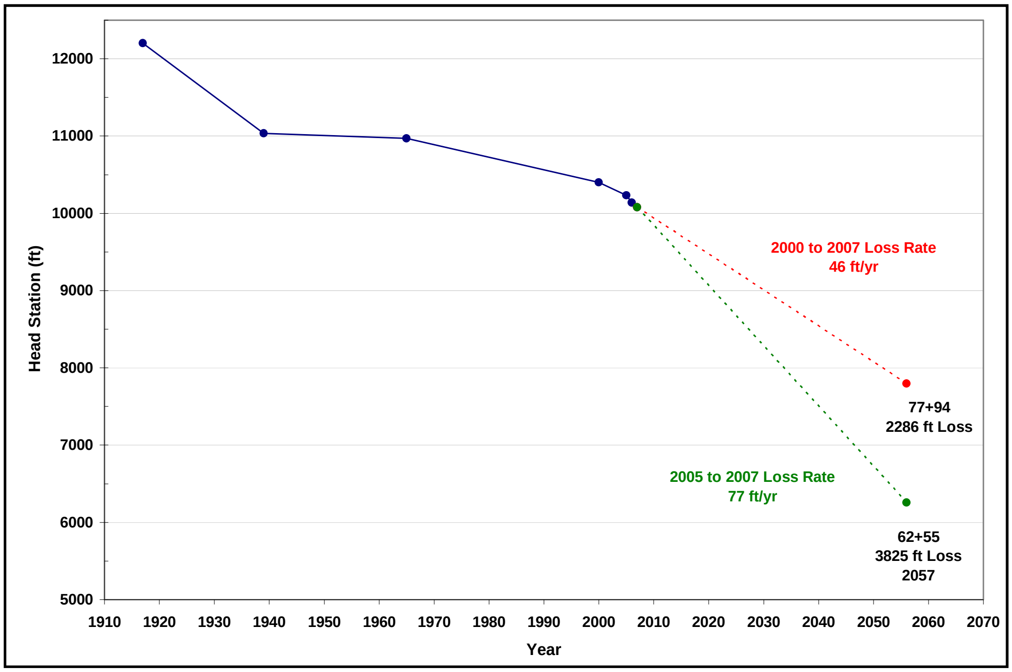

Figure 1-25. North Jetty Crest and Foundation Changes Over Time

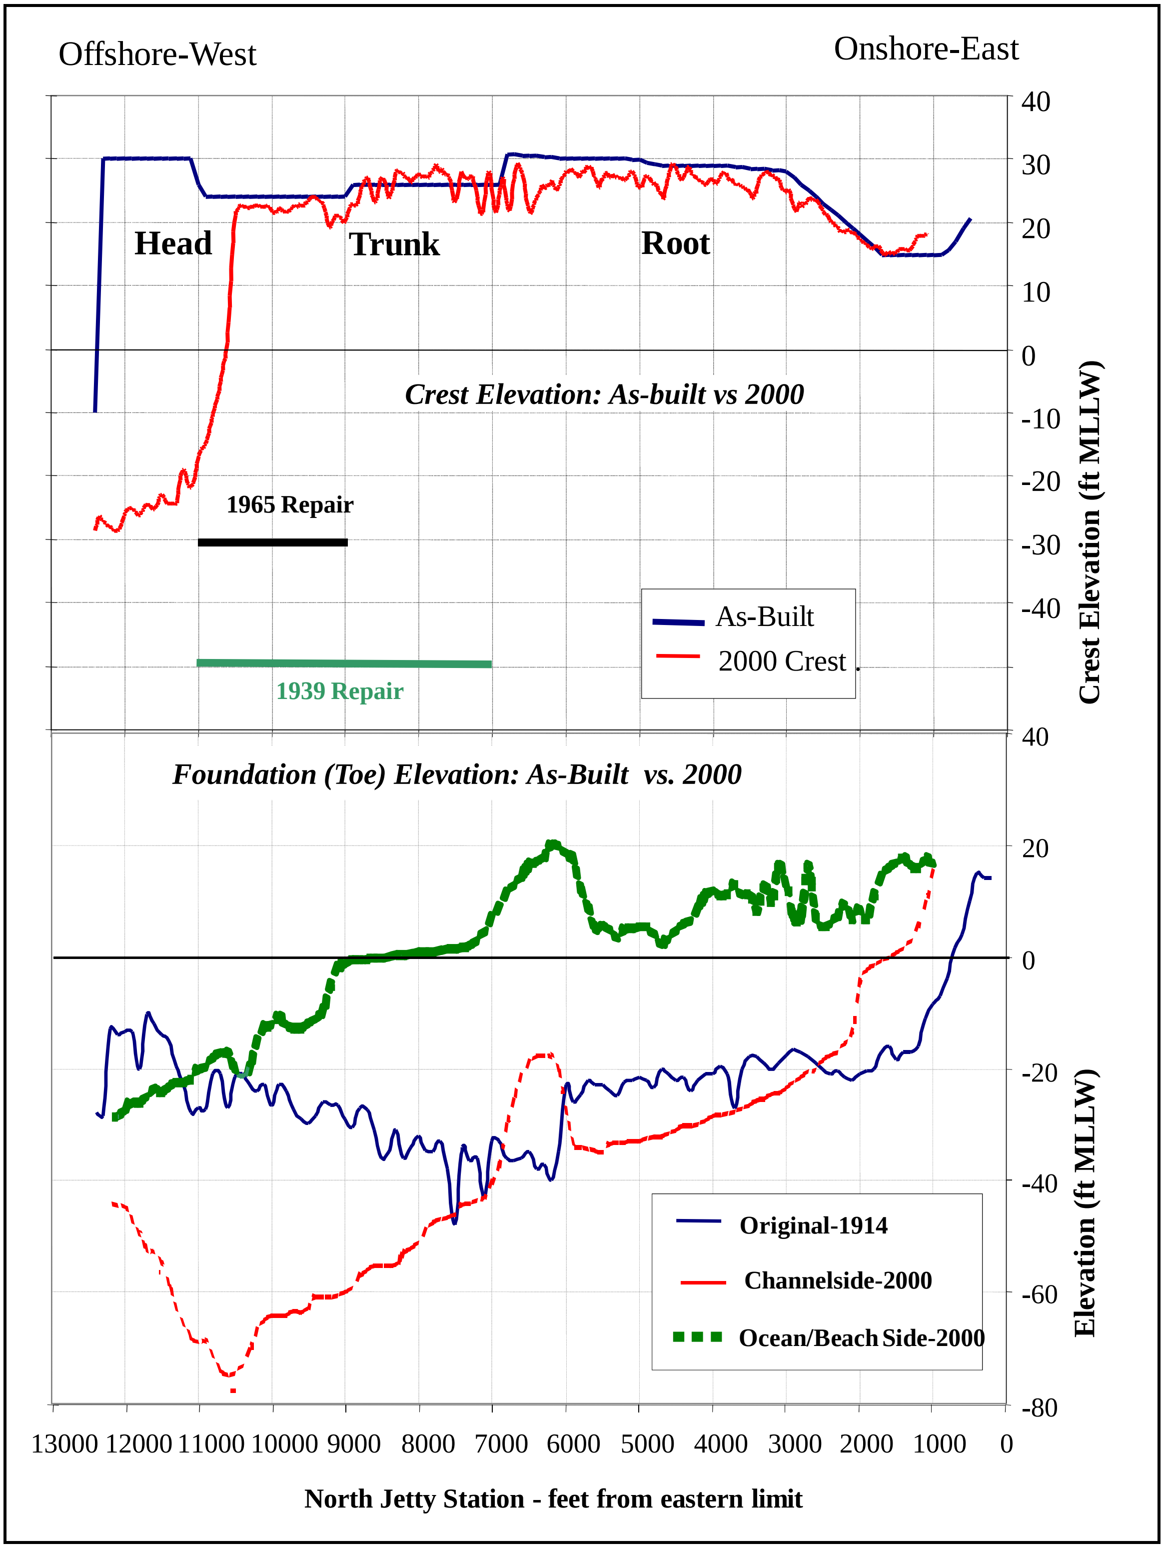

1.5.4.2. South Jetty

The South Jetty has receded about 6,200 feet in length since original construction (Figure 1-26 and Figure 1-27). The part of Figure 1-26 between 1913 and 1964 illustrates the changing morphology and continued loss of the South Jetty length due to extreme wave exposure and ebb tidal shoal changes. Although the concrete monolith was constructed in 1941, the jetty continued to recede landward of the concrete monolith. Continued steepening and scouring of the foundation contributed to loss of structure length. The existence of the spur groins at stations 309 and 333 helped to slow the morphology change at those locations and in addition helped to maintain concrete terminal longevity. These spur groins are shown in Figure 1-28.

The projected jetty length recession in the future as shown in Figure 1-26 is based on extrapolating the existing rate of recession until the concrete monolith is expected to deteriorate to extent it no longer provides some protection to the seaward end of the Jetty. This is expected to occur in approximately 12 to 15 years based on recent observations and engineering judgment. Once the concrete monolith no longer provides protection of the seaward end of the jetty, recession of the jetty length will accelerate in the future.

Repeated repairs to the seaward half of the South Jetty (four repairs) have bolstered that reach of jetty's resilience over time. Other MCR activities which have influenced the recession rate and stability of the South Jetty head and seaward half are the 1954 channel deepening and slight channel realignment and the creation of ODMDS A (see Figure 1-4). Figures pertaining to the 1954 channel deepening can be seen in Appendix A, Figures A1-25, A1-26, and A1-29. The channel realignment shifted the MCR channel slightly to the north allowing Clatsop Spit to achieve more stability on the channel side of the South Jetty, providing more protection there. Disposal efforts at ODMDS A started in the 1950s and it was the primary disposal site for the 1954 channel deepening. Disposal at this site continued until 1994, at which point its use was discontinued. As seen in Figure 1-4, ODMDS A plays a large role in shielding the head of the South Jetty from incoming waves.

Currently, the concrete monolith still exists as a remnant structure seaward of the actual jetty head. Continued wave exposure and foundation scour, however, are undermining its stability. Since it serves as a type of anchor point for the ebb tidal shoal and the south jetty seaward half, if this is de-stabilized, more rapid South Jetty deterioration would be expected.

Like the North Jetty, the South Jetty trunk will degrade by direct wave impact, wave overtopping, and scour at the base of the jetty. The channel side of the jetty is in the lee of waves approaching the jetty directly from the Pacific Ocean. The channel side of the jetty is also protected by the high elevation bathymetry of Clatsop Spit, while the ocean side of the jetty is exposed to larger water depths and the direct attack of the Pacific Ocean wave environment.

Figure 1-26. South Jetty Head Recession

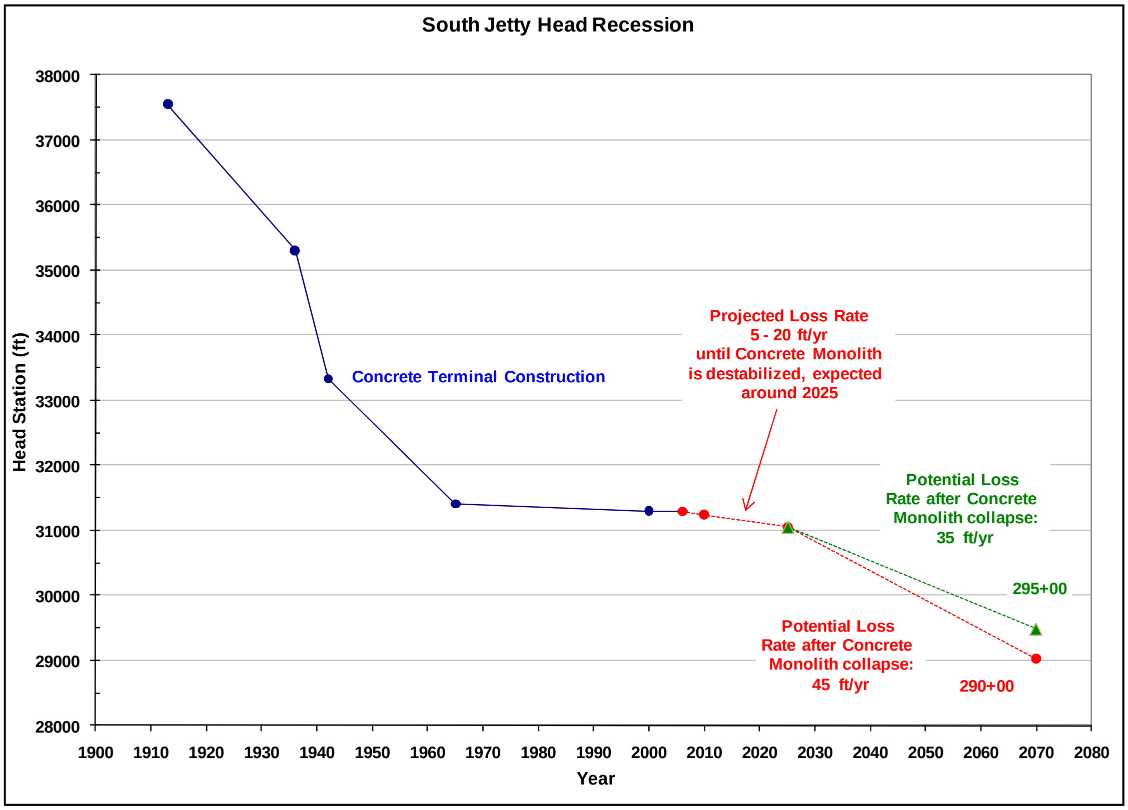

Figure 1-27. South Jetty Crest and Foundation Changes over Time

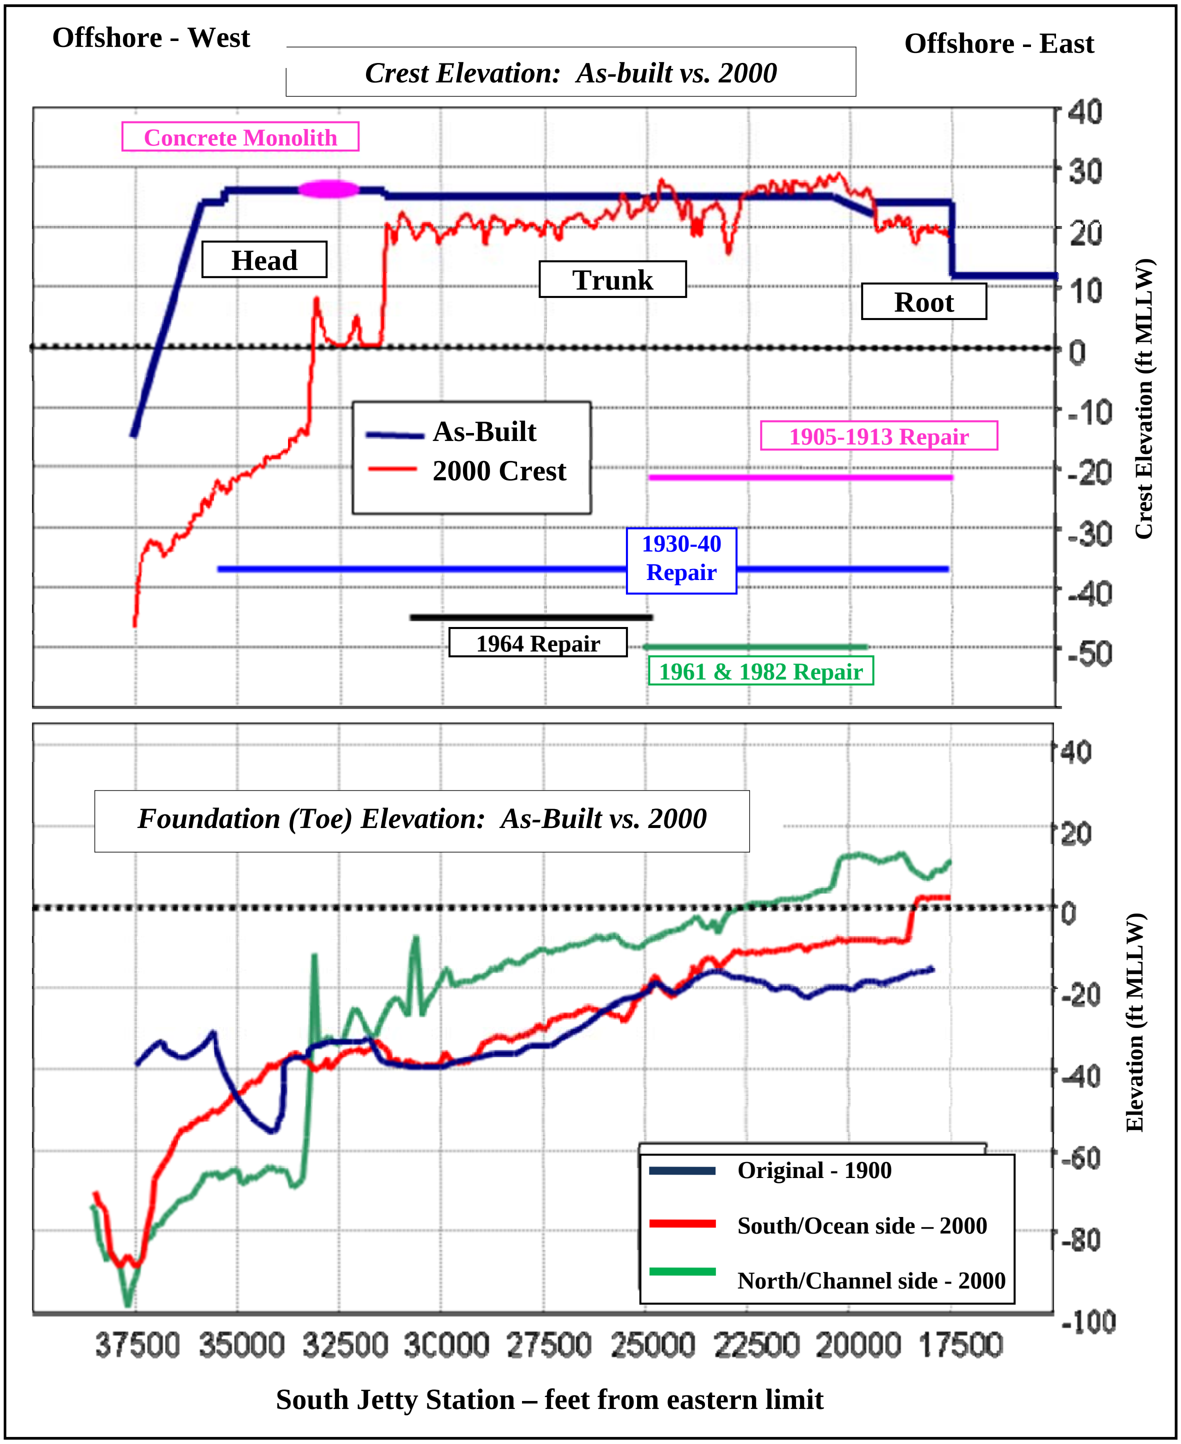

Figure 1-28. Spur Groin Construction and Influence on Stabilizing Underwater Contours along Channel Side of South Jetty

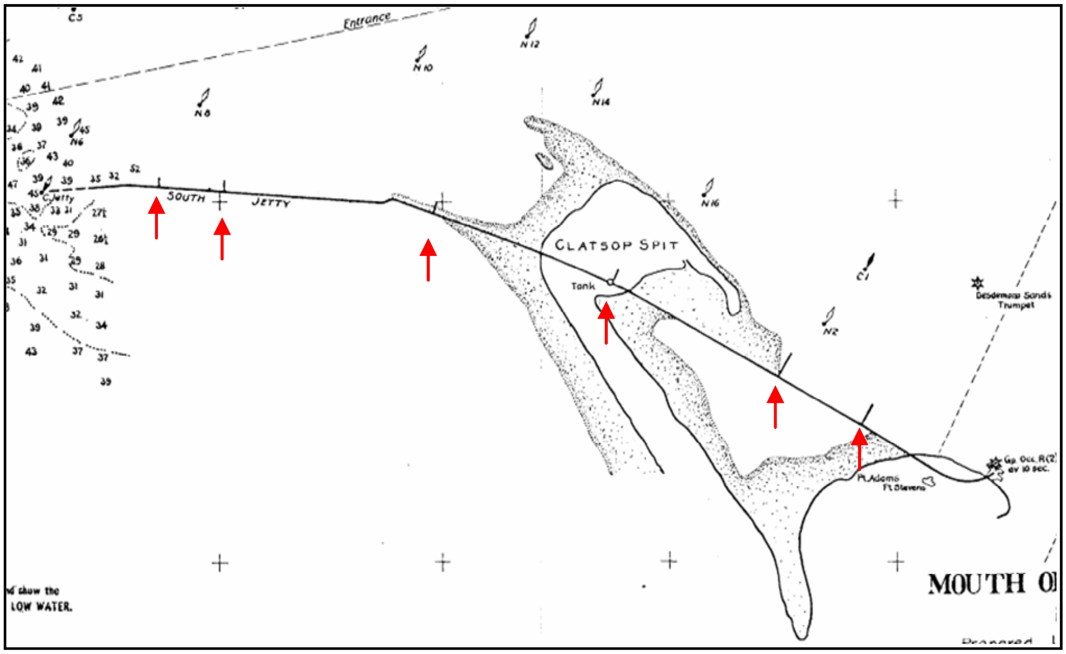
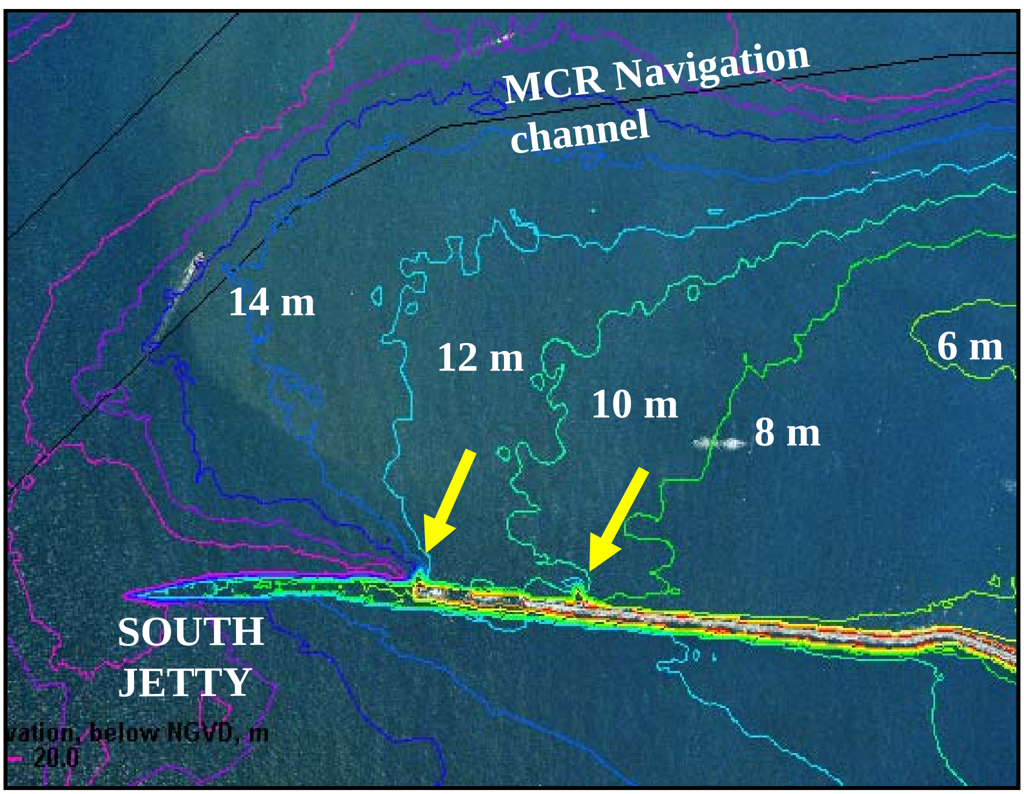




Concrete Monolith

During rehabilitation of the South Jetty in the 1930s, a 500-feet-long concrete cap was constructed to secure the jetty head at station 330. The seaward most 200 feet of the concrete cap was composed of a solid core monolith. (Figure 1-20) This cap has served well since 1940; however, the entire cap has been severely damaged due to the harsh wave climate that exists 3 miles offshore and is progressively failing. This cap serves as an anchor to secure and protect the un-reinforced area of the South Jetty immediately inshore of the cap. When the cap fails completely (i.e., falls off the jetty crest), the jetty trunk adjacent to the cap will rapidly deteriorate due to relentless wave action.

South Jetty Base Erosion

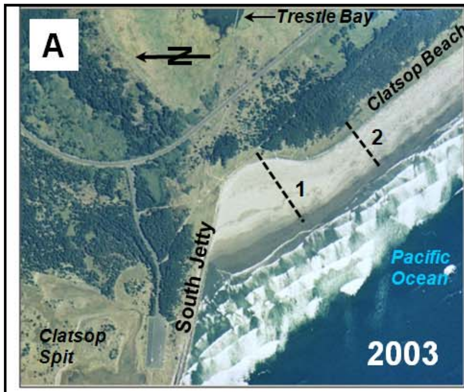
The shore area along the South Jetty root has experienced profound changes since the time of jetty construction. Before construction, the nearshore area immediately south of the jetty was dominated by a broad shallow ebb tidal shoal, exhibiting relatively shallow water depth. Construction of the South Jetty dissipated this shoal, resulting in a rapid trend of increasing water depth through time (see Figure 1-3). As the water depth along the south side of the jetty increased, wave action along the jetty root and adjacent shore area increased. The increased wave environment motivated rapid deterioration of the entire South Jetty and culminated with the significant breaching event along the South Jetty root in the late 1920s. During the 1930s, extensive efforts were undertaken to rebuild the South Jetty and re-establish the shore-land interface along the jetty's south-side root. Although the effort was successful, the result has been subjected to an increasingly harsh environment of wave action and related circulation since the 1930s.

Currently, the coastal shore interface along the South Jetty is in a condition of advanced deterioration (Figure 1-30 and Figure 1-31). The foredune separating the ocean from the backshore is almost breached. The backshore is a narrow strip of a low-elevation, accretion area that separates Trestle Bay from the ocean by hundreds of yards. The offshore area along the South Jetty (and to the south) continues to erode, promoting larger wave action to affect the shoreline along the South Jetty root. The back-dune of Trestle Bay has continued to advance westward due to increased circulation in the bay, seasonal wave chop, and hydraulic surcharging.

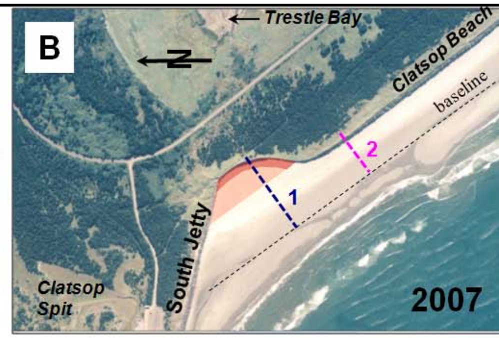
South Jetty Existing Spur Groins

Historical records show that six spur groins (#1-4, #6-7) were constructed along the channel side of the South Jetty (Table 1-6). Four groins were buried by accreted shoreline or sand shoal. The two visible, most seaward spur groins (at ~stations 309 and 333) clearly show an influence on the surrounding underwater contours. The 100-foot spur groins push the more extreme tidal velocities channel-ward, so that the shoal material at the base of the jetty is stabilized.

Figure 1-29   Historical Beach Erosion at South Jetty Root



MCR South Jetty root, south side where Clatsop Spit joins with Clatsop Plains/Beach. Panels A and B show the erosion embayment along the south jetty root for 2003 (high tide) and 2007 (low tide). The embayment & adjacent shore have receded 40 ft landward during 2003-2007, reducing the protective foredune along the embayment



Panel C shows cross-sections 1 and 2 for 2007(shown in panels A & B). Severe erosion in this area had threatened the inlet stability during early 1930s, when jetty rehabilitation and sand augmentation measures were implemented. Erosion has again become chronic since the late 1970s. The foredune protects the backshore (elevation 15-18 ft NAVD) from wave surge action during storms. If the foredune is breached, the backshore will be rapidly eroded. Without erosion abatement, it is estimated that that the Pacific Ocean will establish hydraulic connectivity with Trestle Bay in 10-15 years from 2009, and again threaten inlet stability. Panel C shows two options for protecting the foredune within the erosion embayment: A SAND berm template requires ~225,000 cy of sand placement, and a COBBLE berm template requires ~60,000 cy of cobble placement.

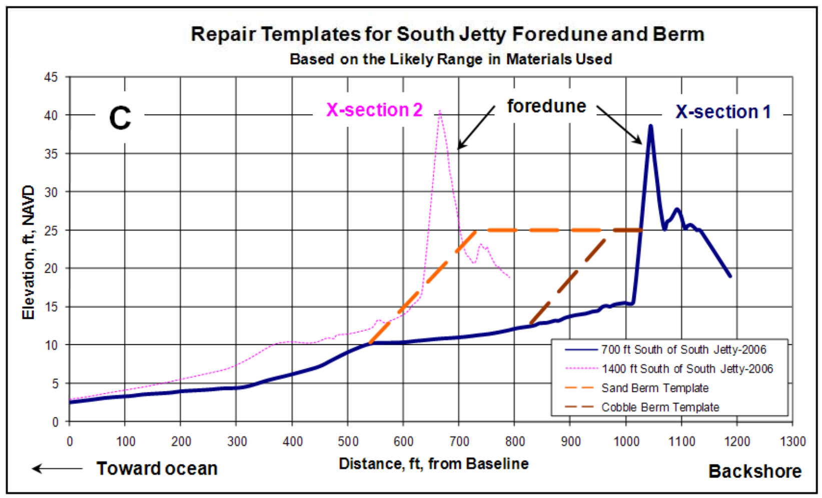


Figure 1-30. Clatsop Spit and South Jetty Root Erosion

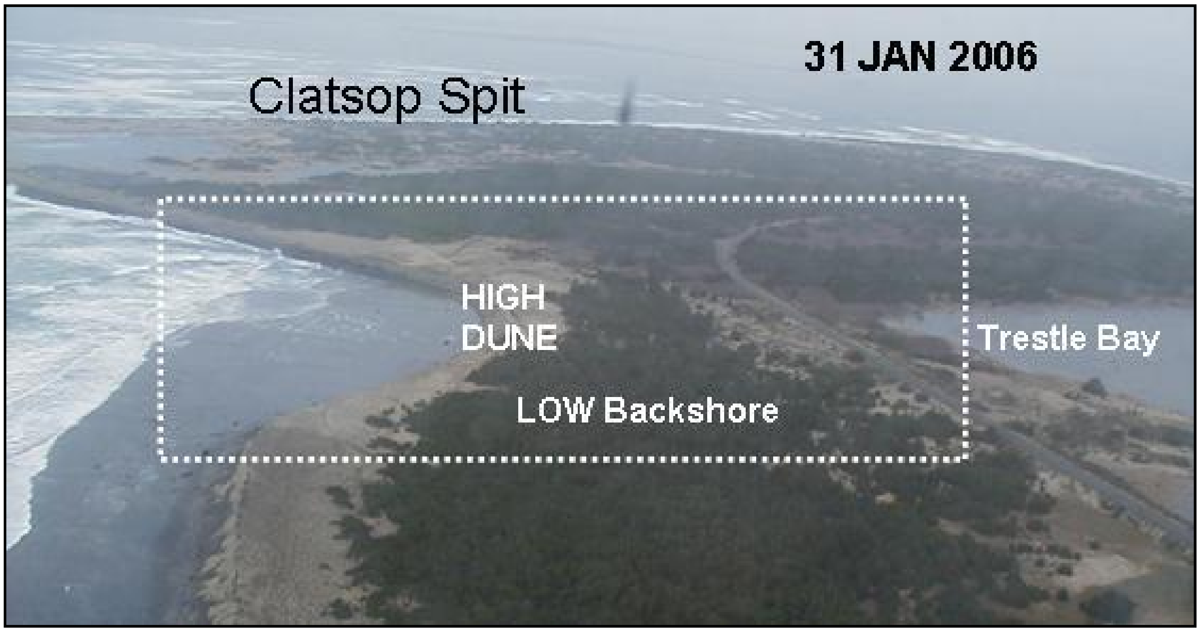

Figure 1-31. Active Shoreline Erosion at the Root of the South Jetty (oceanside)

Figure 1-28 illustrates the important effect of the groins on stabilizing the underwater shoal and protecting the South Jetty. These small structural features help with long-term structural stability by promoting sediment deposition along the jetty foundation and inhibiting the shoreline erosion occurring at the jetty root.

Table 1-6. Additional Structures at the South Jetty

Additional Structures	Year Completed	Station Location	Length (feet)	Current Condition
Spur Groin #1	1893	228+00	500	buried
Spur Groin #2	1893	156+00	600	buried
Spur Groin #3	1895	88+00	1,000	buried
Spur Groin #4	1895	52+00	1,000	buried
Shore Revetment	1896	25+80	3,955	buried
Spur Groin #6	1913	309+33	~110	existing
Spur Groin #7	1913	333+46	~90	existing

1.5.4.3. Jetty A

The purpose of Jetty A is to direct river currents away from the North Jetty. Jetty A has receded approximately 900 feet in length since original construction in 1939 (Figure 1-32 and Figure 1-33). The future recession rate for Jetty A is based on extrapolating the current rate of recession into the future. Two possible future recession rates are shown in Figure 1-32.

The vulnerability of Jetty A is influenced by its exposure to severe foundation scour along its outer end. The ocean side of Jetty A is impacted by ocean waves entering the MCR inlet, whereas the lee side sees practically no wave action. Due to the low elevation of the cross-section cross-section used at Jetty A, the lee side can be destabilized by waves overtopping the jetty from the ocean side. Note the proximity of the navigation channel to the end of Jetty A and how it anchors the entire north side morphology of the MCR inlet (from eastern end of Sand Island to North Jetty; see Figure 1-4). There are existing vulnerable reaches along Jetty A including reaches never repaired since 1917 construction, reaches of significant foundation change and high wave height exposure, and reaches that pose a concern with respect to the potential consequence of breaching.

Figure 1-32. Jetty A Head Recession

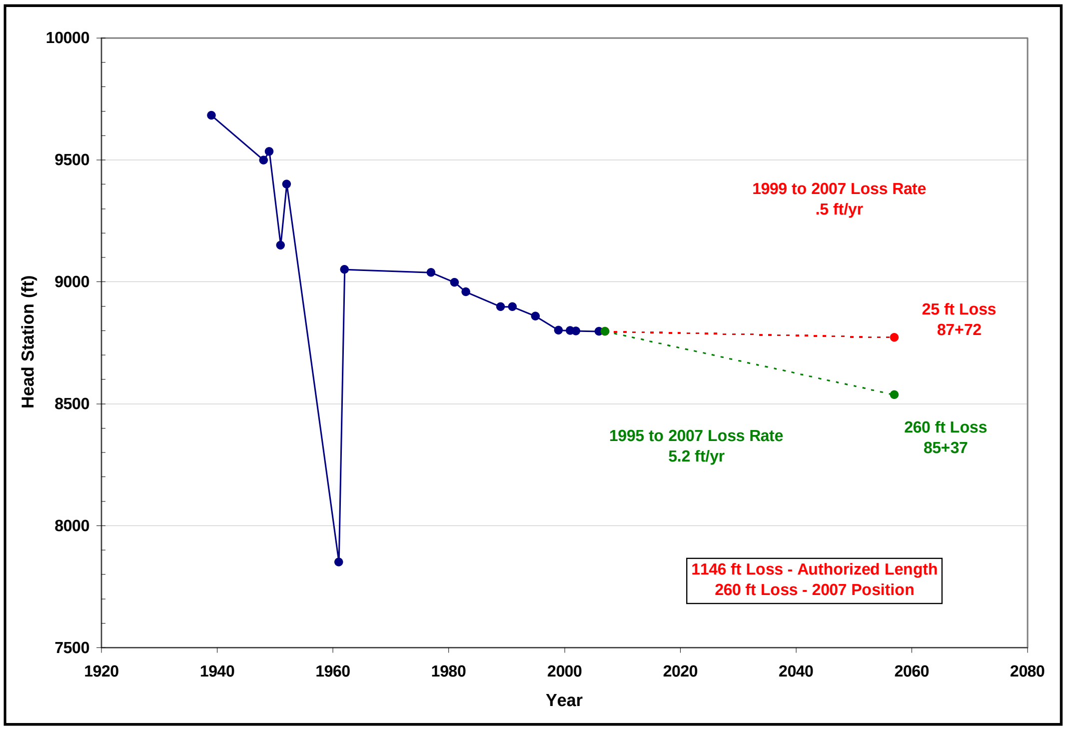

Figure 1-33. Jetty A Crest and Foundation Changes Over Time

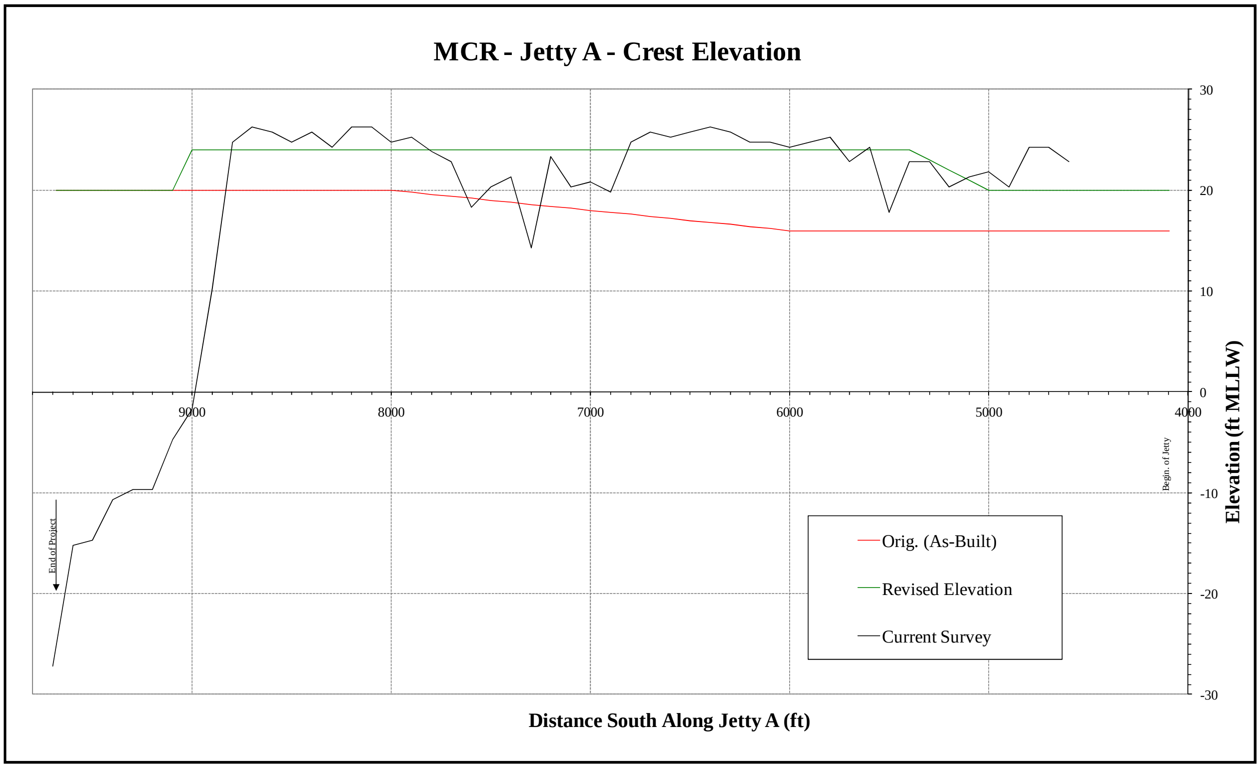

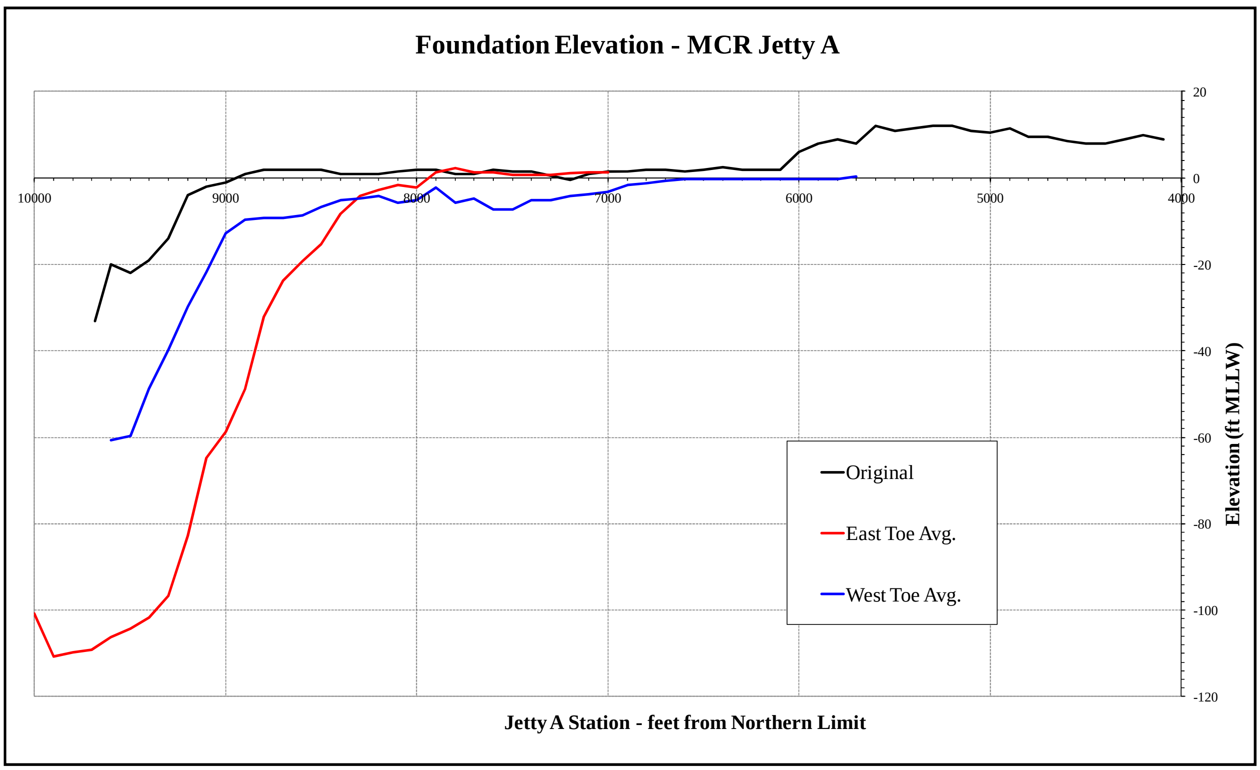

1.5.4.4. Damage and Repair trends for MCR Jetties

The MCR jetties have required periodic and extensive repairs approximately every 20 years. Since initial construction, the North and South jetties have required the placement of 3.9 million tons of stone to maintain the functional integrity of each jetty. Collectively, this represents 47% of the stone used to construct both jetties.

Although considerable resources and effort have been invested to maintain the North and South jetties, the jetties have performed satisfactorily given the environmental setting. Damage sustained by the jetties is a process of both continual and episodic events, much like a linear trend with small steps. Jetty repair actions are not a continual process. They arise infrequently, when the cumulative damages are severe enough as to render the jetty susceptible to complete loss of function. A repair function would resemble an abrupt step-wise trend. Portions of all three jetties are currently in a significantly deteriorated condition, in part due to little or no maintenance of those areas over the structure life. Other reaches of the jetties are exposed to an increasing loading environment generated by ebb tidal shoal changes, increased water depths, and larger wave heights. Future and continued jetty performance will depend upon the level of rehabilitation that will be proposed to re-establish functional integrity.

1.6. DEEP-DRAFT NAVIGATION AT THE MCR – RELEVANCE OF JETTIES

During 1885-1939, phased construction of the three MCR jetties reformed a broad and treacherously variable 5-mile-wide inlet into a stable 2-mile-wide inlet having a consistent channel suitable for year-round navigation. The central project feature at the MCR inlet is the deep draft navigation channel (-48 to -55 feet) which is 2,640-feet wide and 6-miles long and extends through the inlet, connecting the lower Columbia River deep-draft navigation channel with the Pacific Ocean. Continued function of the MCR jetties is essential for maintaining the inlet's present configuration and securing the deep-draft navigation channel, which facilitates $20 billion in annual commerce. These structures have been in service for multiple decades and have, for the most part, functioned well. However, the practice of deferred maintenance, accelerating damage, and evolving site conditions has significantly degraded future functional performance of the MCR jetties. Loss of jetty function would compromise deep-draft navigation at the MCR.

While there's no existing methodology (technology/capability) to quantify impacts of continuing deterioration to deep-draft navigation, we can be sure that continued deterioration will result in a reduced ability to maintain channel depths required for current traffic. If the channel becomes unstable or reverts back to a reduced depth, the significant benefits of the Columbia/Snake River system will be at risk.

Navigation structures that have provided reliable function are now in a condition of high vulnerability. A condition of high vulnerability leads to an uncertain future, which could result in abrupt loss of structure function and various degrees of navigation impact. Active monitoring of vulnerable navigation structures at the MCR has facilitated real-time risk assessment and immediate contingency planning. It has become necessary to assess future life-cycle conditions to enable optimal formulation of long term investment strategies; including the option of jetty rehabilitation. A firm understanding of a structure's present condition and loading and response characteristics is required before one can successfully optimize life-cycle management strategies.

2. ECONOMIC CONSIDERATIONS

2.1. INTRODUCTION

This chapter provides the economic rationale for the federal interest, a summary of how costs are calculated, and the benefit-to-cost ratios of the various repair/rehabilitation alternatives.

The procedures adopted for use in economic[1] cost analysis stem from national policy and the National Economic Development (NED) efficiency objective. Life-cycle cost analysis presents a method by which economic benefits can be compared against economic costs to derive a cost-benefit ratio and to compute net economic benefits. Benefits and costs are converted to average annual equivalent values that represent the stream of investments and benefits accrued from those investments over the period of analysis.

2.2. FEDERAL INTEREST

The guidance for major rehabilitation projects is provided in Engineer Regulation (ER) 1105-2-100, ER 1130-2-500, and in Engineer Pamphlet (EP) 1130-2-500. ER 1105-2-100 states that for the majority of cases, the Federal interest in an existing project will be obvious, and that a reasonable argument showing that Federal interest should be provided in the report.

The Columbia/Snake Rivers are a significant waterway of the U.S. The Columbia/Snake River navigation system from the Pacific Ocean to Lewiston, Idaho is a vital transportation link for the states of Oregon, Washington, Idaho, and Montana, as well as for the Nation as a whole. According to the Center for Economic Development and Research, the Columbia/Snake River navigation system is the leading gateway for the Nation's wheat and barley exports. It is also the leading gateway for west coast wood and mineral bulk exports and the second ranked lead for automobile imports. Marine traffic passing the entrance of the Columbia River has increased by 34% from 32 million tons in 2003 to 42 million tons in 2010.

Failure to maintain navigation through the MCR project could lead to inefficiencies on a main artery of commerce in the region and the nation. The Columbia River is the nation's number one wheat and number one barley export gateway (PNWA). The MCR jetties serve as a gateway to the larger Columbia/Snake River navigation system, carrying about 42 million tons of cargo on an annual basis, with an estimated value of $20 billion in 2010, with about 1400 vessels with drafts 30 feet or greater use the River entrance (See Figures 2-1 and 2-2).

[1] USACE planners use economic cost information to make the basic efficiency decisions about alternative plans. NED costs are used to make these decisions. Once the efficiency decision has been reached, the USACE uses financial costs for project implementation, also referenced as fully-funded costs. A fully-funded cost is a financial cost, not an economic cost.

Figure 2-1 Columbia River Entrance Traffic, tonnage

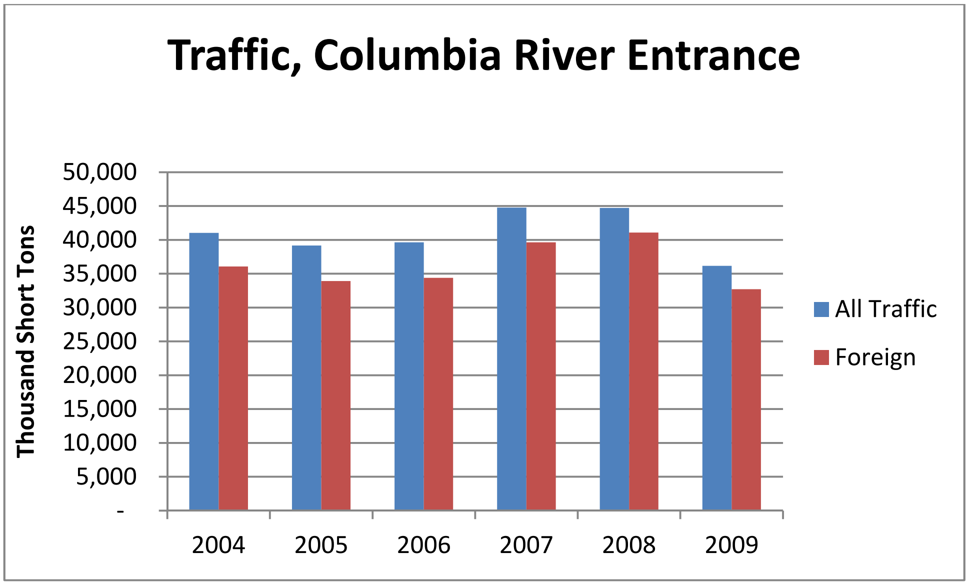

Figure 2-2 Columbia River Entrance Traffic, trips across the bar for all vessel drafts and a subset of those drafts deeper than 30 feet.

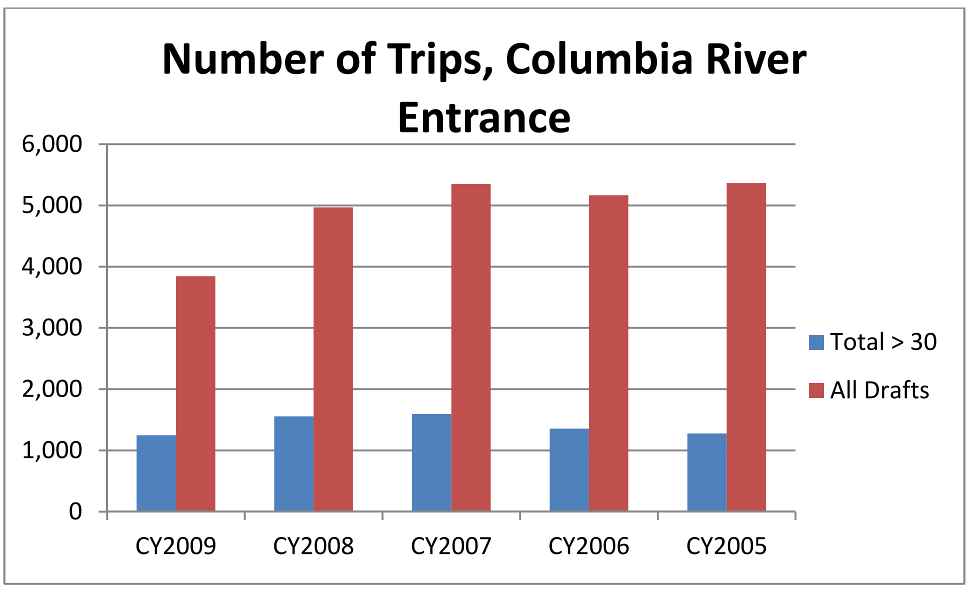

Appendix C, *Economic Analysis*, provides information and data on the importance of the Columbia/Snake River navigation system. The navigation output from the MCR project serves a priority purpose as defined in the Annual Program and Budget request for USACE Civil Works activities.

During 1885-1939, phased construction of the three MCR jetties reformed a broad and treacherously variable 5-mile-wide inlet into a stable 2-mile-wide inlet having a consistent channel suitable for year-round navigation. The central project feature at the MCR inlet is the deep draft navigation channel (-48 to -55 feet) which is 2,640-feet wide and 6-miles long and extends through the inlet, connecting the lower Columbia River deep-draft navigation channel with the Pacific Ocean.

Continued function of the MCR jetties is essential for maintaining the inlet's present configuration and securing the deep-draft navigation channel, which facilitates $20 billion in annual commerce. These structures have been in service for approximately one century and have, for the most part, functioned well. However, the practice of deferred maintenance, accelerating damage, and evolving site conditions has significantly degraded future functional performance of the MCR jetties.

Navigation structures that have provided reliable function are now in a condition of high vulnerability. A condition of high vulnerability leads to an uncertain future, which could result in abrupt loss of structure function and various degrees of navigation impact. Active monitoring of vulnerable navigation structures at the MCR has facilitated real-time risk assessment and immediate contingency planning. It has become necessary to assess future life-cycle conditions to enable optimal formulation of long term investment strategies; including the option of jetty rehabilitation.

Budget guidance in EC 11-2-199 (31 March 2010) defines major rehabilitation based on these thresholds: "The work will extend over at least two full construction seasons and will require at least $6.6 million in outlays. For inland waterways projects, the reliability threshold will be $14 million." The work on all three of the MCR jetties fits this definition for major rehabilitation.

2.3. BASE CONDITION

The base condition is the alternative against which all other alternatives are measured. Several considerations need to be determined when developing the base condition: determining operating trends of maintaining the jetties, current and projected reliability of all critical components, and planned maintenance on the project. These must all be provided throughout the entire study period. Section 3.8.3 describes the base condition in detail for each of the jetties.

The base condition for this study is identified as an interim repair approach where the upper portion of the cross-section is allowed to be damaged until approximately 35% is left remaining above -5 MLLW prior to repair actions being taken. (Since the model measures this damage with a probability density function, for purposes of discussion in this report, 30-40% is averaged to 35%—the fix-as-fails probability density function is averaged to 20%). In this way, maintenance is deferred such that the jetty can be maintained close to the margin of functional loss without breaching. The 35% threshold allows time to plan jetty maintenance before loss of function as efficiently as possible.

The benefit-cost ratio (BCR) evaluated within this report does not include traditional navigation benefit categories (transportation and delay benefits) and is strictly focused on optimizing the life-cycle maintenance costs for maintaining the MCR jetty system. The base condition for this analysis defines a level of maintenance for the jetties that prevents impacts to navigation function.

2.4. WITH-PROJECT CONDITION

The goal of implementing with-project alternatives is to maintain the Federal navigation channel and to avoid any negative impact to mission. All with-project alternatives include monitoring and scheduled repairs (i.e., repairs that are intended to occur before potential breaches impact navigation). Three basic with-project alternatives were developed and considered for the MCR jetties: scheduled repair, immediate rehabilitation, and scheduled rehabilitation. These basic alternatives were further expanded to include holding the head of each jetty. These alternatives are described in detail in Section 3.7 and 3.8 of this report.

2.5. BENEFITS ATTRIBUTABLE TO ALTERNATIVES

Transportation and delay benefits were not assessed because the assumption was the mouth of the Columbia River would remain open to navigation. To quantify transportation and delays is difficult in any entrance and specifically at the mouth of the Columbia River. There are infrequent closures at the MCR that are the decision of the U.S. Coast Guard due to storm and wave conditions at the entrance. The offshore wave climate, river and tidal currents, and shoaling all affect conditions at the bar. Consequently, separating those effects to be dependent upon the jetty would be difficult; therefore, the assumption was made that the Columbia River would remain open.

A fundamental economic assumption of the MCR jetties major rehabilitation study is that the navigation will be maintained throughout the period of analysis. In fact, in only one instance (1929) during the history of the jetty system has navigation been disrupted. This assumption can be made because of the monitoring and advance repair activities initiated by the Corps to maintain the functional integrity of the system.

This assumption implies that NED transportation benefits from the jetty system are constant across any alternative considered. The base condition maintains the functional integrity of the jetty system throughout the period of analysis.

The economic consideration is the cost effectiveness of the alternatives considered with costs avoided being the primary monetized benefit of the study. The alternatives identified as the most cost effective will minimize, to the greatest extent, future Federal investments required to maintain the functional integrity of the jetty system when compared against the base condition. The specific navigation costs considered in this report are the costs of maintenance activities for the three jetty system, these costs can be summarized as the cost of repairing or rehabilitating the structure and the increase in dredging costs relative to the alternative being considered. The direct costs for maintaining the jetties are summarized in table 2.6 by alternative. The costs are differentiated by type of repair; a planned rehabilitation cost, a scheduled O&M cost and an expedited repair cost. Because the alternatives vary in the timing and scope of repair activity, the total costs for an alternative can be compared against the base condition to identify the most cost efficient maintenance strategy. If no efficiency in repair timing and scope can be found that is superior to the base condition, the base condition is identified as the most efficient means of maintaining the jetties, and therefore the most efficient means of maintaining navigation at the MCR. A more efficient means of maintaining the MCR jetties lowers the costs of maintaining navigation at MCR, therefore increasing the BCR even if the navigation benefits themselves do not increase.

2.6. LIFE CYCLE COST ANALYSIS METHOD

The analytical method applied follows standard life-cycle cost accounting principles in that investments occurring intermittently over a fixed period of analysis are adjusted to account for the time value of money to create equivalent values at a common point in time. The common point in time for USACE planning purposes is designated as the base year, which is defined as the first year during which benefits of the project accrue. Investments and benefits that occur prior to the base year are escalated to the base and investments and benefits that occur after the base year are discounted to the base. The present worth equivalent values are then summed and amortized over the period of analysis to derive an average annual equivalent value. The rate that is used for discounting and amortizing is published annually by the U.S. Department of the Treasury for USACE investment and benefit calculations (see Table 2-1).

In order for various alternatives with differing investment strategies to be equitably compared, guidance requires that the same period of analysis be used for all alternative plans. The period of analysis is defined as the time horizon for project benefits, deferred installation costs, and operation, maintenance, repair, rehabilitation, and replacement (OMRR&R) costs. OMRR&R costs are the expected costs over the period of analysis for operation, maintenance, repair, rehabilitation, and replacement necessary to maintain the benefit stream and agreed-upon levels of mitigation of losses to fish and wildlife habitats. For USACE navigation projects, the period of analysis is typically 50 years.

Also an equitable comparison of alternatives requires that a common price level for costs be applied. Usually, comparative economic cost values are developed for planning level estimates of alternatives. Historical bid cost data, experience, and/or unit prices adjusted to expected project conditions are acceptable methods of developing project costs for these alternatives. The selected plan is then refined to create a Total Project Cost using the USACE-certified MCACES (MII) cost model in accordance with guidance.[2]

The costs applied in the life-cycle cost analysis are USACE-provided 2012 values. The period of analysis is 50 years, from beginning of fiscal year 2015 to end of fiscal year 2064. The project economic evaluation rate applied is the FY12 Federal interest rate of 4.0 percent. Prices used do not include inflation. End of year values were calculated for the life cycle cost analysis.

Table 2-1 Parameters specific to the MCR jetties life-cycle cost analysis

Price Level	CENWP-produced 2012 values
Period of Analysis	50 years, BOY 2015-EOY 2064
Federal interest rate	FY12 rate of 4.0 percent
Base Year	2015 No escalation of costs was necessary; only discounting over the period applies over the period. See discussion in Appendix C
Interest during Construction	Not applicable, see discussion in Appendix C
Implementation Schedule	Table 1, Appendix C
Unit Cost Components of Alternatives	Tables 2-5, Appendix C
Results of Cost Effectiveness Analysis	Table 6, Appendix C

2.7. BASE YEAR AND INTEREST DURING CONSTRUCTION

Alternative plans can differ in their implementation timing, that is, not all alternatives or features have to be in place at the beginning of the period of analysis. As project on-line dates are varied, annual benefits and costs will often vary. In general, the more the benefits vary through time and the longer the time to implementation from the base year (first year of period of analysis), the stronger this effect will be. The best schedule for implementing project features shall be considered as an element in the formulation and evaluation of alternative plans.[3]

[2] U.S. Army Corps of Engineers, ER 1110-2-1302, Engineering and Design, Civil Works Cost Engineering, 15 September 2008.
[3] U.S. Army Corps of Engineers, ER 1105-2-100, Planning Guidance Notebook, paragraph 2-4 (o), 22April 2000.

In Appendix C, Table C-4 lists the alternatives evaluated and the construction schedules of the alternatives that have rehab components for the three jetties in the Mouth of the Columbia River Jetty system: North Jetty, South Jetty, and Jetty A. All alternatives have an annual dredging component cost estimated which is not reflected in Appendix C, Table C-4, but is incorporated into the life cycle cost analysis. Other repair costs occur intermittently over the period of analysis and are incorporated into the life cycle cost analysis also.

The base year was set at the beginning of implementation period in the year 2015 based on two factors:

1) The implementation periods are lengthy due to the large quantity of rock required to complete the work, seasonality of construction, the rock supply and storage activities; and,
2) Benefits will begin accruing with each implementation stage.

This method is intended to produce a straight-forward and consistent comparison of alternatives. All alternative costs are discounted at the end of the year to the beginning of the base year 2015 using the stated Federal interest rate and amortized over the period of analysis to produce average annual equivalent values. This method will allow for the simple combination of alternatives among the three jetties to identify a combination least cost plan because all economic costs for all three jetties will be represented as equivalent costs.

Also due to the expectation of an immediate accrual of benefits, interest during construction (IDC) was not calculated. IDC is calculated typically when completion of construction is required before benefits are realized. For the MCR jetties rehabilitation alternatives, benefits are assumed to be realized immediately beginning with each activity for which costs are generated.

Also because the first year of construction is also the designated base year due to the expectation of an immediate accrual of benefits, no escalation of costs prior to the base year was necessary. Costs incurred over the period of analysis were discounted to the base year.

2.8. LIFE-CYCLE COSTING OF MCR JETTIES ALTERNATIVES

This life cycle cost analysis should not be confused with the derivation of total project costs which are financial and take into consideration factors of implementation. The life cycle cost analysis presented represents a method by which alternatives can be compared equitably and decisions regarding economic efficiency can be made.

A life cycle cost analysis was performed over the 50-year project life for the alternatives listed in Appendix C, Table C-17 with consideration, as appropriate, of project construction costs and associated operations and maintenance (O&M) and other costs over the period. Each alternative, with the exception of the “fix-as-fails” alternatives, was modeled allowing the jetty trunks to recede over the period of analysis and then again with holding the current jetty length constant.

2.8.1. Unit Cost Components of Alternatives

Repairs, rehabilitation, and dredging are projected throughout the period of analysis in response to scenarios developed with the SRB Model. USACE-provided 2012 cost variables contribute to the jetty alternatives cost estimates over the period of analysis and are assembled to reflect the activities that define each alternative’s repair strategy:

1. Repair activities: unit costs/ton of rock for expedited, base, and scheduled repairs, specific to jetty structure;
2. Rehabilitation activities: unit costs/ton of rock for a variety of scaled activities ranging from minimal to large;
3. Additional fixed costs of activities associated with rehabilitation for every year that rehabilitation occurs: mob/demob; jetty crest haul road construction; barge off-loading facility; mitigation costs; dredging costs; and offloading costs;
4. Jetty head capping: unit cost/ton of rock specific to each jetty;
5. Spur construction: fixed cost specific to each jetty; and
6. Normal dredging: unit cost/cy of sediment dredged specific for North Jetty, same unit cost for South Jetty and Jetty A.

All alternatives contain expedited repair activities and normal dredging activities. All alternatives contain O&M activities that are base repair, interim repair, or scheduled repair.

Appendix C, Table C-4 presents the array of unit and fixed costs applied in the life cycle cost analysis. The derivation of these costs and their application is discussed in detail in Appendix E, MCACES Cost Estimates. Appendix C, Table C-6 through Table C-16 display the cost components specific to each of the alternatives considered for the three jetties in the Mouth of the Columbia River system. Alternatives that share the same unit and fixed costs are listed together in the displays.

2.9. CE/ICA FOR MITIGATION

Wetland mitigation options for Jetty A and the South Jetty are very limited. No land is available near Jetty A; therefore, it's most cost effective to use lands near the North Jetty because construction mobilization costs are much lower there. Also, it is environmentally preferable to use lands near the North Jetty.

The basic assumption behind the Cost Effectiveness/Incremental Cost Analysis (CE/ICA) for wetland mitigation is that each alternative analyzed has the same specific mitigation requirement because each has the same construction impacts independent of construction methods. Consequently, a CE/ICA was conducted for three options for wetland mitigation on the South Jetty and Jetty A.

Using a 2:1 mitigation ratio, the acreages are 5.30 acres for the South Jetty and 1.82 acres for Jetty A. The options were replacement within the project area, acquiring private property offsite, and mitigation banking:

- Option A: onsite mitigation
- Option B: private property at $6,000 per acre (base cost for Option A plus $6k per acre)
- Option C: mitigation banking at $75,000 per acre (flat rate)

Table 2-2 shows all combinations of the described three options. Since the output is the same for all alternatives, incremental cost analysis is not possible beyond the first calculation (further calculations would be dividing costs by zero). Also due to the output being the same for all alternatives, by default the best value option is the one with the lowest cost. Consequently, the least cost plan was selected—Option AA—for 7.12 acres at $92,560.

Table 2-2 Wetland Mitigation – Cost Effectiveness

	Jetty A Options		South Jetty Options
A	$23,660 for 1.82 Acres	A	$68,900 for 5.3 Acres
B	$34,580 for 1.82 Acres	B	$100,700 for 5.3 Acres
C	$136,500 for 1.82 Acres	C	$397,500 for 5.3 Acres

Alt	Total Output (Acres)	Total Cost ($)
AA	7.12	92,560.00
AB	7.12	124,360.00
AC	7.12	421,160.00
BA	7.12	103,480.00
BB	7.12	135,280.00
BC	7.12	432,080.00
CA	7.12	205,400.00
CB	7.12	237,200.00
CC	7.12	534,000.00

It is an important to note that the EA for the MRR covers mitigation for the base condition, which includes dune augmentation/stabilization on the South Jetty; and lagoon fill and critical repairs (STA 86-99) on the North Jetty. Table 2-3 outlines all mitigation requirements per the EA.

Table 2-3 Mitigation Identified per the EA

Area Affected	Impacted Acreage	Mitigation Acreage	Comment
North Jetty			
Wetland	1.14	2.28	Base Condition: MMR
404 Waters Lagoon	8.02	12.03	Base Condition: MMR
Other 404 Waters	4.36	6.54	CE/ICA during DDR phase
South Jetty			
Wetlands	2.65	5.30	CE conducted
404 Waters	13.84	20.76	CE/ICA during DDR phase
Jetty A			
Wetlands	0.91	1.82	CE conducted
404 Waters	6.60	9.90	CE/ICA during DDR phase

Mitigation for the 404 sites will be assessed and a CE/ICA conducted during the detailed design report (DDR) phase of the MRR project. Since the exact environmental impacts are unknown, the worst-case impacts, from a cost standpoint, were developed—maximizing avoidance of impacts. For instance, impacts associated with delivery of jetty stone are currently unknown; hence, during the DDR phase, when there's more certainty on modes of delivery, these impacts will be reassessed. For the time being we are assuming the worst-case impacts associated with the project footprint, and that they are all the same for each alternative evaluated. For purposes of the cost estimate, barge delivery was assumed and costs associated with mitigation for 404 impacts based on a similar project. The total estimate for 404 waters mitigation is $3.6M.

It is recognized that impacts need mitigation based on the extent and quality. Consequently, the Corps will define the mitigation required in coordination with an Adaptive Management Team (AMT) of state and Federal resource agencies. Then a CE/ICA will be conducted during the DDR phase on the newly defined mitigation requirement.

2.10. INTERFACE BETWEEN THE SRB MODEL AND THE LIFE CYCLE COST ANALYSIS

The life cycle cost analysis is performed separately and subsequently to the SRB Model calculations. The execution of the SRB model results in calculations of jetty degradation and required repair (e.g. material quantities required to create a defined condition based on the alternative considered, described in Appendix A1). The output files containing quantities from this model analysis are then used as inputs to the cost analysis to estimate life-cycle costs and other parameters for each alternative. The cost analysis is performed via a set of Microsoft Excel spreadsheets. This section discusses the life cycle cost component of the analysis and the outputs of the SRB model which feed the life cycle cost analysis.

The SRB model creates outputs that contain a set of mean values for seven types of activities—rehabilitation; expedited repair, emergency repair; interim repair, base repair, scheduled repair, and normal dredging. These output parameters are listed in the life cycle cost spreadsheets which have a consistent nomenclature, generally titled "MCR_LifeCycleCosts_{name of jetty}_{name of alternative}". These files are built automatically from a single template file “cost_template.xlsx” by calling MCR_COST script in Matlab. The script takes SRB Model CSV files from “output” folder for each alternative and converts them into Microsoft Excel files. The main CSV files are listed in Table 2-4.

Table 2-4 Output CSV Files Used to Populate Life Cycle Cost Analysis Spreadsheets

Output File	Description
OUTPUT_Repair_for_COST_MEAN_INNER.csv	Stone volumes for inner range of the jetty for emergency, expedited, fix-as-fail, interim and scheduled repairs.
OUTPUT_Repair_for_COST_MEAN_MIDDLE.csv	Stone volumes for middle range of the jetty for emergency, expedited, fix-as-fail, interim and scheduled repairs.
OUTPUT_Repair_for_COST_MEAN_OUTER.csv	Stone volumes for outer range of the jetty for emergency, expedited, fix-as-fail, interim and scheduled repairs.
OUTPUT_Rehab_for_COST_MEAN.csv	Stone volumes for minimum, small, moderate and large rehab templates and head capping.
OUTPUT_Dredging_for_COST_MEAN.csv	Maintenance dredging volumes.
OUTPUT_Head_Recession_Repair_COST_MEAN.csv	Repairs on North Jetty due to scour associated with Jetty “A” head recession.

Note: Emergency repairs were not used in the SRB Model for the MCR Jetties.

The cost for each activity is calculated in the MCR_LifeCycleCosts spreadsheets, based on actions and volumes projected by the SRB Model to which unit and fixed prices are applied. The unit prices are initially specified in “cost template” spreadsheet on the “Setup” sheet for all jetties and activities. The referencing of the unit costs within the spreadsheets allows for updating, modification, and adjustment, if necessary.

Only the values that occur during the period of analysis, 2015-2064, are considered in the life cycle cost analysis even though the SRB Model outputs a stream of volumes.

In the above example, the cost for repair options is calculated in each “Repair” worksheet (Expedited Repair is shown), and unit costs are linked to the “Setup” sheet for named jetty. The present worth equivalent values for all activities associated with each alternative response scenario are totaled and accumulated into a summary spreadsheet, “Cost_Summary.xlsx,” and then the present worth equivalent values are amortized over the period of analysis to create average annual equivalent values.

Example of Life Cycle Cost Spreadsheet for North Jetty Scheduled Repair Hold Head with Reference Unit Costs and Input Volumes from the SRB Model can be found at the end of this chapter in Table 2-6.

2.11. SUMMARY OF COSTS AND BENEFITS

Table 2-5 displays the most effective alternatives among the 71 alternatives evaluated for the three jetties in the MCR jetty system. The most cost effective alternatives are those that produce the greatest net excess benefits over costs. The full array of alternatives is displayed in Table 6 of Appendix C.

Table 2-5 Costs and Benefits of the Most Cost Effective Alternatives

Jetty	Most Cost Effective Alternative	Net Excess Average Annual Benefits	Average Annual Costs	Benefit to Cost Ratio
North Jetty	Scheduled Repair Holding Head at Current Location	$251,729	$2,984,682	1.09
South Jetty	Base Case without Project	$0	$9,566,691	1.0
Jetty A	Scheduled Repair Holding Head at Current Location	$383,847	$913,260	1.42

The project has a combined BCR of 1.1 for the system (all three jetties).

Table 2-6 Average Annual Costs, Benefit-Cost Ratio (BCR), and Net Excess Benefits for the Alternatives for the MCR Jetties

Alternatives	Location	Present Worth Equivalent (PWE) Rehab cost	OM Repair Cost, PWE	Expedited Repair Cost, PWE	PWE Dredge Cost	Present Worth Equivalent Total Costs	Average Annual Costs, 50 yrs, Discount Rate of 4%	Rank	BCR	Net Excess Benefits

2.12 MRR Benefits Discussion

As with all coastal major rehab projects, the MCR MRR alternatives considered—including the base condition—maintain the navigation benefits of the project. While it would have been possible to formulate a base condition that included substantial interruptions in service, that scenario was deemed untenable as it would have required the Corps to ignore observed jetty degradation and the obvious impending and certain failure of the MCR system.

The MRR base condition (discussed in Sections 2.3 and 3.84) consists of a reasonably efficient plan in which thorough annual jetty inspections are used to initiate repairs when significant degradation is observed. Given the efficacy of the base condition, it is difficult for any alternative that includes large initial expenditures to reduce total present value costs. If none of the alternatives evaluated provide cost savings over the base condition, then the base conditions for all three jetties would become the least cost plan, this would result in an overall BCR of 1:1, indicating that the base condition was the most efficient plan for each jetty.

Essentially, the MCR Jetties System is faced with a binary decision: a maintenance strategy that allows for the possibility of a breach and sediment closing the navigation channel or one that doesn't. The Corps chose the latter.

For the South Jetty, no alternative was identified that could significantly reduce costs relative to the base condition that met the requirement of maintaining reliable navigation. The North Jetty is subject to higher wave energy and has a higher associated risk to navigation. The North Jetty recommended plan recognizes that risk and implements a more aggressive repair strategy which reduces unplanned (expedited) repairs. However, this recommended plan is similar to the base condition and therefore provides real but not dramatic incremental benefits A high functioning Jetty A not only reduces expedited repair on Jetty A but also reduces repair costs to the North Jetty so again, a pro-active repair schedule yielded cost savings over the lifetime of analysis.

For the North Jetty the incremental benefits are achieved by lowering overall repair costs through enacting a more pro-active maintenance plan which reduces expedited repairs by increasing scheduled repairs (see table 2.6 highlighted plan for North Jetty). A similar efficiency was found for Jetty A, and therefore both the North Jetty and Jetty A have positive BCRs reflecting the lower costs of the recommended plans when compared to the base condition. The South Jetty recommended plan is the base condition, therefore the individual BCR for the South Jetty is 1:1, (recommended plan divided by base plan). The South Jetty is also the most expensive of the three jetties to maintain, followed by the North Jetty (BCR (1.09). In order to calculate a combined BCR, the BCRs for each jetty are weighted by the cost of the recommended plan for that jetty. When the weighted average is calculated the least expensive Jetty, Jetty A (BCR 1.42) has less influence on the overall combined BCR than the North and South Jetties and a combined BCR of 1.1 results.

Given that the project's base condition theoretically prevents a breach in the jetties, project navigation benefits are not at risk. Consequently, the major rehab effort described in this report does not produce a high benefit-to-cost ratio because the project prevents a jetty breach and sediment from blocking the navigation channel. Also, with the inclusion of the base condition as the recommended plan for the South Jetty, benefits for that project feature are essentially treated as equaling costs, despite the actual substantial benefits associated with maintaining navigation at the project. The benefits for the major rehabilitation project are incremental relative to the base condition strategy, rather than accounting for the actual overall navigation project purpose benefits.

Lastly, and perhaps most significantly, the project's combined BCR of 1.1 for the system (all three jetties) doesn't capture all the benefits related to protecting the entrance the Columbia River navigation channel (105 miles, 43 feet deep; $182M channel deepening project completed in 2010) and the Columbia/Snake River system. For example, $20B of cargo annually travels through the entrance protected by MCR Jetties. Furthermore, over $900M in new infrastructure investment has been made to date in the Pacific Northwest since 2010.

In brief, the district maintains that the MCR jetty system is the most significant coastal navigation structure in the Pacific Northwest; one that provides economic benefits far beyond a BCR of 1.1 indicates.

3. ENGINEERING CONSIDERATIONS

3.1. GENERAL

This chapter provides the engineering basis for the development and analysis of the alternatives. This chapter includes:

- A characterization of the wave climate and morphologic processes at the MCR;
- The current issues/risks of deterioration or failure for each of the jetties and associated consequences;
- A characterization of the design of each jetty and the relevant performance modes;
- The description of the methodology and model used for assessing the reliability and life-cycle performance of the jetties, including alternatives;
- A summary of how the model was calibrated using historical and hindcast data; and
- A description of each of the repair/rehabilitation alternatives, including the model analysis results related to projected future long-term maintenance actions and reliability.

3.2. PROJECT LOADING BY FORCING ENVIRONMENT

3.2.1. Waves at the MCR Inlet

The ocean entrance at the MCR is characterized by large waves and strong currents and has been considered one of the world's most dangerous coastal inlets (Gonzalez 1984, Ozkan-Haller 2008). The sea state at the MCR during storm conditions is characterized by high swell approaching from the northwest to southwest combined with locally generated wind waves from the south to southwest. During October-April, the seasonal average wave height is 9 feet and period is 12 seconds. During intense winter storms, waves can exceed 30 feet; individual waves with a height of 45-55 feet were recorded 5 miles south of the MCR in water depth of 135 feet (Moritz 2001). During May-September, average wave height and period is 5 feet and 9 seconds, respectively.

As waves propagate shoreward toward the MCR, the waves are modified (waves begin to shoal and refract) by the asymmetry of the underwater morphology of the MCR. Nearshore and tidal currents are also modified by the jetties and morphology. These modified currents interact with shoaling waves to produce a complex and agitated wave environment. The asymmetric configuration of the MCR and its morphology is characterized by the significant offshore extent of Peacock Spit on the North Jetty's north side, southwesterly alignment of the North and South jetties and channel, and the absence of a large shoal on the south side of the MCR. The asymmetry of the MCR causes incoming waves to be focused onto areas that would not otherwise be exposed to direct wave action.

3.2.2. Time-varying Changes in MCR Nearshore Wave Climate

The changes in regional and localized waves at the project site since original construction can be described from two separate perspectives. The first approach is to look at any trends of the regional wave environment associated with variable climate effects. The second approach is to look at the impacts of morphology evolution on the depth-limited characteristics of the waves at the project.

Measurements of the deep water waves offshore of the MCR project area are available from 1984 to present (National Data Buoy Center). Analysis of this deep-water wave data set suggests that the storm-related wave heights and frequency of storms may be increasing over the period or record. Due to the relatively short data record, it is not known whether this trend is persistent or just a subset of a larger data set that experiences a wide range of wave heights. The data record describes deep water wave conditions. However, the wave heights actually impacting the MCR jetties are shallow water waves, being transformed to shoreward over the nearshore bathymetry. The actual impact (associated with climate variation) on shallow wave heights at the structure will be dampened by the depth-limited characteristics of the project site; namely, wave height is physically reduced as the water gets shallower, oftentimes eliminating any increased increment of wave height by the time it reaches the project. This fact introduces the second element of wave height change over the project life: morphology change at the inlet. If the nearshore bathymetry (submerged shoals) at the project area becomes deeper over time, waves (height) affecting the structure can increase. The opposite is true for morphology accretion; increased waves will likely erode the shoals.

The morphology created by and surrounding the jetty construction protects the jetties from large damaging waves. If the morphology along the jetties recedes excessively, large damaging waves can attack and destabilize the jetties. A combined wave- and water-level modeling approach was applied to account for the evolving nature of the morphology at the MCR. The modeling effort used a numerical model called STWAVE (Steady-State spectral WAVE; Smith et al., 2001) to transform offshore waves to the project site. This model is used to simulate the two-dimensional propagation of a wave field as it travels through winds and current and encounters variable bathymetry. Jetty life-cycle analysis and design utilized this wave model to estimate waves in the past, present, and future.

3.2.3. **Water Levels at the MCR Coastal Margin**

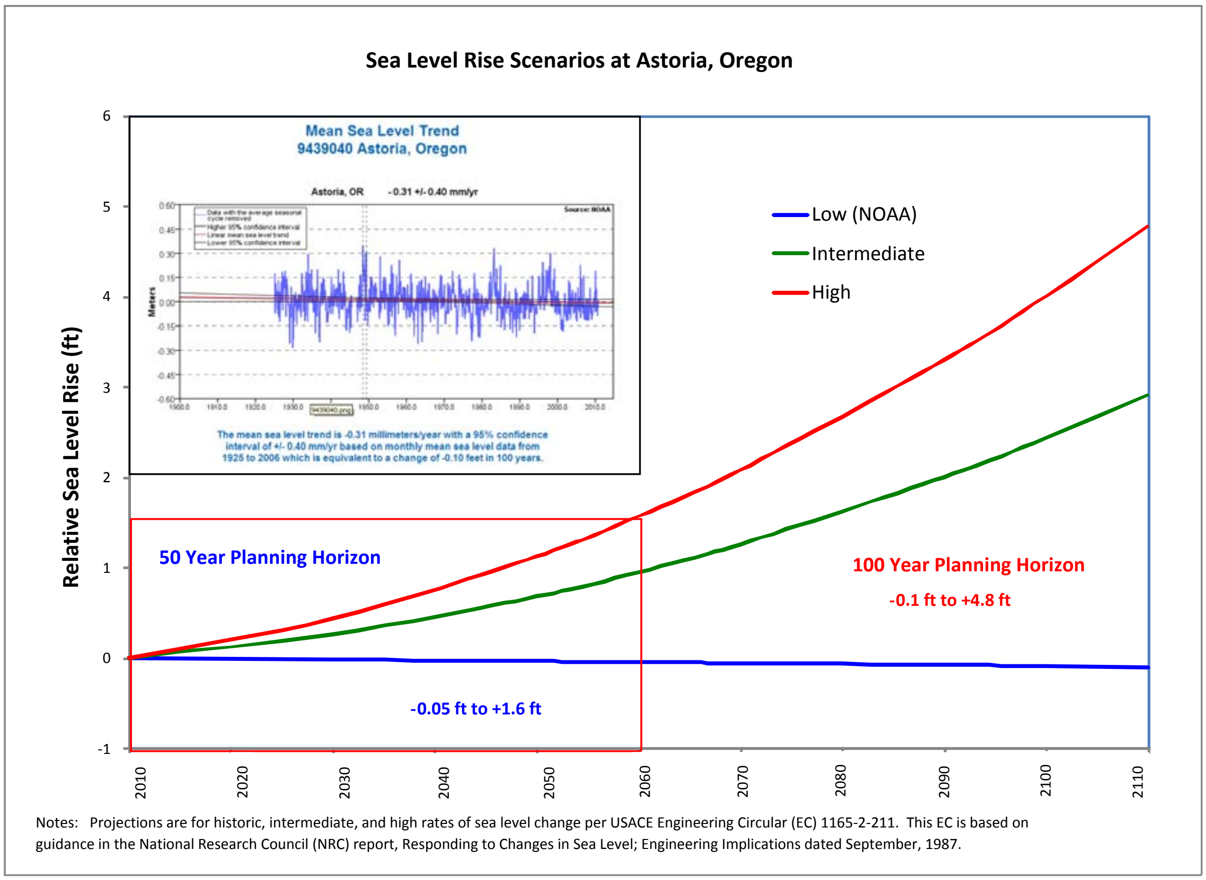
Astronomical tides at the MCR are mixed semi-diurnal with a diurnal range of 8.5 feet. Twice each day, the MCR is the hydraulic battlefield between two distinct water masses, the freshwater outflow of the Columbia River and the marine inflow from ocean tides. The instantaneous flow rate of estuarine water leaving the MCR during ebb tide can exceed 2 million cfs and the flow rate of marine water entering the MCR during flood tide can exceed 1 million cfs. Currents in the navigation channel can attain 5 knots (8 feet/second) and are highly variable in time and space. The nearshore wave and tidal environment is greatly affected by Peacock and Clatsop spits, due to the spits' significant offshore extent. The orientation of the shoals/spits has arisen due to the interaction of jetties, waves, currents and sand; thus, the morphology and coastal processes at the MCR are linked.

A high water level along the coastal margin allows larger waves to attack the jetties and displace armor stones, if the armor layer is not adequately designed and constructed. Water levels along the Oregon Coast are primarily a function of astronomical tide influences. Other factors that can influence water levels are atmospheric pressure, wind set-up, and wave set-up. Wave set-up can be modulated by infragravity transients, which are low frequency variations of the water surface (1-4 minute period) induced by groups of storm waves. Collectively, these "other factors" are called storm surge; when the observed water level exceeds the predicted tidal water level during storms. The total storm-induced water level (SWL, used for calculation of nearshore wave height) was estimated by adding "storm surge" to predicted tidal water level. Each component for water level was defined in terms of a probability density function used for generating a randomized total water level when simulating the life-cycle of the MCR jetties within the life-cycle analysis model (see Appendix A2, *Reliability Analysis, Event Tree Formulation and Life-cycle Simulation*).

3.2.4. **Potential for Sea Level Change**

The potential effect of sea level rise was included for assessments of future jetty performance at MCR. Future sea level rise was estimated within the Stochastic Risk-Based (SRB) model as outlined in EC-165-2-211 [USACE 1 October 2011]. The EC prescribes a method for defining three future projection curves which are used to bound the estimate for sea level rise over time. The sea level projections (curves) are site specific and are derived based on the historical sea level trend blended with the eustatic effect (see Fig. 3-1). EC curve #1 defines the lowest expected bound for sea level rise and basically provides an extrapolation of the historical observed rate. EC curve #2 defines a “prudent” intermediate trend and EC curve #3 defines the highest expected bound incorporating potential acceleration. A MCR (SRB) model, discussed in detail later in this report and appendix A2, was developed to evaluate jetty response to wave forcing at the MCR. The sea level projections that were used within the SRB model were based on the National Ocean Survey (NOS) station at Astoria, Oregon. The potential sea level change at the project site over the 50 year planning horizon ranged somewhere between -0.05 ft to +1.6 ft. See Figure 3-1 for the projected sea level change curves used.

Figure 3-1. Sea Level Rise Scenarios



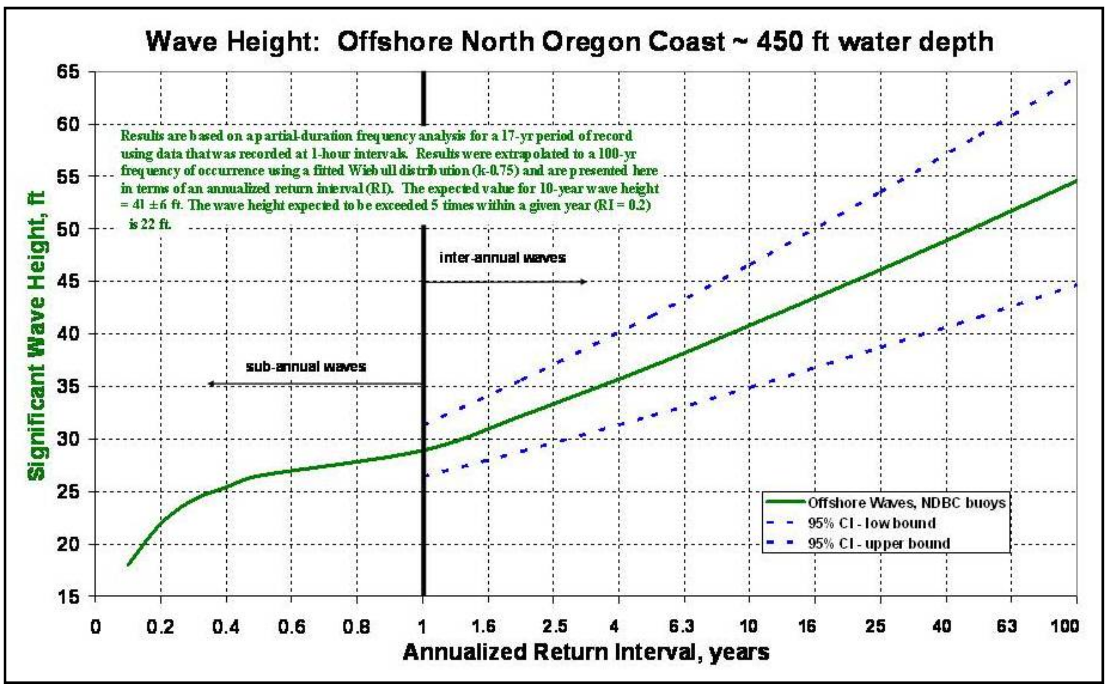
Within the SRB model, each jetty life-cycle realization was assigned a randomly generated sea level rise trend, which is bounded by EC curve #1 and EC curve #3. A total nearshore water level is estimated for each storm by adding the estimated sea level rise (for a given year) to the nearshore storm-induced water level. With the slightly greater water level at the project site during these realizations, the incident wave height was also adjusted accordingly. So the future case scenarios incorporate both a higher water level as well as the impact on wave height. Sea level rise effects were not included within the historical assessment of jetty performance (hindcast).

The relatively minor sea level change at the project site makes the inclusion of sea level change in the total loading environment less of a driving factor for a long-term maintenance strategy. In addition, due to the uncertainty of future sea level rise scenarios, the most likely approach for very large rubblemound structures for future maintenance would be to develop an adaptable maintenance strategy that could be modified as the gradual change is observed.

3.2.5. **Definition of Wave Climate at the MCR Jetties**

An analysis of the wave record from buoys at the National Data Buoy Center (1984-2008) is the basis for defining the offshore wave environment at the MCR (Moritz 2006, 2007). Results from this analysis are shown in Figure 3-2. The storm wave "climate" affecting each MCR jetty was estimated by synthesizing the offshore storm wave environment in terms of a series of observed wave events. Each offshore wave event was described in terms of a directional wave spectrum. A phased-average spectral wave model was used to transform the candidate offshore wave events to various locations along each jetty, for a range of water levels. The wave environment at the jetties was estimated using STWAVE (Smith et al., 2001).

Figure 3-2. Offshore Wave Height Expressed in Terms of Annualized Return Interval



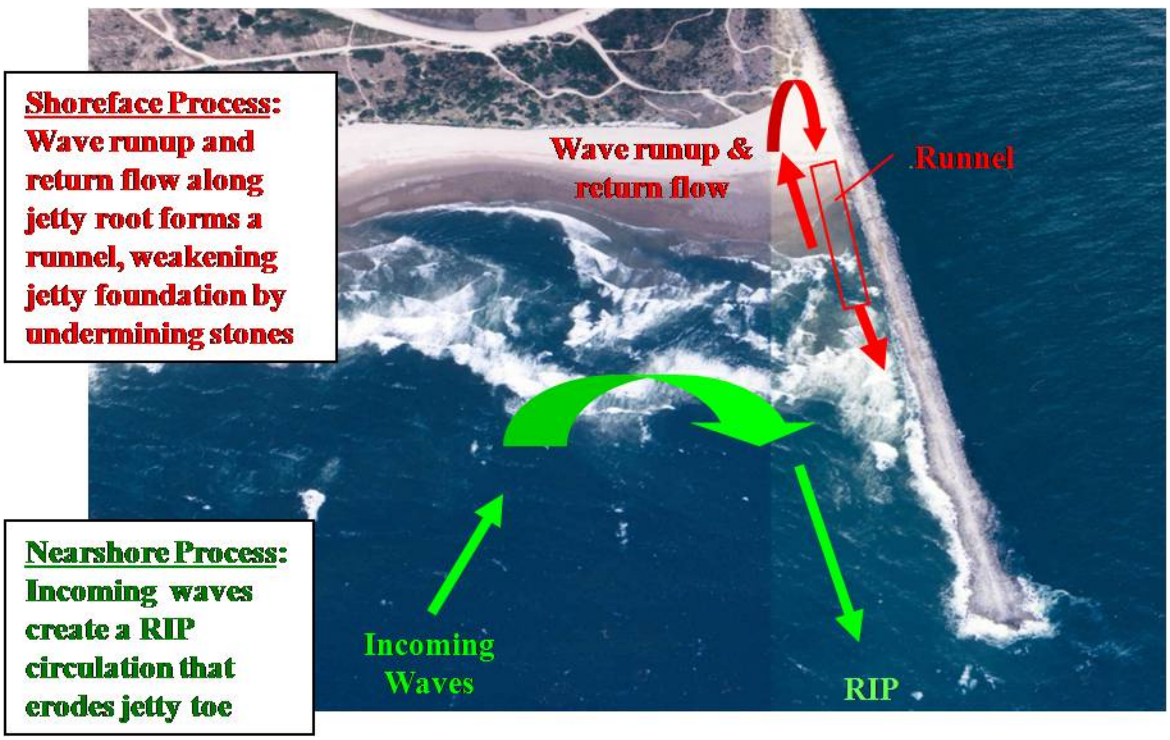
3.3. STRUCTURES AND MORPHOLOGY

3.3.1. **Interaction of Structures and Morphology**

Since original jetty construction, several large physical process changes have altered the current and projected future reliability of the MCR jetty system. These large process changes gradually impact the stability of the structures and the reliability of the system and are primarily driven by changes in inlet morphology and observed changes in wave climate. Increased channel depths and ebb tidal shoal erosion has led to increased depths along both sides of the seaward portions of the jetties. As increased depths are secured in the improved navigation channel, larger waves are able to enter the channel and attack the jetties, in addition to undermining the sandy foundation upon which they rest. These increased channel depths primarily affect the channel-side of the jetties and particularly the North Jetty, which is closer to the navigation channel.

During 1993 to 2000, the 40-foot contour on the ebb tidal shoal receded landward at a rate seven times faster than during 1930 to 1993, as shown in Figure 1-10 (Chapter 1). As the ebb tidal shoal recedes, the wave and current regime at the entrance and jetties changes. The jetty length and the ebb tidal shoal configuration are somewhat inter-connected. As one changes, the other is altered as well. Shoreline position and stability on the outsides of the jetty system is also connected to the jetty head position and jetty length. As the jetty length recedes, the shoreline is exposed to greater wave and storm impacts, eventually having a negative effect on the stability of the jetty roots. Figure 3-3 illustrates shoreface and nearshore processes adjacent to a jetty.

Figure 3-3. Shoreface and Nearshore Processes at a Jetty



3.3.2. **Existing Condition of MCR Jetties and Shoals**

The existing condition and robustness of the MCR jetties can be characterized by looking at the maintenance history, as well as the current cross section deficit of each jetty compared to a standard or typical design cross-section. The maintenance history of each jetty was discussed in Chapter 1. Figure 3-4 through Figure 3-6 summarize that information in approximately 50-year increments, a typical design life for a coastal structure. Also plotted on these figures is the estimated expected maintenance for the jetties over that same time period using 0.7% multiplied by the construction volume per year of structure life. In extreme exposure of the structure, the expected maintenance requirements described above would predict more stone would be required to maintain the cross-section integrity.

In particular, the last 50 years has seen a reduction in maintenance activity at the jetties. Some of the repair activities for Jetty A utilized readily available but under-sized stone for maintenance activities, which is reflected in the fairly large stone volume placed on the structure over its lifetime.

Another measure of the existing rubble-mound structure condition would be to simply calculate the deficit of stone volume between the existing structure surface and a standard or typical design cross-section. Figure 3-4 through Figure 3-6 illustrate that comparison for the three jetties. Existing South Jetty deficits range from approximately 410,000 to 700,000 tons of stone to bring the existing structure up to a minimum or small cross-section. For the North Jetty, approximately 240,000 to 570,000 tons of stone would be needed to bring the existing structure up to a standard minimum or moderate cross-section. Jetty A would need approximately 87,000 tons to bring the existing structure up to a smaller cross-section. A range of stone volumes is reported here to provide a framework for considering design or structure modifications necessary to respond to increased loading of the structure at some locations. The design cross-sections will be discussed in more detail later in this section of the report.

Figure 3-4. North Jetty Maintenance Record Summary

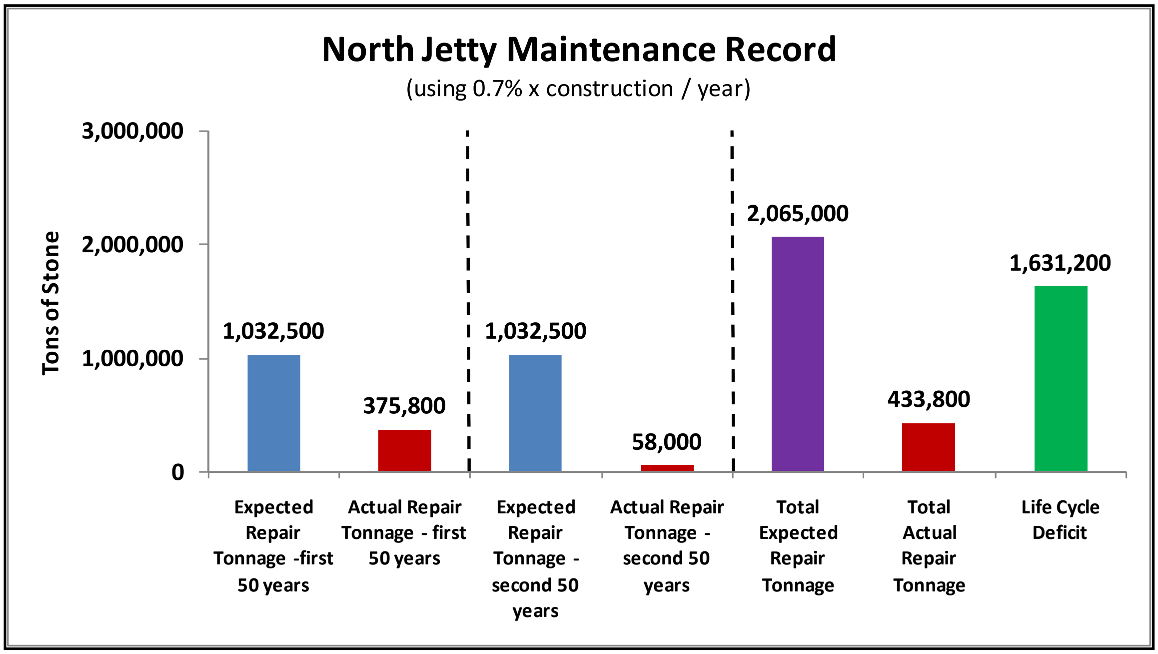


Figure 3-5. South Jetty Maintenance Record Summary

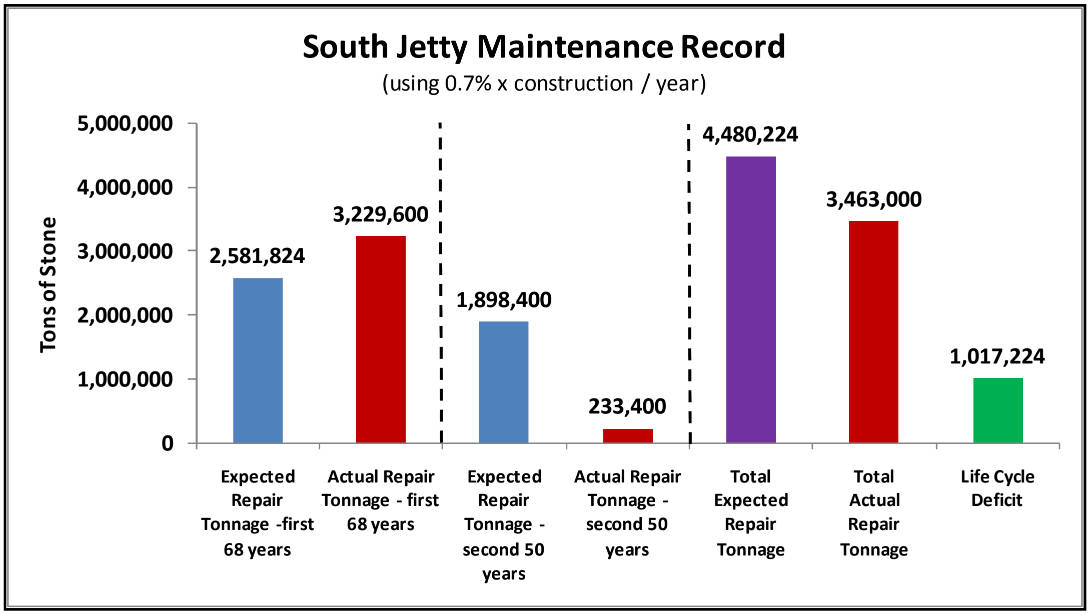

Figure 3-6. Jetty A Maintenance Record Summary

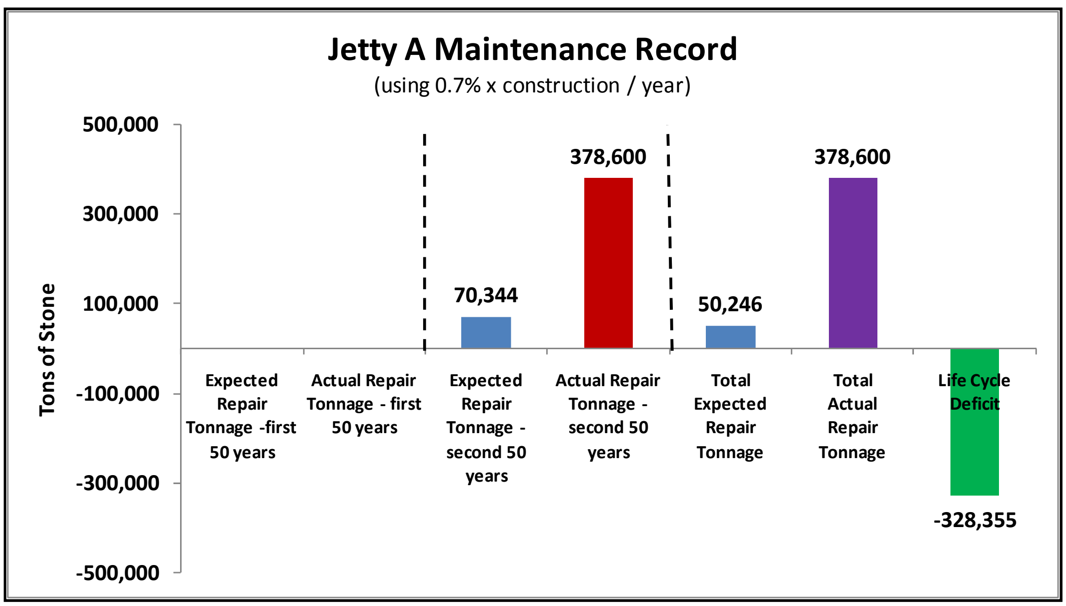

The existing condition of the three jetties provides information that is utilized in numerous ways throughout this analysis and study. First and foremost it serves as an ending point for the hindcast analysis of the jetties. Secondly, it provides information on the level of deterioration of the structures and the existing reliability. Survey methods range from aerial light detection and ranging (LIDAR) combined with bathymetric surveys to annual, on-the-ground surveys using GPS and hip-chain to locate station. The 2010 on-the-ground survey is included as Appendix A-4 in the report. Future surveys will use LIDAR/bathymetric methods and be compared biannually to track damage and jetty stone loss. Existing condition information for this analysis was obtained through a comprehensive multi-beam and above water survey of the structures which was combined into a digital terrain model of each structure.

The results from that survey for the North Jetty are illustrated in Figure 3-7 through Figure 3-8. The results from that survey for the South Jetty are illustrated in Figure 3-9 through Figure 3-10. These figures contain key condition characteristics relevant to reliability and design: crest elevation and crest width. A standard minimum design crest width is included in these figures for comparison purposes. This minimum design cross-section will be discussed in more detail later in this section of the report. The crest widths illustrated in these figures show a wide variation with widths within a segment varying from zero to greater than a typical minimum design crest width. Additional information about the existing condition of the MCR jetties and shoals, and historic maintenance records can be found in Appendix A1, Section 6.

Crest elevation and jetty length changes are documented in Figure 1-25, Figure 1-27, and Figure 1-33 with respect to a complete project survey conducted in 2000. For the North Jetty, jetty length loss of approximately 2,100 feet and significant channel-side foundation erosion (up to 60 feet change in depth) impacting approximately the seaward half of the jetty are the most significant. In addition, as shown in Figure 1-6, the north side of the North Jetty is being increasingly exposed to higher wave and water level conditions due to the erosion of Benson Beach. For the South Jetty, jetty length loss of approximately 6,200 feet has worked interactively with ebb tidal shoal changes to increase loading particularly for the seaward half of the structure. The concrete monolith at approximately station 330 and the channel-side spur groins have slowed down the physical morphological changes at that location. Jetty A has lost approximately 900 feet and in addition, a large scour hole at the southern end of the Jetty A head, up to 120 feet in depth, has impacted its stability.

The service life of stones on the jetties is one of the important factors in determining how well the jetty will hold up through time. Significant amounts of stone broken or worn away by wave action through time could lead to jetty structure instability. Stone composition and durability varies from quarry to quarry, so it’s important for stones to meet a minimum criterion to ensure their longevity, such as the current Portland District Jetty Stone Standards discussed in paragraph 4 in Appendix B. The high standards in place by the District for over the past 50 years aids in the overall performance of the jetties. Unfortunately for many jetties along the Oregon coast, original construction took place without any measureable stone quality requirements. As a result, inferior stone, often sandstone, was utilized extensively, which had the potential to shorten the life expectancy of the jetty. All stone utilized for original construction of the MCR jetties, as well as for subsequent repairs, came from volcanic sources, which perform much better than those from sedimentary sources.

Stones utilized for the North Jetty came from a variety of sources, as identified in Table 1-3. All sources of stone, including those for original construction, came from quarries in volcanic rock that have met current District quality standards. Both Fisher and Skookumchuck quarries are in existence today, and even though lab tests weren’t conducted at the time of their first use, stone quality, by visual observation has not changed through time and would still meet current stone requirements. Stones have good survivability with very little breakage occurring after initial placement and while some wear is present to edges of the stones, it is not enough to significantly compromise the interlocking properties.

Stones for the South Jetty original construction, as shown in Table 1-2, came from quarries along the lower Columbia and Willamette Rivers. Although actual quarry locations are unknown, design requirements stipulated use of basalt, which is a hard, durable volcanic rock that holds up well in a marine environment. Subsequent repairs and extensions through 1982 utilized stone from the well known Fisher Quarry, over 7.5 million tons or 83% of all stone used on the jetty during original construction and maintenance to present day. This consists of all stone currently exposed on the outer surface of the jetty and meets the current stone requirements and continues to perform well in the jetty structure.

Stone for Jetty A original construction and early repairs, as identified in Table 1-4, came from the Skookumchuck Quarry as well as the Naselle Quarry, both of which are volcanic rock and have been tested recently and meet the current quality standards. Stones from both of these quarries, which provided the full base material for the jetty and 53% of the total volume of material placed, have undergone very little additional breakage and wear and continue to perform well. The latest repairs to Jetty A, from 1951 to 1962, utilized local volcanic basalt breccia from Cape Disappointment. This material is considered inferior and was considered to be marginal quality at the time. Service records in 1958 (USACE), however, based on visual performance through time, showed the material to be wearing well and was allowed for use in subsequent repairs. This material continues to perform adequately to this day and annual inspections of the jetty show very few additional instances of breakage or wear.

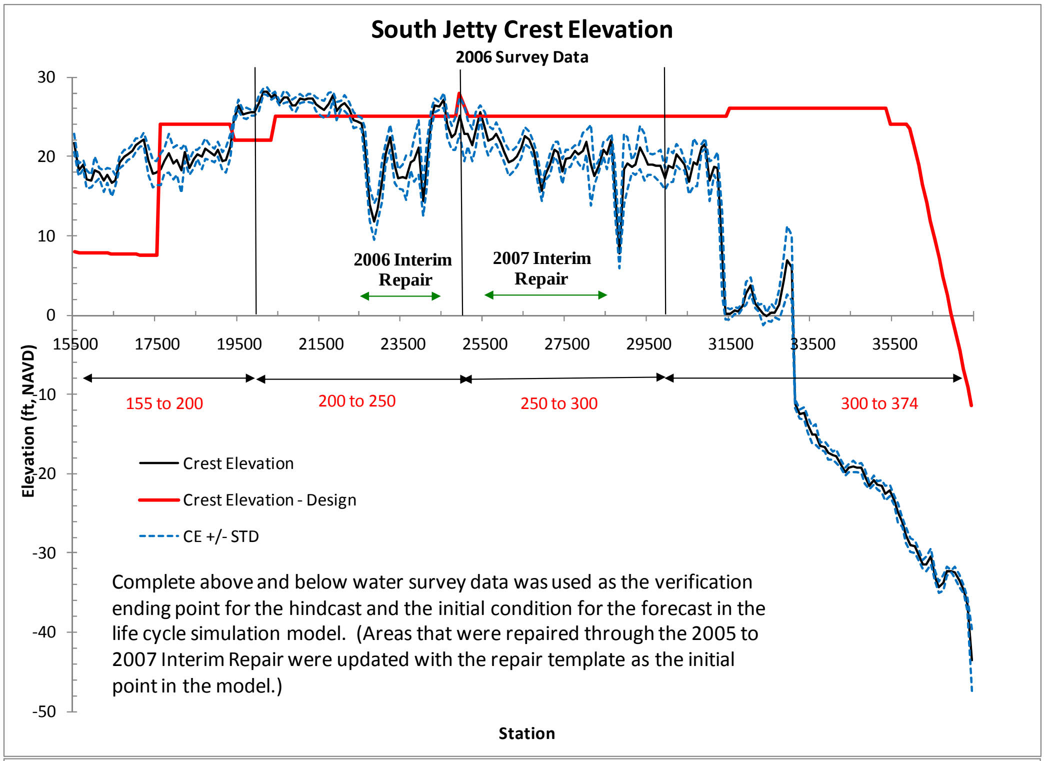

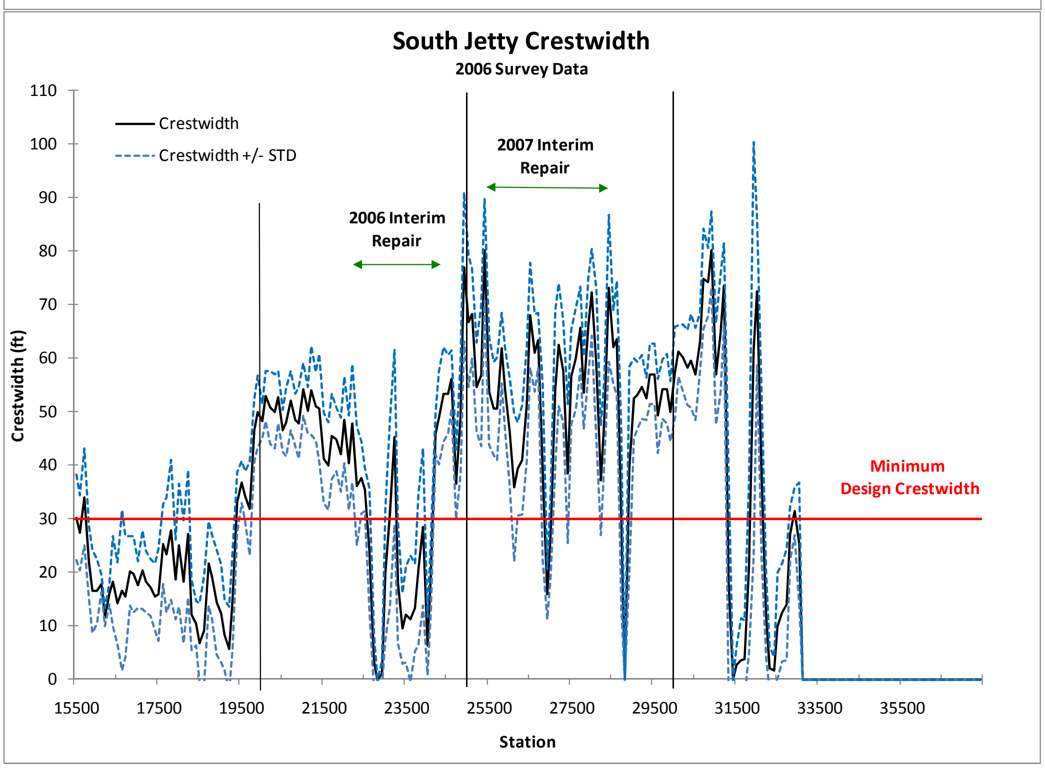

Figure 3-10. South Jetty Cross-section Deficit.

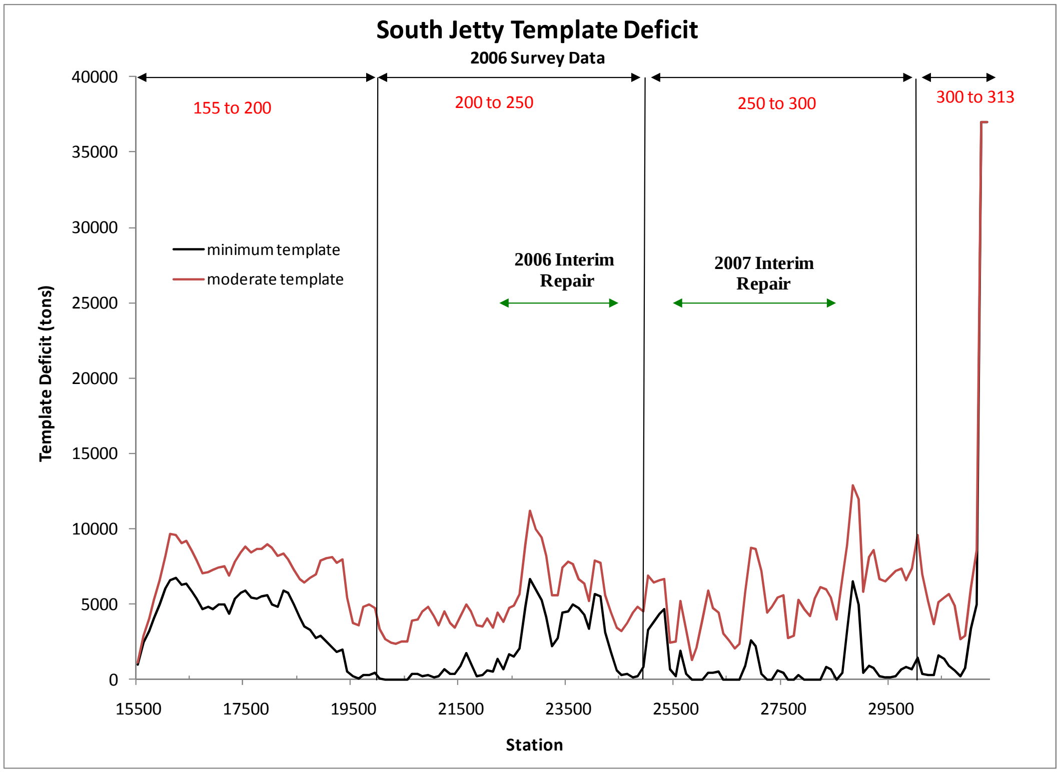

Figure 3-11 illustrates the critical shoals surrounding and supporting the MCR jetties. Ebb tidal shoal changes and jetty length recession impacts all areas identified in Figure 3-11. Ebb tidal shoal recession and reorientation is shown in Figure 1-10. The jetties continue to recede from their original length. The head positions of the South and North jetties and Jetty A are currently shorter than authorized lengths by 6,200 feet, 2,200 feet, and 900 feet, respectively. Due to the interaction of wave patterns and currents with the jetty configuration, the shorter jetty lengths can increase underwater shoal erosion and motivate increased recession of shoreline position adjacent to the jetties. Loss of jetty length also exposes the remaining structure to increased forces.

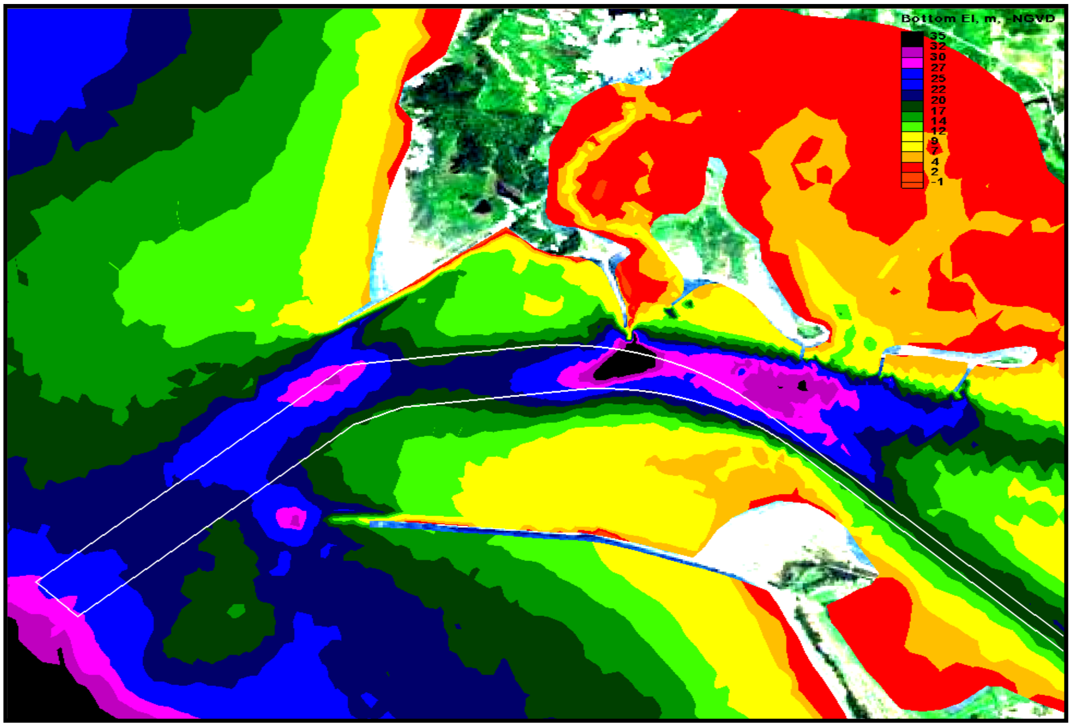
Figure 3-11. Areas of MCR Morphology (#1-#8) Affected by Jetty Deterioration



The South Jetty was constructed in 1885-1895 to stabilize the highly transient tidal shoals (bar) and establish a deep draft navigation channel through the MCR inlet. During 1903-1913, the jetty was rehabilitated and extended offshore to increase jetty function for stabilizing the inlet.

Jetty A length recession has additional impacts on areas #2 to #7 in Figure 3-11. In particular, Jetty A was constructed in order to help stabilize the location of the navigation channel and to reduce shifting of Clatsop Spit (#5 to #7) northward. This added control helps stabilize the channel-side foundation shoal for the North Jetty (#2). Morphology areas #1 and #8 are directly related to jetty length, as well as ocean processes that develop rip currents along the jetty length.

Figure 1-25, Figure 1-27, and Figure 1-33 illustrate foundation changes along each side of each jetty with respect to the 2000 survey. In addition to the foundation changes along the exposed areas of the jetties, along the landward half of the North Jetty another de-stabilizing flow path has developed through the structure as tidal flow moves through the structure to the accreted part of Peacock Spit, along the north side of the structure. Increased storm activity and intensity over recent decades has accelerated adjacent shoreline erosion threatening to expose the deteriorated jetty root structure on both the North and South jetties.

3.3.3. **Projected Relevant Future Geomorphologic Change**

There are many processes that drive scour effects along the toe of coastal structures. In the past, the mechanism for jetty scour at MCR has been due to many interacting processes. Initially, tidal channel re-alignment due to jetty construction was the dominate mechanism for morphology change and scour. As the inlet responded to incremental jetty construction during 1885 to 1939, channel re-alignment stabilized as the inlet equilibrated to its present configuration. Rip currents, tidal currents, vortex shedding and other secondary flow effects, and wave action are now the processes that are believed to affect scour along the jetties. Even if the hydrodynamic aspects of scour are fully understood, there remains the difficulty of coupling the hydrodynamics with sediment transport. Consequently, most scour prediction techniques consist of rules of thumb and fairly simplistic empirical guidance developed from laboratory and field observations. If consistent hydrodynamic conditions persist over a sufficient time span, scour holes and trenches eventually reach a stable configuration. Appendix A5 summarizes historical morphological changes at the MCR project.

What is known about jetty scour at MCR is based primarily on observation of bathymetric change over time and space, with insight being supplemented by hydrodynamic modeling. The scour depth realized at the terminus of the originally constructed jetties has stabilized to a point of equilibrium; scour depth is no longer increasing along the jetty tips. The scour at areas inshore of the jetty tips continue to evolve along each jetty, but at a rate reduced from the initial stages of inlet response to jetty construction. Table A2-6 to Table A2-8 (Appendix A2) summarize scour depths that have been observed to date along each jetty. The maximum vertical extent of scour is believed to have equilibrated, but the scour zone is believed to migrate along each jetty based on jetty head recession and landward recession of the shore-jetty root interface. Future projection of scour depth is presented in these tables, based on past scour trends. It is likely that the spur groins evaluated will be subjected to some scour as the seabed locally adjusts to the presence of these elements. A given percentage of overbuild (10-20%) has been included within the MCACES cost estimate to account for natural reshaping of the groins as they are placed.

For this study, the jetty head features evaluated, would occur on existing relic stone which is the remnant from previous jetty construction and repair sequences. Relic stone has been in its present configuration for more than 10 years at the areas where jetty head features were evaluated. Construction of jetty head features on relic stone serves two purposes, (a) keeping the jetty head feature on the stable relic stone base and avoiding construction of the jetty features on scour-susceptible sand, and (b) minimizing material cost and construction complexity by maximizing the use of relic stone. If the jetty head cross-section extends beyond the relic stone, the quantity of material needed to complete the cross-section rapidly increases and the operating radius requirement (reach) for material placement rapidly increases.

For all three jetties, the jetty head features evaluated would terminate significantly shoreward from the originally constructed jetty head. The North, South, and Jetty A head locations were evaluated at approximately 2000 ft, 6000 ft, and 400 ft landward of the original jetty head position. The significant underwater relic stone base remains in place. For the North and South jetties, the jetty head feature evaluated would be placed at a location approximately 100 ft offshore from the present above water jetty terminus, within the extent of significant relic stone which makes construction of the head structure more practical. For Jetty A, the jetty head feature evaluated would be placed at a maximum distance of approximately 400 ft from the present jetty terminus, also within the extent of the significant relic stone. The rationale for the 100-ft extension for the North and South Jetties is that a complete standard jetty head structure requires at least 100 ft of new armor placement with an additional 100 ft of transition from the head structure within the existing jetty terminus. For Jetty A, the jetty is extended further to restore the required performance in stabilizing the navigation channel. In all cases, the catch point for the bottom slope of the jetty head feature is intended to be set back at least 10 ft from the fall line of the relic stone. The final location and configuration of the evaluated jetty head features will reassessed using detailed survey data and physical model studies and refined during the design documentation report phase prior to construction if part of the selected plan. Because the jetty head features will be constructed on a relic stone base, jetty head features are not expected to require scour blankets or launched toes.

The effect of toe scour on future life-cycle performance of jetty head features has been evaluated using future scour depths presented in table A2-6 to A2-8. Future scour depth along evaluated jetty head locations is estimated to extend below the present seabed elevation by 10-20 ft, depending on jetty location. The strategy for dealing with scour along the jetty head feature locations is to minimize the exposure of these features to scour by keeping the feature entirely on the relic stone and to account for toe continued scour of the relic stone base in assessment of the jetty head feature.

3.3.4. Present Risk and Reliability Issues for the MCR Jetties

Given the age of the infrastructure (+100 years for the primary structures), the existing condition of the jetties, and the modifications to morphology and possibly design wave climate over the project life, there are specific areas along each jetty that at a higher level of risk for accelerated deterioration or failure. Risk and reliability issues are also related to the potential consequence should a failure occur and are covered in more detail in the following sections. Table 3-1summarizes the relative risk and sensitivity of the primary reaches of each of the jetties.

Table 3-1. Relative Sensitivity and Importance of Jetty Reaches

(for all categories, "High" indicates sensitivity and higher risk and "Low" indicates non-sensitivity and lower risk)

	Construction Accessibility[1]	**Degree of Annual Loading[2]**	**Impacts of Failure[3]**
North Jetty			
20 to 50	Low	Low	Low
50 to 90	Medium	Medium	High
90 to 122	High	High	High
South Jetty			
150 to 200	Low	Low	Low
200 to 250	Medium	Medium	Medium
250 to 300	High	High	Medium
300 to 375	High	High	High
Jetty A			
40 to 60	Medium	Low	Low
60 to 80	Medium	Medium	Medium
80 to 97	High	Medium	High

[1]***Construction Accessibility*** *– The ability to mobilize quickly to the failure area and execute a repair action. Rated on sensitivity, i.e.* ***High*** *= not easily accessible,* ***Medium*** *= accessible under some conditions at reduced production rates,* ***Low*** *= easily accessible to achieve a repair.*
[2]***Degree of Annual Loading*** *– The degree of annual loading indicates the magnitude of loading and the potential for multiple loading directions. Rated on sensitivity, i.e.* ***High*** *= high magnitude and/or frequent and multiple loading directions,* ***Medium*** *= moderate magnitude of loading and some cases of multiple loading directions,* ***Low*** *= low magnitude and little potential for multiple loading directions.*
[3]***Impacts of Failure*** *– Potential for high impacts upon failure either structurally or regarding sediment movement. Rated on sensitivity, i.e.* ***High*** *= high impact on rest of structure or other structures, potential for significant increased dredging,* ***Medium*** *= moderate impact on rest of structure or other structures, potential for moderate increased dredging,* ***Low*** *= low impact on rest of structure and little impact on dredging.*

3.4. POTENTIAL CONSEQUENCES OF JETTY FAILURE

3.4.1. Systematic Jetty Performance and Impacts

In an aerial sense, a jetty consists of three parts (Figure 3-12). The head is the seaward terminus and is exposed to the most severe wave action. The trunk forms the connection from jetty head to subareal (subtidal) beach, retains subtidal shoals, and confines circulation within the inlet. The root forms the connection from the jetty trunk to shore and prevents accreted landforms from migrating into the inlet. Deterioration of a jetty's head, trunk, or root will have different impacts on the functionality of the structure and inlet. Stabilization of the jetty head is critical to long-term project function and maintenance. The most critical parts of a jetty in the short-term are the root and trunk. Appendix A1, Section 13 discusses each of these failure consequences further. The consequences of a breach at the North and South jetties and Jetty A were discussed in Section 1.6.

The head performs as a type of anchor for all of the components of the navigation entrance, serving to protect the landward portion of the jetty structure, the configuration of the underwater shoals and the adjacent shoreline position, the location and configuration of the seaward-most part of the navigation channel, and finally the overall ebb tidal shoal. Omission of stabilization of the jetty head in any long-term maintenance or rehabilitation plan would introduce a higher level of uncertainty regarding maintenance funding (jetty repair and dredging), as well as projected performance of the navigation entrance.

The jetty root (trunk) retains the subareal part of a shoal that would otherwise encroach upon the navigation channel. A breach at the root or trunk would release the tidal shoal and result in rapid in-filling of the navigation channel. Additional complications resulting from a breached jetty root (or trunk) include reduced hydraulic efficiency of the inlet, destabilization of the remaining jetty foundation, and severe shoreline erosion within or outside of the inlet.

Figure 3-12. North Jetty, View to the North

General components of a coastal jetty and damage consequences. Jetty head recession leads to progressive loss of jetty function which can impact inlet dredging requirements and stability of other jetty areas. Cumulative jetty trunk damage can result in a trunk breach which can have functional consequences on the inlet. Cumulative jetty root damage can result in a root breach which can have serious functional consequences on the inlet. Note plume of suspended sediment transported past the jetty head and into the MCR inlet.

In some instances, a jetty segment may be damaged at such a high rate as to fail before timely repair can be implemented. A given jetty segment is assumed to lose function when the upper cross-section area has been reduced to less than 15 ±5% of the original standard upper cross-section. If a jetty segment fails within the body of the jetty, the segment is considered breached. If the breached segment was acting to retain the inlet's morphology, the failed segment may release a large volume of sand into the inlet which has the potential to impact MCR navigation. Figure 3-13 and Figure 3-14 show an example of a breached jetty at a smaller navigation entrance and the resulting adjacent shoreline sediment loss. Figure 3-15 through Figure 3-16 illustrate various navigation entrance impacts subsequent to different areas of jetty failure.

Figure 3-13. Example of a Breached Jetty

Figure 3-14. Adjacent Shoreline Response to Jetty Breach

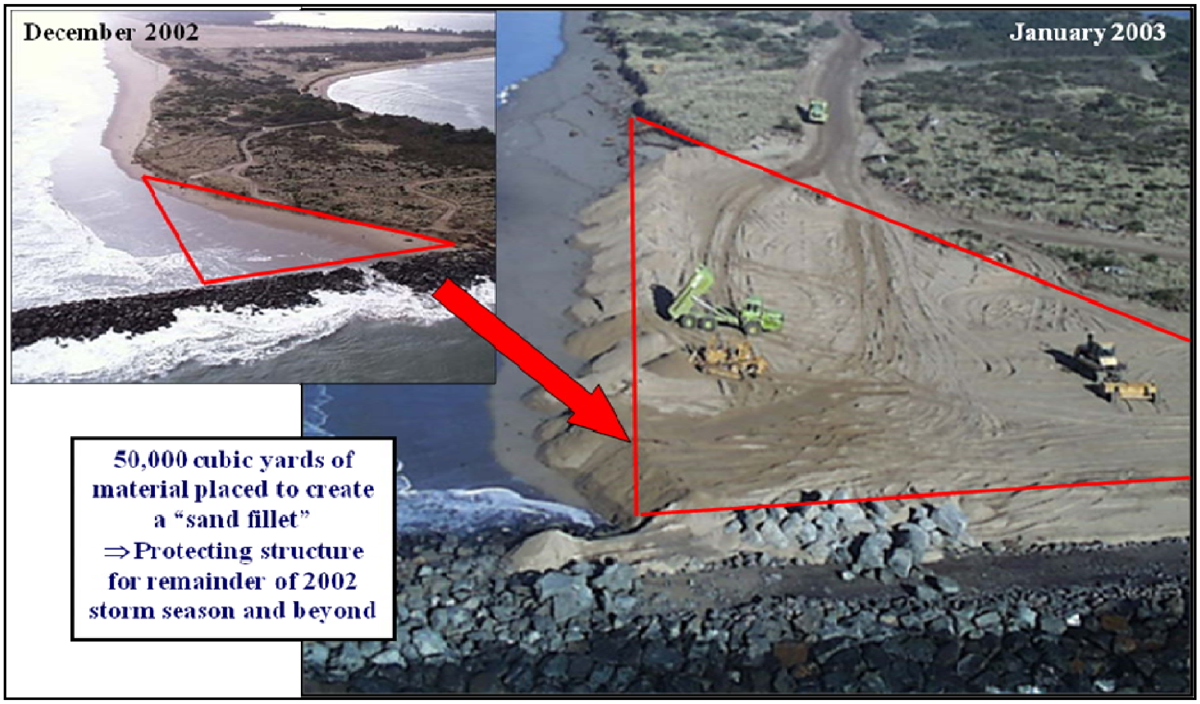


Figure 3-15. Response to Jetty Head Recession

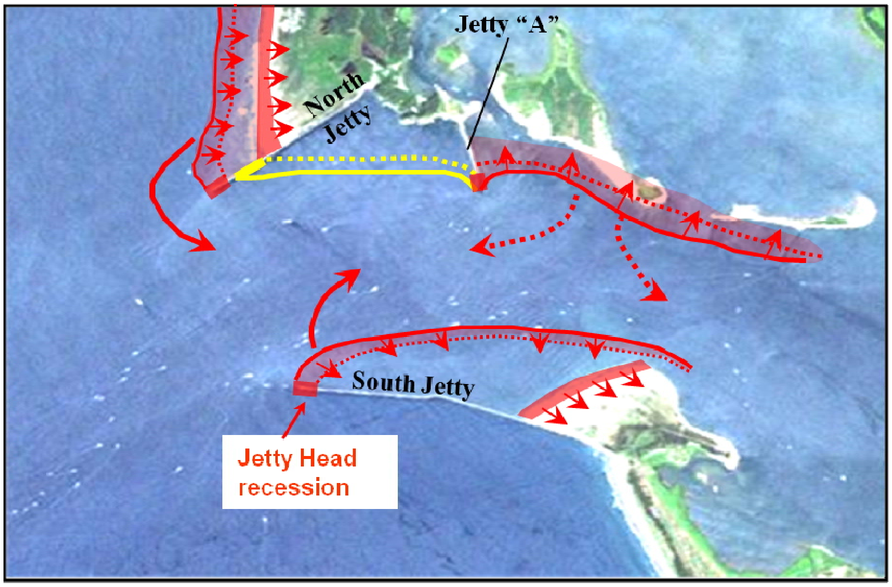
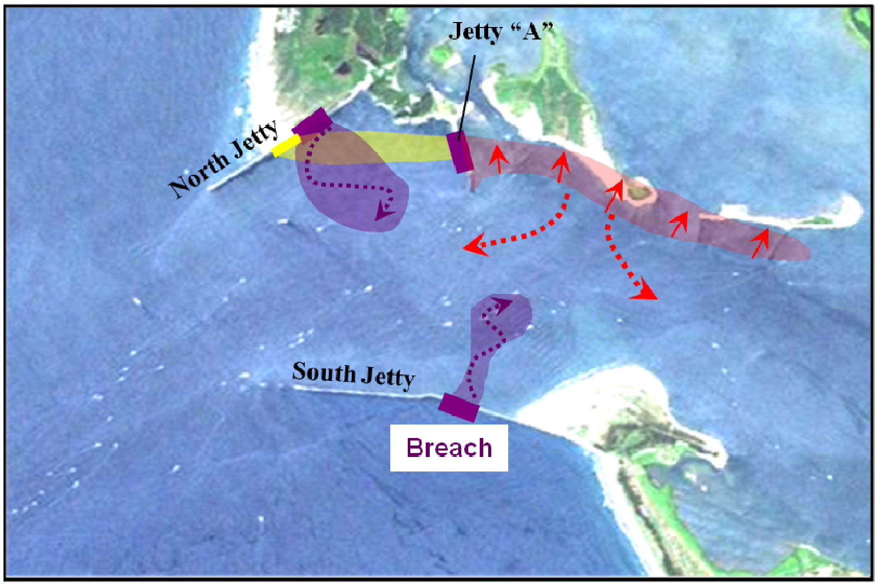


As a jetty head recedes landward, sand from the retained morphology is released and transported past the receding jetty and deposits in the navigation channel. The bathymetry deepens adjacent to the jetty and the morphology recedes, exposing the jetty to increased wave action. Head recession at Jetty A exposes the North Jetty to increased scour.

Enhanced rip currents form along the jetties acting to erode the jetty foundation (dotted line) and motivate continual loss of morphology adjacent to roots of the jetties, exposing the jetty foundation of each jetty to increased wave action and scour. Much of the eroded sediment is tranported into the MCR inlet.

Figure 3-16. Response to Jetty Breach



A jetty breach, if allowed to occur at the MCR would allow flow through the jetty and destabilize adjacent morphology. Elevated shoaling at the MCR would occur. Aggressive dredging may be required to maintain the MCR navigation channel and the jetty may require emergency repair. The distinction should be made between jetty damage and jetty failure and MCR project function failure. The primary function of the MCR project is to maintain the navigation channel for deep draft shipping. The secondary function evaluated in the structure rehabilitation effort is to significantly extend the life and reliability of the jetties in order to reliably maintain the primary function. Sub-categories addressed in order to accomplish the primary purpose included prevention of a significant breach to the jetties, minimizing dredging of the channel, minimizing the frequency and magnitude of the required jetty repairs, and reducing the degradation rate of the jetties over time.

A jetty breach, if allowed to occur, would likely occur during winter (October through March) in response to storm waves. Due to the typically severe weather conditions at the MCR during winter months, emergency jetty repairs (to fill the breach) and/or emergency dredging activities (to maintain the navigation channel) may not be possible or may only be possible at a reduced rate, with the end result potentially being impacts to navigation until the actions can be completed. Jetty repairs are expensive and due to the sheer size of the structures usually include high costs of mobilization. Because these jetties are typically repaired from the top of the structure (especially during winter months), construction of a haul road is required for each jetty repair effort. In addition, there are some areas along the seaward half of the North and South jetties for which emergency jetty repairs during the winter months could not be conducted, due to the exposure of the construction site to overtopping wave conditions.

The degree of navigation impact motivated by a breached segment is dictated by how many neighboring segments breach, the volume of shoaling that could be mobilized into the inlet, and the proximity of the breached segment(s) to the navigation channel. In the analysis of the MCR project, a breach of the North Jetty is expected to be a more serious threat to the primary function of the project.

This is due to its proximity to the navigation channel, as well as its current function of holding back Peacock Spit from encroachment into the channel. If this scenario occurs, impacts to navigation are quite likely.

3.5. Engineering Approach

The engineering analysis of the potential rehabilitation plans covered two primary areas: (1) jetty cross-section repair, and (2) engineering features which address larger process deterioration of the jetty structures. Tools used for design analysis in this study included historical performance at the MCR, other case studies, two-dimensional physical modeling, hydrodynamic numerical modeling, and life-cycle performance analysis. The South Jetty and Jetty A were evaluated for cross section repair options, spur groins to reduce jetty scour, and jetty head reconstruction as shown in the figures. The North Jetty was evaluated for cross section repair options, spur groins to reduce jetty scour, stabilization of backfill area along the jetty root and jetty head reconstruction.

3.5.1. Delineation of Structure Design Reaches

Utilizing the design climate for each jetty structure, the existing condition of each structure, and the identified potential process impacts along each jetty length, the key design reaches for each jetty are shown in the figures and tables in the following subsections. The basic categories of design concern can be grouped into the following categories:

- Front-slope wave attack;
- Back-slope overtopping wave attack;
- Foundation loss;
- Adjacent shoreline recession; and
- Backside foundation loss.

3.5.1.1. North Jetty Design Reaches

The North Jetty is divided into five reaches (Figure 3-18 and Table 3-2). The different design reaches are used in the composite design cross-sections to engineer the size of the armor stone to the requirements of the reach. Half of the jetty is backed by accreted land on the north side. The seaward half of the jetty, while it does not have land behind it, is also backed by the substantial underwater shoal in the form of Peacock Spit. The North Jetty, as well as its significant submerged jetty head, functions to hold back this significant shoal from the navigation channel. These features can be clearly seen in Figure 3-18. Benson Beach is located on the north side of the jetty at the transition between above and below water features of the spit. Also visible in Figure 3-18 are the deepening contours on the channel-side of the jetty and the lagoon located on the North side of reach 1 and reach 2 that is considered for repair in the maintenance report; lagoon fill is part of the base condition for this rehabilitation study. Each of the North Jetty design reaches is further described in Appendix A1, Section 8.

Figure 3-17. North Jetty Design Reaches and Adjacent Bathymetry

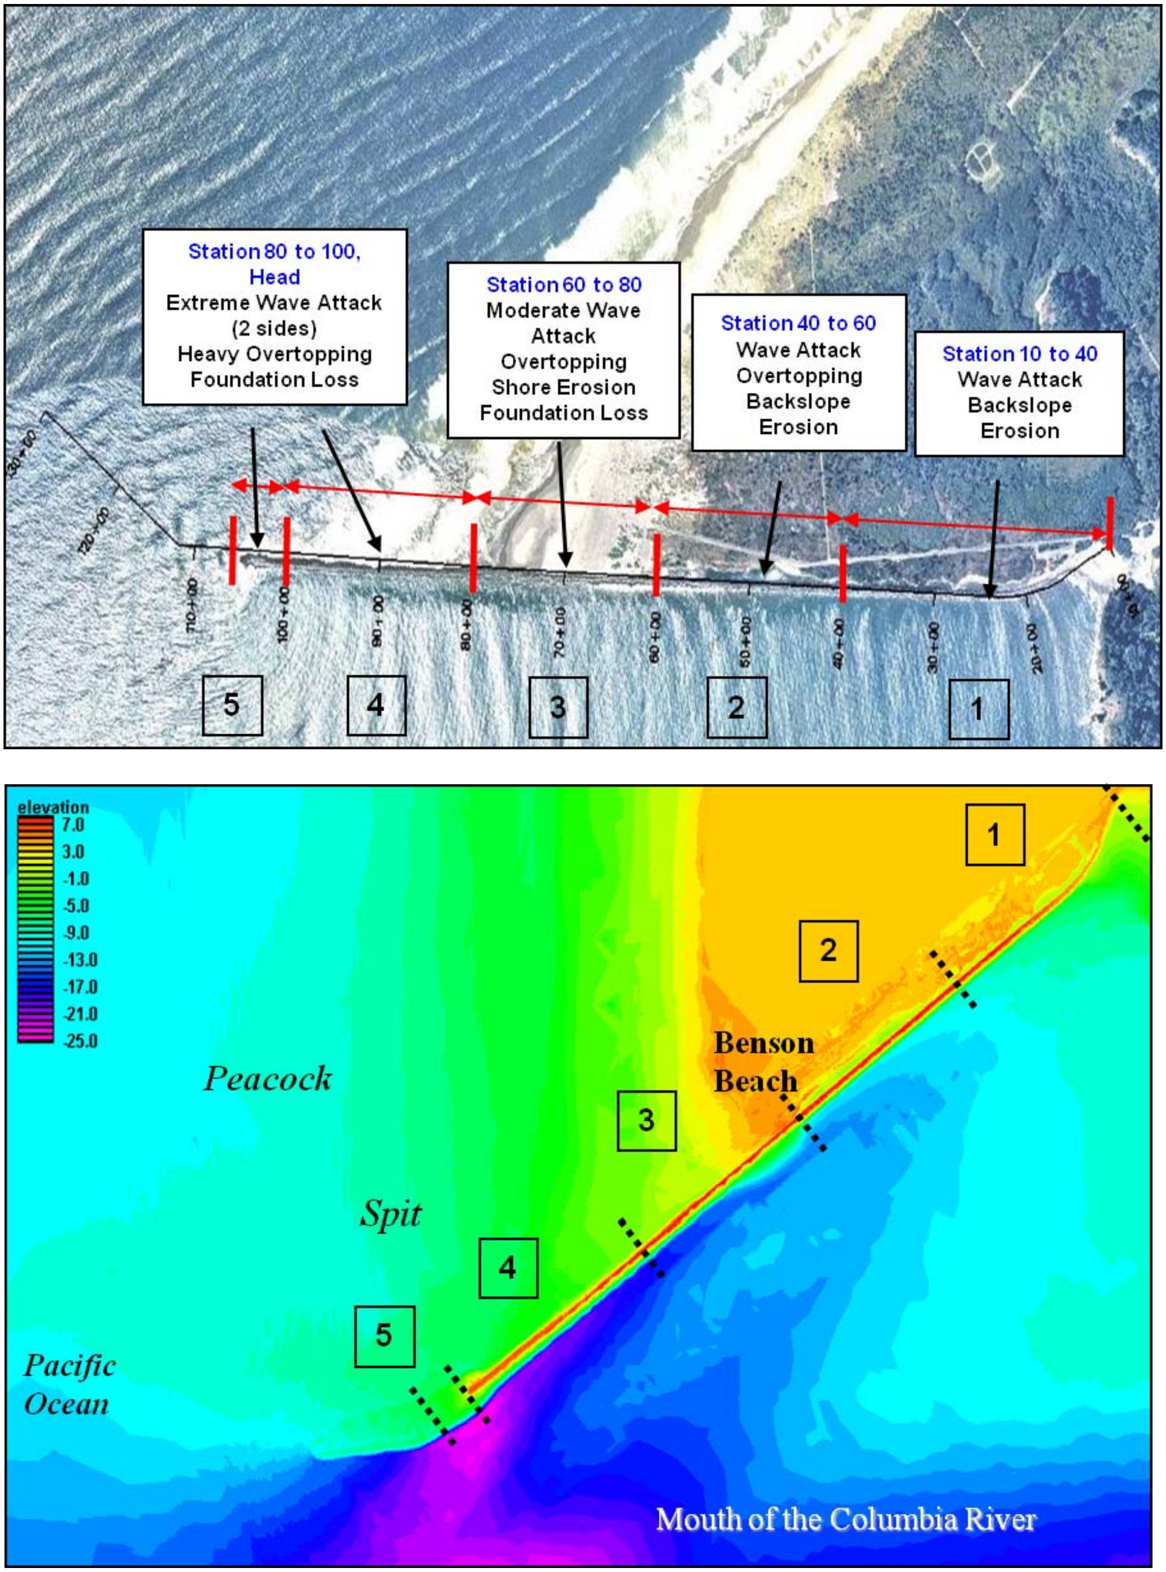


Table 3-2. North Jetty Design Input Parameters

Reach/ Stations	Crest Elevation (ft, MLLW)	Crest Width (ft)	Design Wave Height (ft)		Depth at Toe (ft, MLLW)		Design Issue
			Ocean	Channel	Ocean	Channel	
Reach 1 (Stations 10 to 40)	15 to 25	10 to 30	0	10 to 14	+4 to +15	-10 to -20	Minor frontslope wave attack (1), Backside foundation
Reach 2 (Stations 40 to 60)	20 to 27	10 to 30	0	14 to 17	+3 to +11	-9 to -13	Moderate frontslope wave attack (1), overtopping (1), Backside foundation
Reach 3 (Stations 60 to 80)	20 to 25	20 to 35	5 to 21	17 to 18	-1 to +15	-15 to -55	Moderate frontslope wave attack (2), overtopping (2), Foundation loss (1), Shore erosion
Reach 4 (Stations 80 to 100)	17 to 25	10 to 40	21 to 25	18 to 20	-2 to -15	-55 to -65	Extreme frontslope wave attack (2), Heavy overtopping (2), Foundation loss (1)
Reach 5 (Head)	19 to 20	15 to 40	26	20	-10 to -17	-65 to -75	Extreme frontslope wave attack (3), Heavy overtopping (3), Foundation Loss (3)

3.5.1.2. South Jetty Design Reaches

The South Jetty is divided into six reaches (Figure 3-19 and Table 3-3). Only the first reach of the South Jetty is backed by above-water accreted land. The remainder of the structure is exposed to environmental forces from both sides. The significant underwater shoal on the north side of the South Jetty provides protection both in terms of foundation stabilization and reduced wave height exposure. Although the South Jetty extends out into fairly deep water depths, the portion being evaluated for this rehabilitation effort is located shoreward of the greatest water depths. Each of the South Jetty design reaches is further described in Appendix A1, Section 8.

Figure 3-18. South Jetty Design Reaches and Adjacent Bathymetry

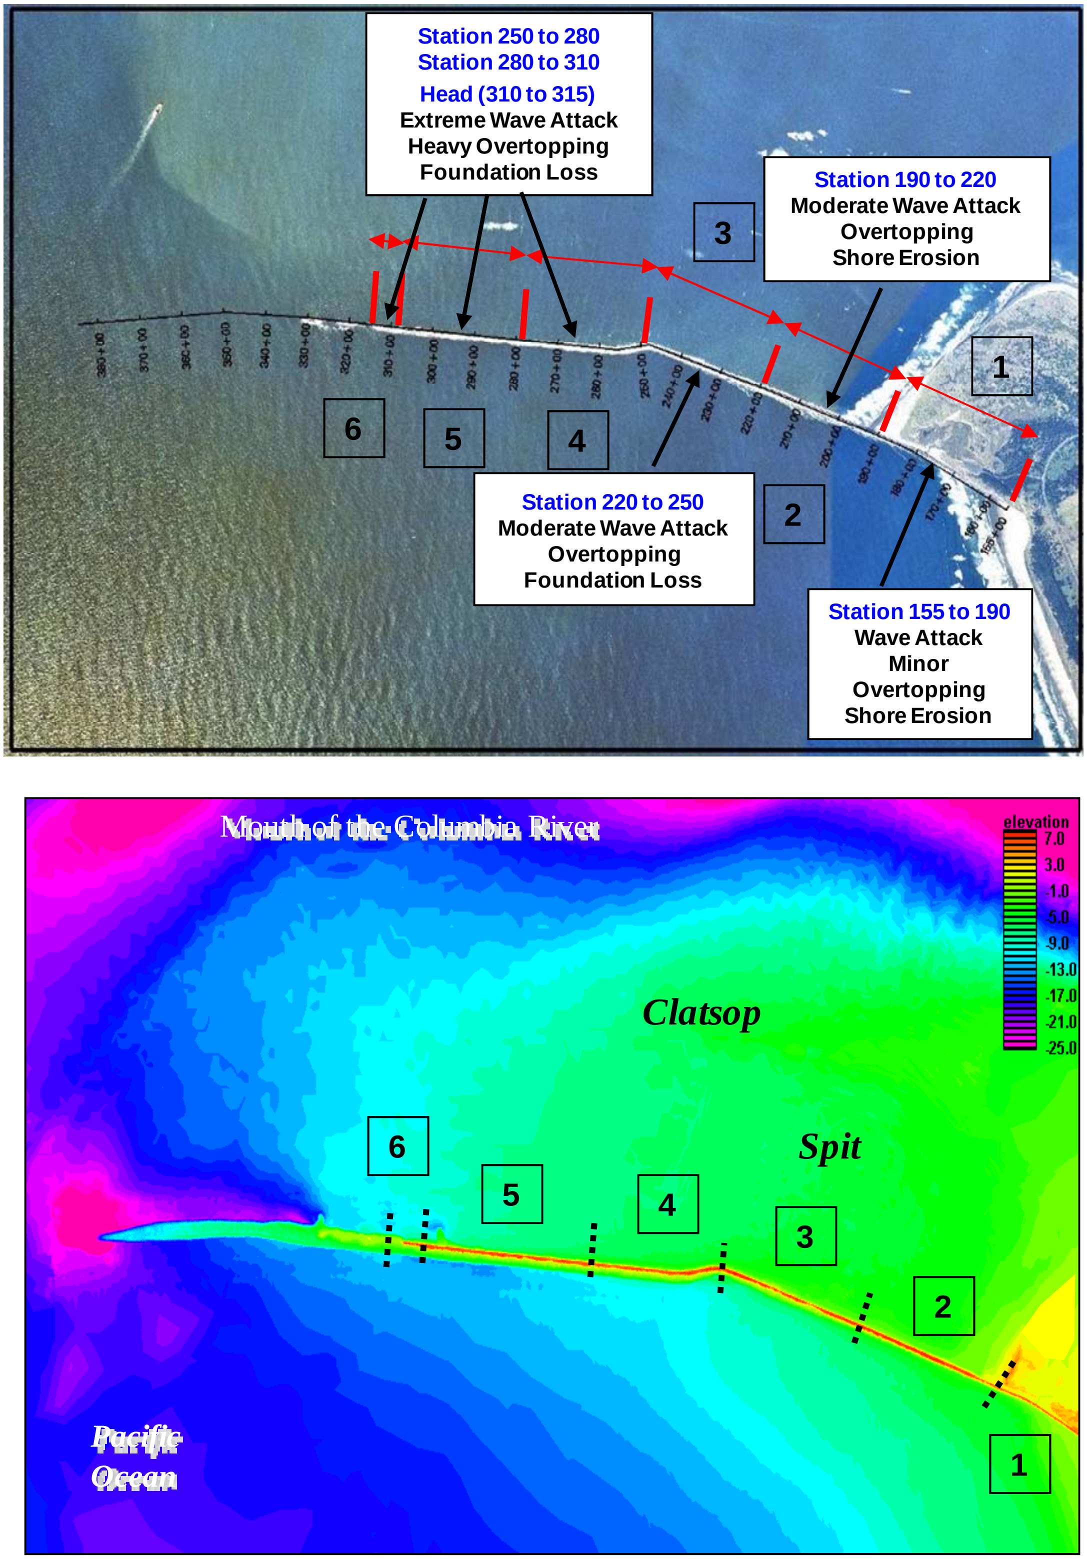

Table 3-3. South Jetty Design Input Parameters

Reach/ Stations	Crest Elevation (ft, MLLW)	Crest Width (ft)	Design Wave Height (ft)		Depth at Toe (ft, MLLW)		Design Issue
			Ocean	Channel	Ocean	Channel	
Reach 1 (Stations 155 to 190)	13 to 20	4 to 20	10 to 16	0	-2 to +15	+4 to +37	Minor frontslope wave attack (1), Minor overtopping (1), Shore erosion
Reach 2 (Stations 190 to 220)	14 to 25	4 to 37	16 to 25	16 to 18	-2 to -10	-4 to +4	Moderate frontslope wave attack (1), overtopping (1), Shore erosion
Reach 3 (Stations 220 to 250)	20 to 25	20 to 30	25 to 32	18 to 20	-10 to -22	-5 to -8	Moderate frontslope wave attack (1), overtopping (1), Foundation loss (1)
Reach 4 (Stations 250 to 280)	20 to 25	25 to 40	32 to 35	20 to 21	-23 to -32	-8 to -15	Extreme frontslope wave attack (2), Heavy overtopping (2), Foundation loss (2)
Reach 5 (Stations 280 to 310)	15 to 25	14 to 40	35 to 36	20 to 21	-32 to -39	-15 to -22	Extreme frontslope wave attack (2), Heavy overtopping (2), Foundation Loss (2)
Reach 6 (Head)	7 to 20	6 to 30	36	21	-33 to -39	-23 to -30	Extreme frontslope wave attack (3), Heavy overtopping (3), Foundation Loss (3)

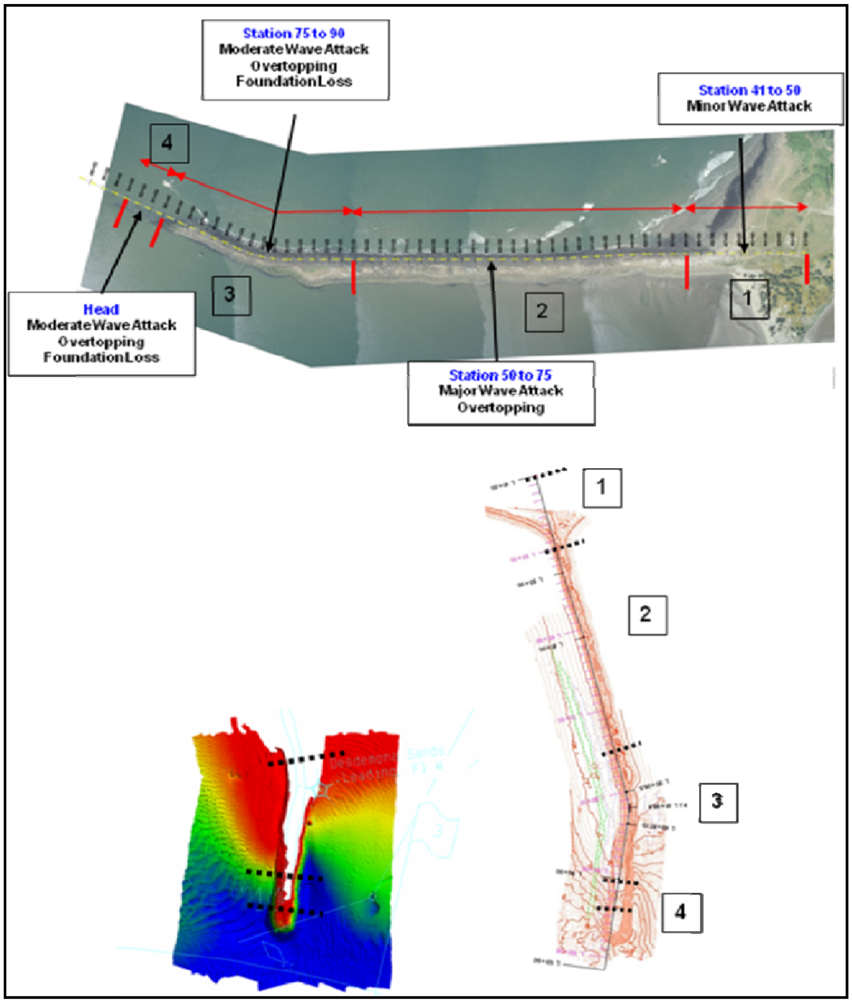
3.5.1.3. Jetty A Design Reaches

Jetty A is divided into four reaches (Figure 3-20 and Table 3-4). Jetty A was constructed as a very large spur groin directed perpendicularly into the Columbia River to help train the navigation channel away from the North Jetty foundation. While it is exposed to a lesser wave climate than the other two jetties, it has suffered severe scour at its southern tip that has contributed to its recession. In addition, wave modeling at the MCR entrance has identified an area of increased wave attack at the center part of the jetty length. Wave attack on Jetty A is limited to the ocean or western side of the structure. Similar to the other two jetties, Jetty A was constructed on top of a large underwater shoal, the continued erosion of which will undermine the structure, as is already evident on its southern end. Each of the Jetty A design reaches is further described in Appendix A1, Section 8.

Table 3-4. Jetty A Design Input Parameters

Reach/ Stations	Crest Elevation (ft, MLLW)	Crest Width (ft)	Design Wave Height (ft)		Depth at Toe (ft, MLLW)		Design Issue
			Ocean	Channel	Ocean	Channel	
Reach 1 (Stations 40 to 50)	20 to 22	40 to 50	5 to 11.5	0	+2 to +18	0 to +14	Minor frontslope wave attack (1)
Reach 2 (Stations 50 to 75)	20 to 25	20 to 50	11.5 to 22.5	3.5	0 to -8	0 to +2	Major fronstlope wave attack (1), Overtopping (1)
Reach 3 (Stations 75 to 90)	18 to 25	15 to 50	17 to 20	5.5	-8 to -20	0 to -75	Moderate frontslope wave attack (1), overtopping (1), Foundation loss (2)
Reach 4 (Head)	-2 to 20	NA	20	5.5	-15 to -50	-75 to -105	Moderate frontslope wave attack (1), Overtopping (1), Foundation loss (2)

Figure 3-19. Jetty A Design Reaches and Adjacent Bathymetry



3.5.2. Design of Jetty Repair Cross Section

3.5.2.1. Cross Section Intent and Design Philosophy

Cross section development for jetty repairs was guided by the following constraints.

- The repair cross-section must be cost-effective in terms of construction materials as well as quantity of material, to allow the maximum repair within funding limitations. Quarried stone is expected to be used for the majority of the work. The vast majority of the repair stone which will be needed for the jetty repair will be within the easily acquired stone size range. Quarried armor stone is available from numerous sources in the Pacific Northwest. Concrete armor units are considered as an option for only the most extreme part of each structure.

- The repair cross-section must be constructible. In order to limit potential impacts to the surrounding environment, the minimum modification to the jetty footprint is desirable.

- The jetty repair should be structurally consistent with the present jetty configuration and future rehabilitation scenarios. There should be no dissimilar attributes between the present jetty section and the repair cross-section. Areas of the jetty that are repaired, using the repair cross-section, must be able to be augmented later, if necessary. Each action taken should be directed toward improving the long-term reliability of the jetty system and its function to protect the navigation channel.

Historical performance of previous jetty designs, expected and feasible construction techniques, and existing structure configuration were considered when specifying structure design parameters. Table 1-2 through Table 1-4 summarize the design cross section history for the three jetties. Verification of evaluated design cross section elements in the project environment was conducted in the two-dimensional physical model. Due to the extreme wave climate along the northern Oregon Coast, the design of a rubble-mound structure to eliminate overtopping is infeasible. In addition, the crest width and to some extent the crest elevation for these structures is related to construction method. The current method of construction has necessitated a crest width that is wide enough to safely accommodate the necessary construction equipment. In addition, especially for the exposed area of construction, the crest elevation is required to be high enough for the equipment to be safely out of the wave attack area.

3.5.2.2. Design Cross Section Development

Design cross-section attributes are selected to minimize the cost of repairs while achieving sufficient stability and life-cycle restoration for each portion of the jetty. Due to the variability in design climate and repair history, alternatives vary between the three structures and along the length of each structure. Jetty cross-section options examined crest elevation, crest width, and side-slope adjustments. The location along the jetty alignment was important to the degree of robustness needed for each design parameter. In addition, for those jetty reaches where foundation stability was a concern, special designs were developed for the toe area of the cross section in order to stabilize the upper portion of the section over the long term. Above and below water adjustments were made in cross-section design to address both variability in design forcing and accuracy and expected method of construction.

Cross section cross-sections for graduated levels of cross-section design are provided in Appendix A1, Section 14.

3.5.2.3. Two-dimensional Physical Model Study

Two-dimensional physical modeling was used to assess and fine tune the cross-section designs, and then each cross section was tested for long-term reliability in the life-cycle model used for this rehabilitation study (the design input parameters are shown in Tables 3-2, 3-3 and 3-4).

The primary failure modes impacting cross-section design vary along each structure but are generally believed to be a combination of one or more of the following: (1) armor instability due to direct wave impact, (2) armor instability due to overtopping, (3) scour de-stabilization of toe, and (4) static instability of underwater slope. The primary issues from the structural design perspective include: (1) technical viability given the condition of the existing structures and the Pacific Ocean environment, (2) risk and/or robustness of design to achieve a minimum 50-year life under extreme annual loading, and (3) reliable constructability of design.

The USACE Engineering Research and Development Center in Vicksburg, Mississippi was contracted to conduct a two-dimensional physical model of the jetty cross-section design. The range of structural repair types addressed in the model included crest elevation and crest widths variations, side-slope variations, underwater berms, armor stone, and concrete armor unit options. The purpose for the two-dimensional physical model was three-fold:

1. Assist in defining damage initiation and damage progression relationships (damage function) for existing condition and evaluated alternatives to feed into a reliability analysis of the three structures.
2. Conduct a qualitative screening of a wide range of alternatives that will bracket potential structural and material-type options that could be applied on the three structures.
3. Assist in cross section optimization and material type design for the range of alternatives to be assessed in the rehabilitation study.

Both the North and South jetties were tested under low and high water conditions. Incident wave heights up to 35 feet were applied to the jetty cross sections. Armor units tested included quarry stone and dolos concrete armor units. An additional concrete armor unit was tested called a c-roc. More information on the c-roc can be found in Appendix A1. The c-roc armor unit more closely resembles a large rock with interlocking members. Due to its rock-like configuration, it is expected to be less fragile than concrete armor units which have thinner flange-like elements.

Existing condition and potential design alternative cross sections were modeled. The physical model testing of the jetty cross section resulted in a range of graduated design options that achieve varying levels of structure reliability. These design options were carried forward into the life-cycle analysis model of the jetty system. The general categories of plans tested in the physical model included in graduated levels of robustness:

- Existing jetty cross section;
- Interim repair cross section;
- Minimum repair cross section;
- Increased slope and increased toe berm;
- Extended slope cross section;
- Combination berm/side-slope cross sections; and
- Increased crest elevation cross section.

Physical modeling results showed that the primary failure modes for the North and South jetties were high water level wave attack and overtopping. Individual results are summarized below.

1. Armor unit assessment:
   - The majority of the North Jetty can be reliably designed using attainable rock. The seaward head of jetty may require advanced design combination approach.
   - Dolos concrete armor units did not hold up well in the tests. Very flat slopes would be needed to make this armor unit viable.
   - C-roc appeared to hold up well during preliminary testing (concerns regarding c-roc include reliability of one-layer system, not field-tested, elaborate construction control requirements, and uncertainty about interlocking with relic base).
2. Cross section element assessment (preliminary):
   - Heavy overtopping may require special crest and leeside design in some areas.
   - Large toe berm is not needed on the south jetty due to the existing relic stone base.
   - Side slopes from 2h:1v to 3h:1v provide reliable section designs.
3. Damage relationship information is used in the reliability analysis:
   - Existing and Interim damage relationships define base condition.
   - Various alternative damage relationships define alternative reliability.
   - Alternative information interpolated for design based on position on jetty.

Detailed information on each jetty's cross-section design parameters is located in Appendix A1.

3.5.2.4. Graduated Levels of Jetty Cross-section Design

The physical model results, discussed in the previous section, were used to develop a series of design options. These options were run through the SRB Model to identify the most efficient and cost effective design (see Table 1.1 for construction history).

In the following jetty cross-sections (Figure 3-20 through Figure 3-22), the light brown represents sand foundation or land, the dark brown represents existing relic stone (existing rock structure from earlier construction efforts), and the light blue represents new cross section and new rock under evaluation. The border around each cross section is also color coded (pink, yellow, blue, black) to help describe the composite cross section.

Jetty Head Cross Section. The jetty head cross section stays constant regardless of the cross section applied along the trunk of a jetty. All jetty caps are very substantial features designed to withstand wave attack from three sides and significant overtopping forces. Note that primarily to control costs, all of the jetty head cross-sections are designed to be constructed on top of the existing relic stone base.

Minimum Cross-section and Scheduled Repair Cross Section. This cross section rehabilitates both jetties along their current length using a minimum cross section that extends above the waterline and lies essentially within the existing jetty footprint.

Small Cross-section Cross Section. This cross section was only considered for the South Jetty and Jetty A because the minimum and small cross-sections were essentially the same for the North Jetty. This cross section rehabilitates the South Jetty along its current length using a small cross section that only extends above the waterline; however, it is not constrained to fit within the existing footprint of the jetty.

Moderate Cross-section Cross Section. This cross section was considered for the North and South jetties and rehabilitates both jetties along their current lengths using a moderate cross section that encases the existing jetty both above and below the waterline and extends beyond the existing footprint.

Large Cross-section Cross Section. This cross section was considered for the North and South jetties and rehabilitates both jetties along their current length using a large cross section that encases the existing jetties both above and below the waterline, and also places a stabilizing toe berm along key reaches of each structure. The cross section would extend outside of the existing jetty footprint.

Composite Cross Section. This could entail any combination of the above cross-section types tailored to address structure concerns along specific jetty reach sections. Up to four cross sections could be used together over the length of a jetty to make a composite plan.

Figure 3-20 through Figure 3-22 are intended to be generic examples of the cross-section types. It is important to realize that the particular cross-section/cross section shown (and the relic stone base it is constructed on) will vary along the full length of each structure.

The top sketch in Figure 3-21 and Figure 3-22 shows the minimum cross-section or scheduled repair approach to the rehabilitation which does not require as much rework of the relic stone as the larger, more substantial designs. The figure showing the minimum cross-section is trying to convey that the repairs conducted will just build off of the existing relic configuration as much as possible. No attempt will be made to modify the back slope for additional stability in that area. The moderate and large cross-sections are more substantial and comprehensive design cross-sections requiring more re-work, more stone, and a larger area of placement.

The large cross-section for the North Jetty does not show the gravel and sand area on the backside because, in general, for most of the alternative where this cross-section is used, it is seaward of the lagoon fill area that requires the sand and gravel backfill. The horizontal red lines in the cross sections indicate transitions to different stone sizes within the cross section.

Figure 3-20. Jetty Head Cross-sections

Light brown represents sand foundation or land, the dark brown represents existing relic stone, and light blue represents new cross section and new rock under evaluation. The border around each cross section is also color coded (pink, yellow, blue, black) to help describe the composite cross section.

3.5.2.5. Structural Performance Modes for a Rubble-mound Jetty

Structural performance modes for a rubble-mound jetty can be characterized in terms of its ability to remain stable during wave attack (dynamic stability), and to maintain a stable footprint/slope configuration on the seabed foundation (static stability). These performance modes are described below and are shown conceptually as failure modes in Figure 3-24 and Figure 3-25. Jetty structure reliability can be separated into above and below water areas controlled essentially by wave-driven and erosion-driven processes. An effective and long-term rehabilitation effort needs to address both sets of damage processes.

Dynamic stability affects the upper part of a jetty cross-section as a result of wave action, generally from -5 feet and up to the jetty crest, on the ocean side and channel side of a jetty. On the side of the jetty directly exposed to ocean waves, dynamic stability is manifest by the direct impact of waves on the jetty and the resultant displacement of individual armor units. On the lee side of the jetty, dynamic stability addresses the effect of waves overtopping the jetty crest and displacing armor units down-slope, off of the jetty cross section.

Static stability affects the lower part of the jetty cross-section, generally below -5 feet on the ocean side and channel side of the jetty. Static stability addresses the susceptibility of the jetty toe to wave-current scour, and resistance of the jetty slope to sliding down grade along a slip-plane. Damage due to static stability issues propagates up-slope to affect the upper region of the jetty cross section.

3.5.3. **Engineering Features**

The second phase of the study investigated and evaluated actions to address the larger system-based degradation processes that impact the project as a whole and over the long term. Engineering features included jetty head stabilization through a robust head construction, construction of spur groins at key locations along each jetty to promote foundation stabilization, and lagoon fill behind the North Jetty root. These features were evaluated individually and incrementally in the life-cycle model using the minimum cross section repair plan and are discussed below.

3.5.3.1. Spur Groins

In areas where foundation scour threatens the overall jetty stability, spur groins were considered in some alternatives. If constructed, the spur groins would be perpendicular to the jetty to facilitate stabilization via accumulation of sediment along the jetty foundation. Historical experience and numerical modeling were used to select the type, depth, and length of spur groin necessary to impact the processes causing increased scour at each jetty (e.g., rip currents, eddies). A range of information was utilized in developing a set of possible spur groin applications along the MCR jetties. Furthermore, one set of alternative plans was evaluated within the framework of trying to specify the lowest impact spur groin layouts (size and number of spurs) suitable to achieving the intended long-term stability purpose of the structures. Information utilized included knowledge of problem erosion areas along the three primary jetties, experience of spur groin application at the South Jetty and Yaquina South Jetty, observation of jetty relic stone wing impacts on shoreward sedimentation, other spur groin studies, and numerical hydrodynamic modeling. The effectiveness of the spur groins is evaluated in the model and compared using average annual costs to decide whether it’s more effective to have higher up-front costs by constructing them, or repeated maintenance in those areas to secure the foundation on the jetty trunks without them.

Figure 3-23. Jetty Performance Modes for Dynamic Stability

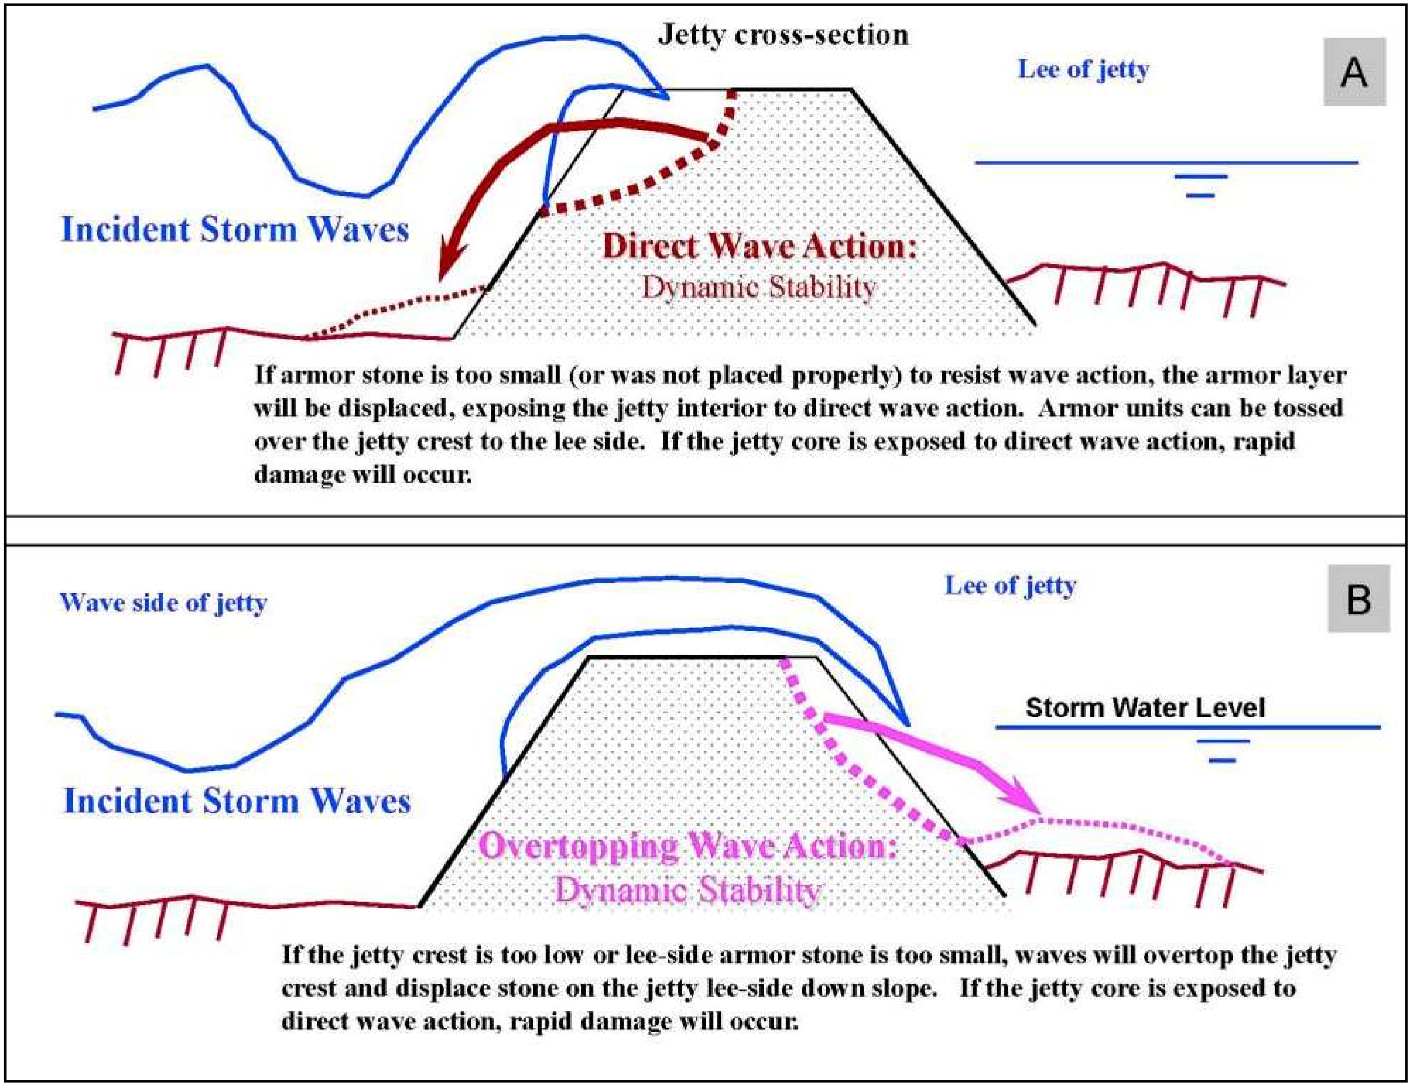

Figure 3-24. Jetty Performance Modes for Static Stability

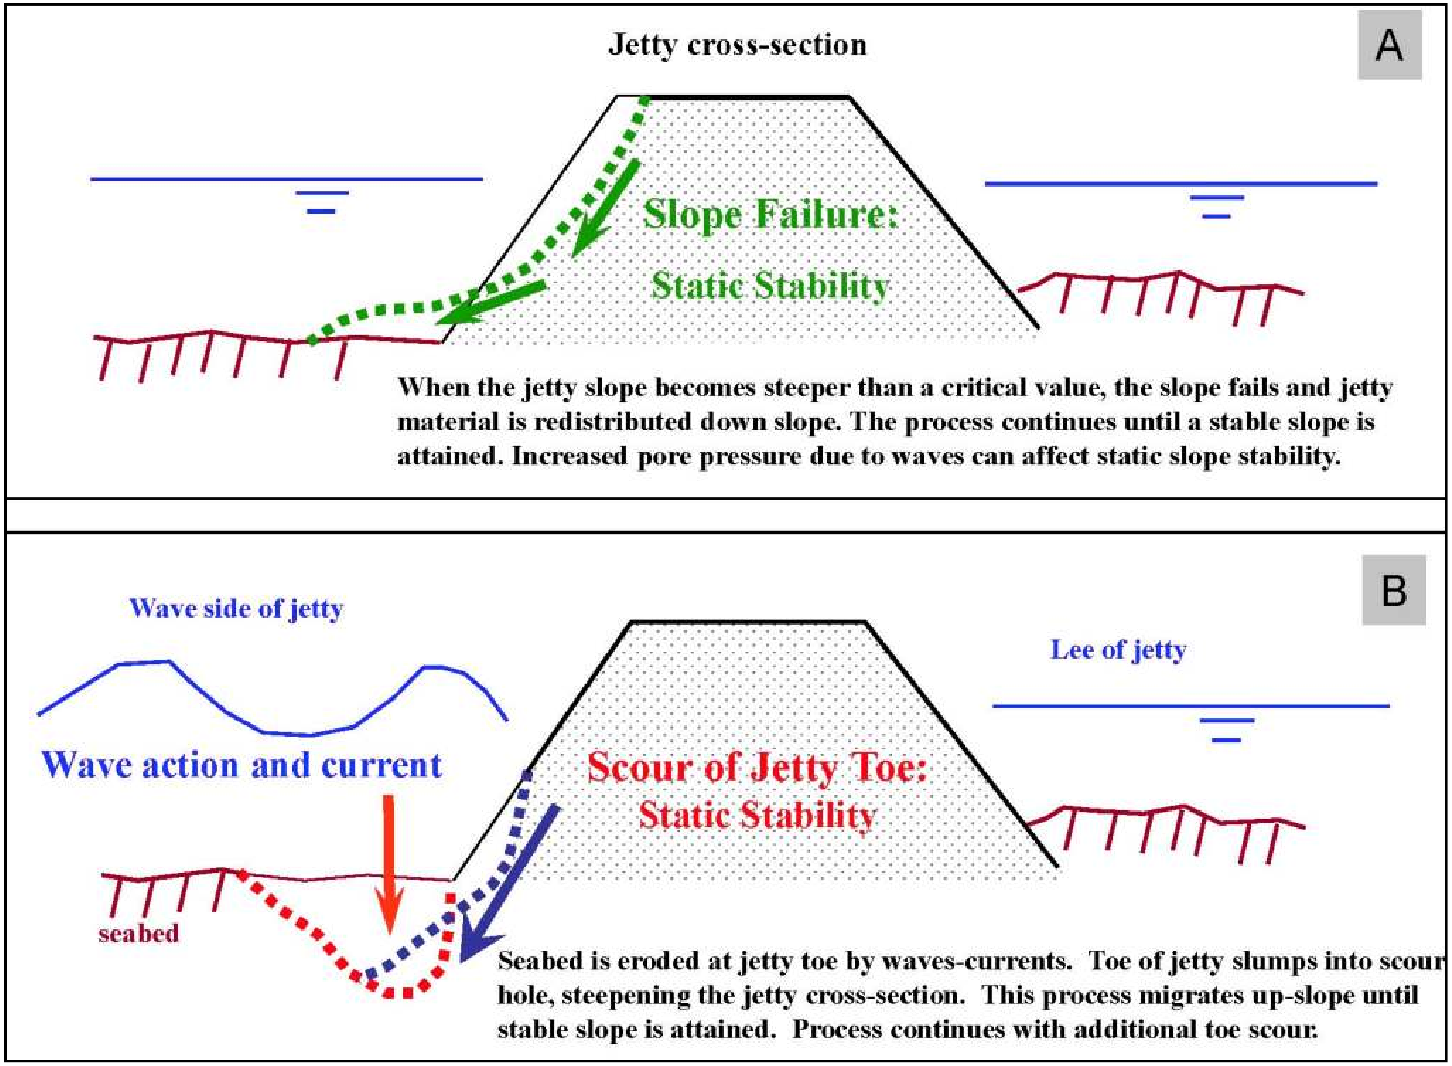

A jetty spur or spur groin is a relatively short structure (in comparison to jetty length) extending outward from the main axis of a jetty. Spur groins are constructed for a range of reasons dealing with the need to effect currents and sediment transport along the jetty. There are two prominent reasons why spurs are implemented:

1. On the ocean or beach side of a jetty to deflect the long-shore (rip) current and related littoral sediment away from the jetty and prevent littoral sediment from entering the navigation channel (Figure 3-24 and Figure 3-25 illustrate how jetty length recession can also impact shore tie-in erosion conditions).
2. On the channel side of a jetty to divert the tidal or river current away from the channel side toe of the jetty. In this application, spur(s) act to reduce the scour affecting the jetty's foundation, while increasing the current in the navigation channel and thus reducing the deposition in the channel.

The Engineering Research and Development Center (ERDC) analyzed the hydrodynamics and circulation patterns in the MCR entrance, as well as the potential impacts and effectiveness of placing spur groins on the jetties. This analysis was conducted with the coastal modeling system and other models to select the type, depth, and length of spur groins necessary to protect each jetty from the processes causing increased scour (e.g., rip currents, eddies). Each spur groin will have a crest width of about 20 feet and will be constructed using a bedding layer (mixture of gravel and rock) that will be covered with large stone sized for the location and exposure.

Potential locations for jetty spurs were evaluated based on calculated peak ebb and flood currents as simulated with the regional-scale, two-dimensional CMS model. In addition, the length of each of the spur groins was optimized based on the water depth at its evaluated location (i.e., a shallower depth requires a shorter spur groin to have a positive impact). The final approximate location of the spur groins evaluated can be seen on Figure 3-26. A typical spur groin for the North Jetty is shown in Figure 3-27. Table 3-5 summarizes the characteristics for the spur groins evaluated for each MCR jetty. More information on spur groin evaluation can be found in Appendix A1, Section 11.

Figure 3-25. Approximate Locations for evaluated Spur Groins along Each Jetty (one set of alternatives)

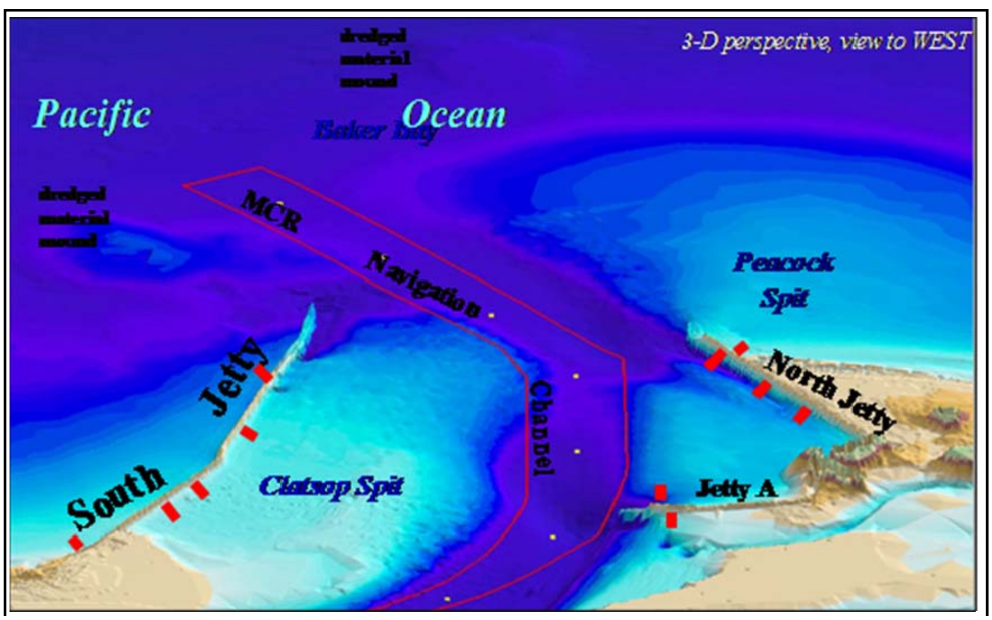

Figure 3-26. Typical Spur Groins along the Channel Side of the North Jetty

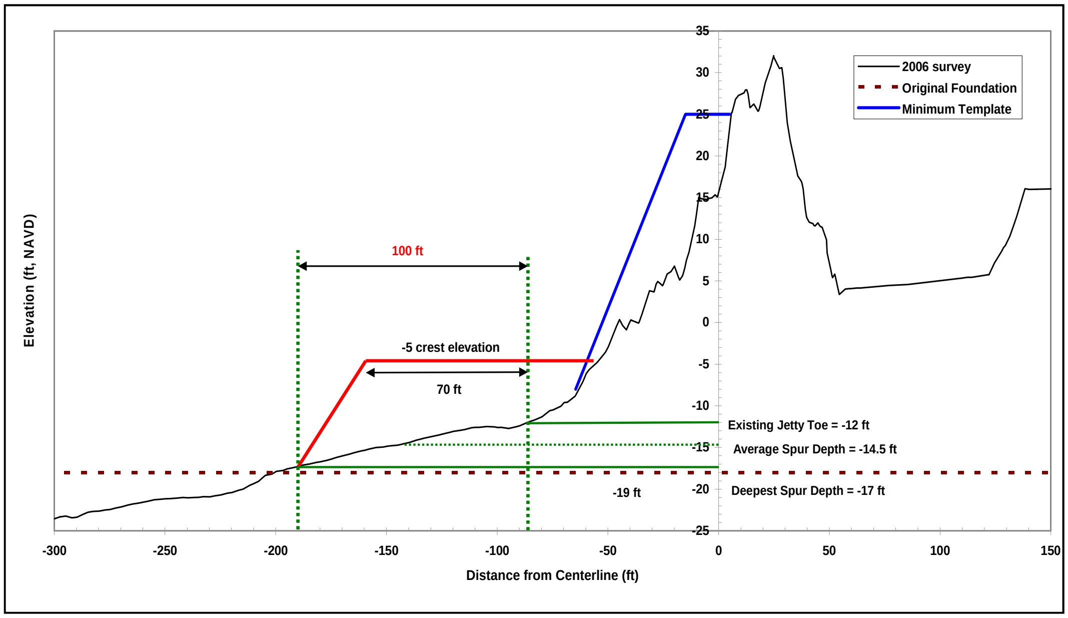

Table 3-5. Characteristics for the Spur Groins Evaluated

Features	North Jetty	South Jetty	Jetty A
Number of spurs on channel side, or downstream for Jetty A	3	3	1
Number of spurs on ocean side, or upstream for Jetty A	1	2	1
Total rock volume per spur	NJ1C: 3,350 tons NJ2C: 11,090 tons NJ3O: 2,010 tons NJ4C: 29,250 tons?	SJ1O: 1,680 tons SJ2C: 2,350 tons SJ3C: 2,350 tons SJ4C: 3,180 tons SJ5O: 18,750 tons	JA1C: 9,650 tons JA2O: 7,330 tons
Total rock volume (all spurs)	45,700 tons	28,310 tons	16,980 tons
Area affected by each spur	NJ1C: 0.18 acres NJ2C: 0.45 acres NJ3O: 0.11 acres NJ4C: 0.80 acres	SJ1O: 0.11 acres SJ2C: 0.13 acres SJ3C: 0.13 acres SJ4C: 0.19 acres SJ5O: 0.55 acres	JA1C: 0.33 acres JA2O: 0.29 acres
Total area affected (all spurs)	1.55 acres	1.10 acres	0.61 acres
Area of spurs above water	NJ1C: 0% NJ2C: 0% NJ3O: 24% NJ4C: 0%	SJ1O: 29% SJ2C: 7% SJ3C: 7% SJ4C: 0% SJ5O: 0%	JA1C: 0% JA2O: 0%
Area of spurs below -20 MLLW	NJ1C: 0% NJ2C: 88% NJ3O: 0% NJ4C: 100%	SJ1O: 0% SJ2C: 0% SJ3C: 0% SJ4C: 0% SJ5O: 92%	JA1C: 1% JA2O: 0%
Dimension of spurs: length x width x height (feet)	NJ1C: 100 x 80 x 10 NJ2C: 170 x 115 x 19 NJ3O: 60 x 80 x 10 NJ4C: 170 x 115 x 19	SJ1O: 60 x 80 x 9 SJ2C: 70 x 80 x 10 SJ3C: 70 x 80 x 10 SJ4C: 90 x 90 x 12 SJ5O: 190 x 125 x 22	JA1C: 135 x 105 x 18 JA2O: 125 x 100 x 15

Two potential construction methods could be used for spur groins, either land-based or marine-based depending on location. Barges or similar equipment could be used to dump the bedding layer rock into place and a clamshell would be used to place larger stone on top of the bedding rock layer in locations with sufficient water depth. Material could also be placed using land-based equipment from on top of the jetty. Land-based construction may require a wide turnout crane placement with over-excavation down to grade as the crane walks back onto the main jetty axis. In addition, the emergent spur groins may be used as turnouts for construction equipment. The land-based construction method could be used for all but the deepest spur groins. See Section 12 of Appendix A1 for a detailed explanation and discussion of the modeling and results.

3.5.3.2. Jetty Head Stabilization and Rebuild

As stated earlier, jetty length recession has various consequences to the stability of the structures and the MCR jetty project. Investigations examining the reconstruction of jetty length focused primarily on maintaining the underwater and adjacent shoals which have proven to be critical for controlling the impinging wave climate and maintaining the current length to provide effective control of sediment movement into the navigation channel. Increased lengths were investigated to determine if those might provide a more sustainable project over the long term.

The U.S. Geological Survey (USGS) Menlo Park assisted the USACE with evaluating potential improvements and impacts of jetty head rebuilds evaluated. The USGS efforts focused on using the Delft-3D model to identify potential changes in circulation, salinity and sediment transport that could result from the offshore re-build of the three jetties. (See section 12. C. Appendix A1)

Based on the several constraints (see discussion in Section 11 of Appendix A1), the rebuild of the South Jetty head (presently located 1,500 feet inshore of the concrete monolith) was not considered a viable rehab option. Constructing the jetty head offshore from the current position of the end of the jetty to its authorized length was deemed infeasible due to the extensive scour hole and depth of water at the authorized south jetty terminus location. The head of the South Jetty was considered to be stabilized at approximately its current location (stations 313-315). Maximum viable rebuild of the North Jetty head was determined to be station 105, which would result in a re-established head position 1,700 feet inshore of the fully authorized length. Maximum viable re-extension of the head for Jetty A was determined to be station 93, which is 500 feet seaward of its current position and 400 feet landward of its full authorized length. Jetty A length is important to controlling erosion along the North Jetty foundation; however, the substantial scour hole south of the Jetty A head limits a cost-effective head rebuild.

Figures 1-24, 1-26, and 1-31 illustrate the original length modeled by USGS and the lengths and head positions of the authorized project. The loss of littoral sediment can be reduced by stabilizing the jetty heads which maintains the overall morphology of the inlet. Because the recommended jetty lengths for the considered alternatives are about the same as existing jetty head locations, it is not expected that these project alternatives will have a negative impact on the hydrodynamics or sedimentation processes of the MCR inlet. It should be noted that a project plan that does not stabilize the jetty heads will more than likely result in erosion of Clatsop and Peacock spits.

3.5.4. **Reliability of Rubble-mound Structures**

A detailed discussion of reliability and risk concepts is provided in Section 2 of Appendix A2. The specific discussion on the reliability of rubble-mound structures concludes that because rubble-mound structures can afford a large degree of resiliency before being functionally compromised, less conservative maintenance strategies can be implemented to manage the structure's life cycle providing that project risk is correctly managed. A less conservative maintenance strategy is essentially a deferred repair condition: the structure is permitted to experience significant degradation before repairs are undertaken. Deferred maintenance can suppress life-cycle expenditures, up to the point at which the structure is on the verge of losing function (failing). When this condition is reached, the damaged structure will require extensive repairs to renew the life-cycle to a point where repairs can once again be deferred.

There are two general elements of reliability: structural and functional. Structural reliability is the likelihood that a structure will not be damaged within a given time interval. If the structure is susceptible to damage, structural reliability indicates the relative degree of damage that could occur. In many cases, a structure can incur damage (or degradation) without affecting the overall function of the structure. The capacity for sustaining damage without failing is called resilience. When a structure sustains cumulative damage (deferred maintenance) to the point of exceeding its resilience, the structure can lose the ability to perform its intended function. At this point the structure fails. Table 3-6 summarizes target reliability indices and corresponding probability function, P(u), for structure performance in reference to major rehabilitation guidance. Note that the values shown in the table indicate the likelihood of a structure to exceed a given performance limit state, or the probability to experience unsatisfactory structural performance P(u). Unsatisfactory structural performance occurs when a structure incurs damage. The values in Table 3-6 are intended to be used only for the MCR jetties.

Table 3-6. Target Reliability Indices for Structure Performance

Values for conventional practice apply to rigid non-compliant steel structures such as bridges, lock gates, or vertical walls. Values and corresponding consequences given for rubble-mound structures are applicable for MCR jetties only and are assumed to have two or more layers of armor units protecting core material.

Expected Performance Level		**Beta (β) Reliability Index**	**Probability of Unsatisfactory Structure Performance P(u)**	**Functional Reliability**	**Potential Structure Consequences to MCR Jetties**
Conventional Practice (steel structures) ETL 110-2-532	**Rubble-mound Structures @ MCR**				
High	Excellent	5	0.0000003	0.0000097	No likelihood of any structure degradation
Good	Excellent	4	0.00003	0.00097	
Above Average	Very High	2	0.023	0.977	Little likelihood of any structure degradation
Below Average	High	1.2	0.10	0.9	Low likelihood for any structure degradation in response to extreme waves
Poor	Good	0.8	0.2	0.8	Low likelihood for minor structure degradation in response to extreme waves
Unsatisfactory	Average	0.5	0.3	0.7	Moderate likelihood for minor structure degradation in response to extreme waves
Hazardous	Below Average	0	0.5	0.5	High likelihood for minor structure degradation in response to extreme waves
N/A	Poor	-0.2	0.6	0.4	Low likelihood for elevated structure degradation
N/A	Unsatisfactory	-0.5	0.7	0.3	Moderate likelihood for elevated structure degradation
N/A	Hazardous	< -0.8	> 0.8	<0.2	High likelihood for elevated structure degradation

**This table and the values presented within are applicable ONLY to the rubble-mound jetties at the MCR. Do not use this table for citation or reference.*

Functional reliability is the likelihood that a structure will satisfactorily perform its intended function within a given time interval. Functional reliability is derived by combining structural reliability metrics with metrics that describe the present structure cross-section configuration. Unchecked degradation of a structure (reduction in structural reliability) leads to reduced functional reliability.

Appendix A2 provides a more detailed discussion of structural and functional reliability.

3.6. LIFE-CYCLE PERFORMANCE ANALYSIS

3.6.1. General

Project life-cycle costs are affected by two risk elements. *Structural risk* is associated with consequences of a structure being damaged and is driven by structural reliability. Consequences of incurring structural risk are realized when the cumulative damage exceeds a given threshold maintenance level, which may initiate repairs to maintain the structure at a minimal level of resilience.

Functional risk is related to a structure's functional reliability and is associated with the consequences of a structure failing to provide its intended function. Functional risk and project risk are synonymous. The cumulative aspect of incurring structural risk (damage) can add significant cost over time to a structure's life cycle and should be considered with the same emphasis as functional risk (breach). These life-cycle risks are discussed further in Section 2 of Appendix A2.

The difference between structural and functional reliability is indicated by the ability of a structure to incur damage (expressing structure unsatisfactory performance) before losing function (functional failure). A structure that has no capacity to incur damage before losing function will express a functional reliability that is the equivalent to structural reliability. Resiliency is the marginal difference between structural and functional reliability.

3.6.2. MCR Project Event Tree

Complex decisions are the result of progressing through a series of sequential choices and evaluating the consequences of each choice to reach a "best" decision (IWR 1992). For example, as the MCR North Jetty is intermittently damaged by progressive foundation scour and wave damage, areas of the jetty become weakened to the point where the structure has an elevated risk of failing. Several choices are available, such as continuing to defer repairs, performing minimal localized repairs, performing jetty rehabilitation, and/or to implement features to address processes affecting chronic damage. Each choice can produce different consequences, such as the consequences of not repairing the jetty, robustness of the repairs, and at what point in time should repair or rehabilitation occur. An event tree can be used to visually portray sequential decision problems and identify critical sequences in the life cycle of a given structural feature or system. Within this reliability analysis, a project event tree was developed and used to link engineering reliability to economic consequence.

An event tree is a schematic diagram that defines all permutations involving relevant structure performance modes and relates reliability-based outcomes to quantifiable consequences. The compilation of all consequence permutations results in an event tree. An event tree consists of decision points, probabilities of event occurrence, and conditional outcomes (composed of consequence and cost assessment).

The project event tree for the MCR jetties is shown in Appendix A2. The event tree diagram summarizes the annual functionality of a jetty in terms of structural performance modes, sustained damages, consequences, and costs. The event tree starts with the initial condition (*year i*); the forcing environment for *year i* is realized through simulation, jetty performance modes are assessed, and jetty damage for *year i* is evaluated. Cumulative damages are determined at *year i* based on the previous years' performance. Finally, the consequences and costs for *year i* jetty damage are calculated, if repair activities are realized in *year i*. The event tree diagram is repeated n-years, until the life-cycle period is completed. As described above, the project event tree provided the basis for evaluating various life-cycle stages for each MCR jetty. Life-cycle stages evaluated in this report included:

1. Hindcast life cycle (original jetty construction to present, 1900s - 2007).
2. Future life cycle (2006-2007 to 2070) for the current jetty condition and current baseline maintenance strategy.
3. Future life-cycle realizations based on alternative maintenance strategies.
4. Future life-cycle realizations based on alternative rehabilitation strategies.

The following sections describe how reliability and risk are expressed within the event tree and incorporated into the SRB model to perform life-cycle analysis of the MCR jetty.

3.6.3. Stochastic Risk-Based Life-cycle Simulation Model

The MCR SRB model was developed to be a statistical tool to assist engineers and project managers in determining the most cost-effective and reliable method of maintaining and repairing the MCR jetties into the future. The SRB model was written for use in MATLAB® (The Mathworks Inc. 2009). A detailed description of the SRB model is provided in Appendices A2 and A3. Described below is a general overview of the intent, operation, and organization of the model, the coastal engineering functions, and an overview of the model inputs and outputs.

MCR SRB Model Intent

The general intent of the MCR SRB model is to predict the lifecycle costs of repairing and maintaining the MCR jetties based on several repair and maintenance alternative plans. The ultimate objective is to utilize the predicted lifecycle cost ranges and reliabilities computed from each modeled plan to select the option that best balances least cost with highest reliability. The SRB model provides estimates, not definitive answers and is useful in comparing alternatives, costs and consequences but is not the only basis for plan selection. At the foundation of the model is a Monte Carlo simulation which comprises numerous model runs (in the hundreds), each with varying random parameter values. The model, therefore, relies heavily on statistical analysis. Random variation of specific parameters is necessary due to the uncertainty involved in predicting the future demand on, and resultant response of, the jetty structures. Also through this analysis, it is possible to observe the parameters that are most sensitive to random variation and have the largest impacts on lifecycle costs and/or reliability. If the impacts of these parameters are understood and their variation can be controlled to a certain degree, it is logical to conclude that the lifecycle costs can likewise be managed to a similar degree.

MCR SRB Model Operation

The SRB model can be operated in two distinct manners, as a *hindcast* model or a *forecast* model. The hindcast mode incorporates historical jetty geometries (e.g., cross-sectional elevations and widths), costs, and other relevant information from the actual repairs that occurred to each structure since original construction (or since a specified historical date in the case of the South Jetty). Generally, if there is good agreement between modeled and measured data, then the model has good skill (predictability) and is deemed to be performing well. In calibrating the SRB model, *historical* costs and repair schedules were compared to *modeled* costs and schedules. Based on analysis of modeled results (i.e., plots of costs and repair schedules), the hindcast predictions for the MCR jetties are judged to have good model skill.

The hindcast model results are also used to initialize the model for operation in the forecast mode. In the forecast mode, the SRB model predicts structural damages (based on randomized storm conditions), implements repairs and rehabilitations, and calculates dredging and stone quantities over an anticipated jetty lifecycle. The forecasting procedure is similar to the hindcast procedure in the model. For simplicity, only the model forecasting procedures will be described below, but the general methods are essentially equivalent.

MCR SRB Model Organization

Within the SRB model, lifecycle runs are facilitated as nested loops (nested indicates that routines are called to run within other routines, in essence creating loops within loops). Models can be setup to run for several years (e.g., life cycles) and damages can be estimated over a range of storms (annual number of storms) on individual jetty segments (100-foot segments).

For each Monte Carlo simulation and for each year in the forecast, each 100-foot jetty segment is analyzed for damages from each storm predicted to occur in that year. This continues sequentially until all jetty segments have been analyzed for all predicted annual storms in a given year. Subsequently, the model year is incremented and loops through the routines again until a complete life cycle has been modeled. This process is repeated for each Monte Carlo simulation (200 simulations) until the total number of simulations has been analyzed. The flowchart in Figure 3-28 graphically depicts the same concept.

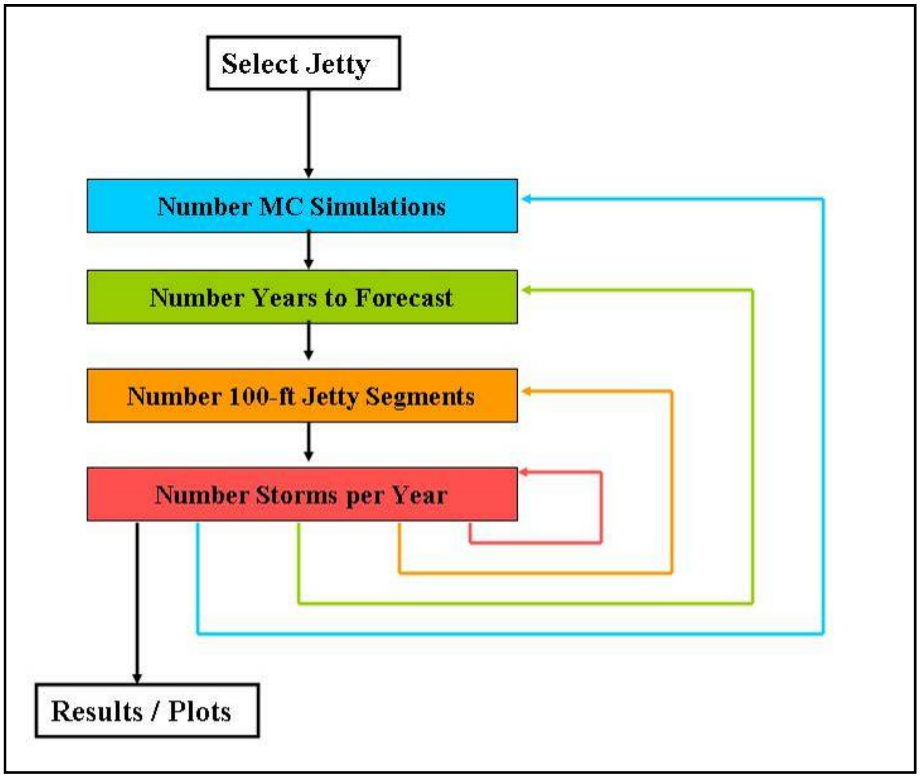
Storm Events

Storm wave heights along the jetties used in the model were generated using a wave propagation numerical model (STWAVE). This model computes nearshore wave heights, periods and directions by propagating offshore wave conditions to the nearshore. A total of 52 observed storm events were selected as representative events to include in the storm database. These are the largest storm events on record, as measured by offshore observation buoys in proximity to the MCR inlet. Each event has impacted the MCR in the recent past, and the potential exists for a similar event to occur and impact the MCR jetty structures in the future.

The storm database used in the SRB model was created prior to any forecast modeling. It comprised near-jetty wave heights at specific along-jetty locations that were predicted by the STWAVE modeling. Each near-jetty wave height correlated directly with an offshore storm condition.

In the SRB model, for each storm predicted to occur in any given model year, a storm event was randomly selected from the database of 52 storms. Subsequently, the corresponding near-jetty wave heights for that particular storm event were extrapolated from the storm database. The wave heights were interpolated along the lengths of the jetties, so that wave heights at each 100-foot jetty station were known and damages calculated at each jetty segment.

Figure 3-27. Simple SRB Model Flowchart



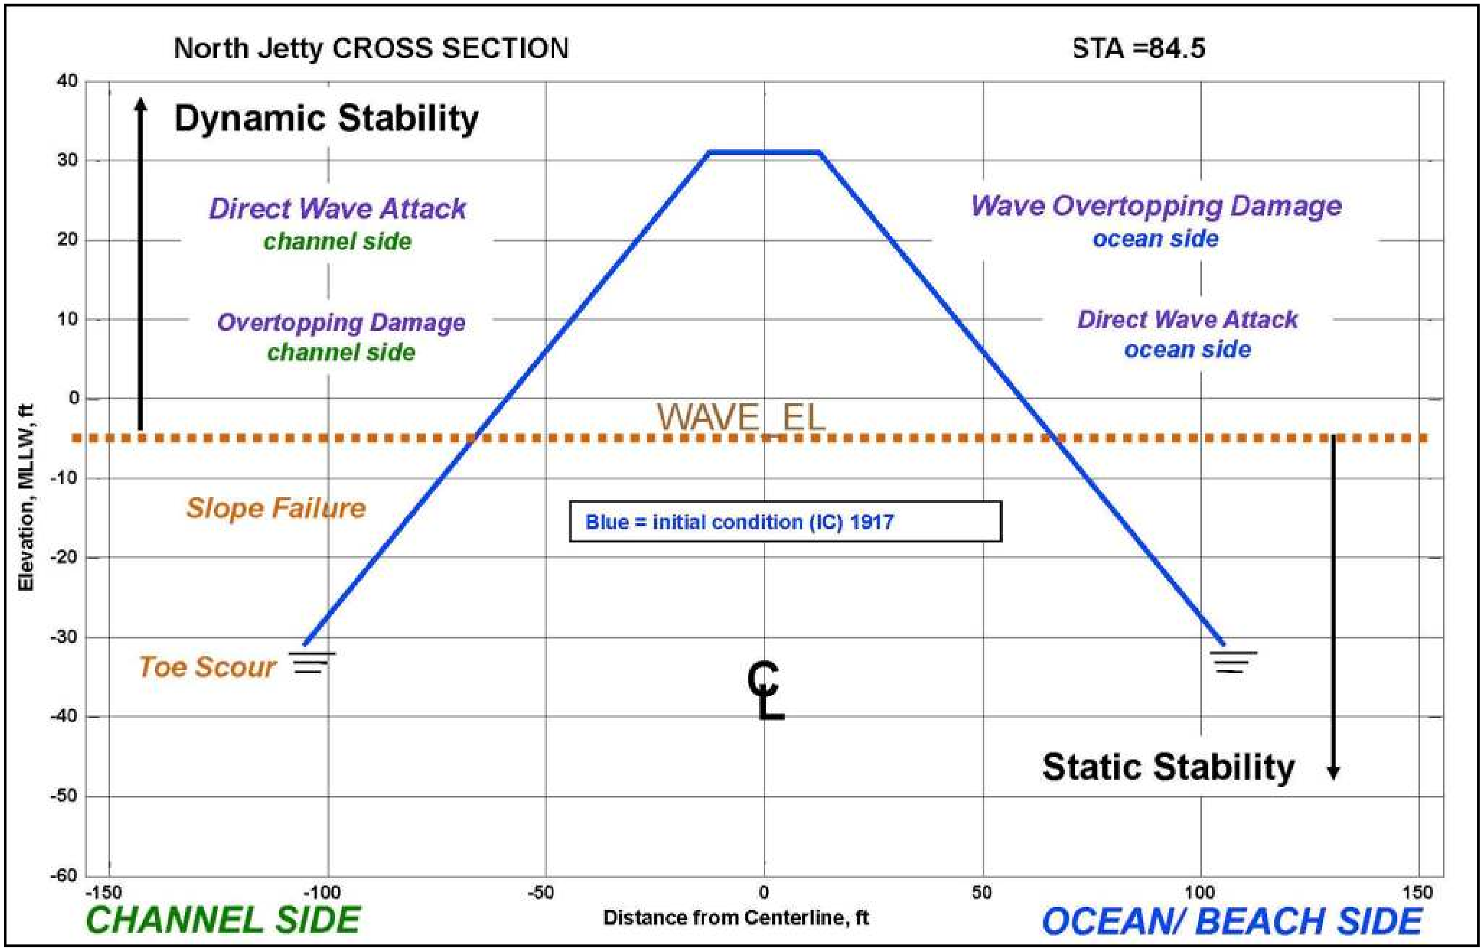
Jetty Damage and Reliability

In the MCR SRB model, both static and dynamic effects contribute to structural damage of the jetties (Figure 3-28). Static damage is attributable to toe scour and side slope failure. Toe scour and resulting toe and slope stone settlement typically results from river and tidal currents scouring the foundation sediments away. Side-slope failure often occurs subsequently because of foundation settlement and may also be a result of scour. The damage associated with static effects are estimated based on historical knowledge of scour and slope failure occurrences. In the SRB model, damages from scour are only applied below the wave elevation surface (defined as the elevation below which wave action does not affect jetty stone).

Dynamic effects are attributable to wave action on the jetty stone (wave breaking and wave overtopping). The damage associated with wave action is computed directly from damage functions attained through physical modeling of various jetty repair alternative designs. The damage functions are simply correlations between wave height and damage. Damage is measured as area damage (square feet) with respect to the jetty cross-section for a particular 100-foot jetty segment (e.g., for a certain wave height at the jetty, a corresponding amount of damage (in square feet) is expected to occur). The damage is combined with any previous damage that has occurred at a particular jetty segment such that cumulative damages are tracked at all stations along a jetty from storm to storm and year to year. The damage thresholds set in the models determine when repairs are implemented and when failures occur.

Figure 3-28. Jetty Breaching Processes and Consequence Emulated within the SRB Model

Representation of a jetty cross-section segment as emulated by the SRB model for every 100 feet of jetty. The jetty is bisected horizontally by the centerline (CL) and vertically by the elevation (WAV_EL) at which wave damage becomes the driving process for structure degradation. Below WAV_EL, scour and static slope stability performance modes govern jetty degradation. Jetty degradation is simulated separately for each side of the jetty.



Within the SRB model, as jetty segments incur damage, the structural and functional reliabilities are adjusted accordingly (decreased). Likewise, when segments are repaired, reliabilities are increased to reflect the increased structural stability of the repaired segments. If a jetty segment fails (e.g., the functional reliability falls below a certain threshold), then emergency repairs may be initiated.

If a jetty segment fails within the trunk or root, the segment is considered breached. If the jetty head or an area within one segment distance landward from the head fails, it is *not* considered a breach. The cost of repairing a breached jetty segment can be significantly higher under emergency conditions as compared to normal repair conditions. Although the likelihood of jetty breach is low, the consequences of jetty breaching can be high. The approach adopted for this rehabilitation study (and SRB model) is to prevent impacts to MCR navigation, should a significant jetty breach occur. To do this, intervention measures such as rapid-reaction jetty repairs are activated if a severe jetty breach occurs.

A series of risk-based calculations are executed within the SRB model to evaluate the consequences of a jetty breach (see Tables A2-7 to A2-9 in Appendix A2 for the unit costs for responding to various MCR jetty breach scenarios). Emergency response actions occur immediately after a jetty breach occurrence and include significant cost escalation for rapid mobilization to the project site and resource acquisition. Deferred and expedited response actions occur during the first construction season (summer) following the breach occurrence and include a modest cost escalation to enable timely jetty breach intervention.

Model Input

The SRB model requires a certain amount of input information in order to complete a Monte Carlo simulation for a specific jetty. This input information includes damage functions, storm events and wave heights, jetty initial geometry, hard-coded variables, and repair cost. These are described further in Appendix A3. During a Monte Carlo simulation, these items are loaded into the model workspace from existing data files or the interactive user interface.

Model Output

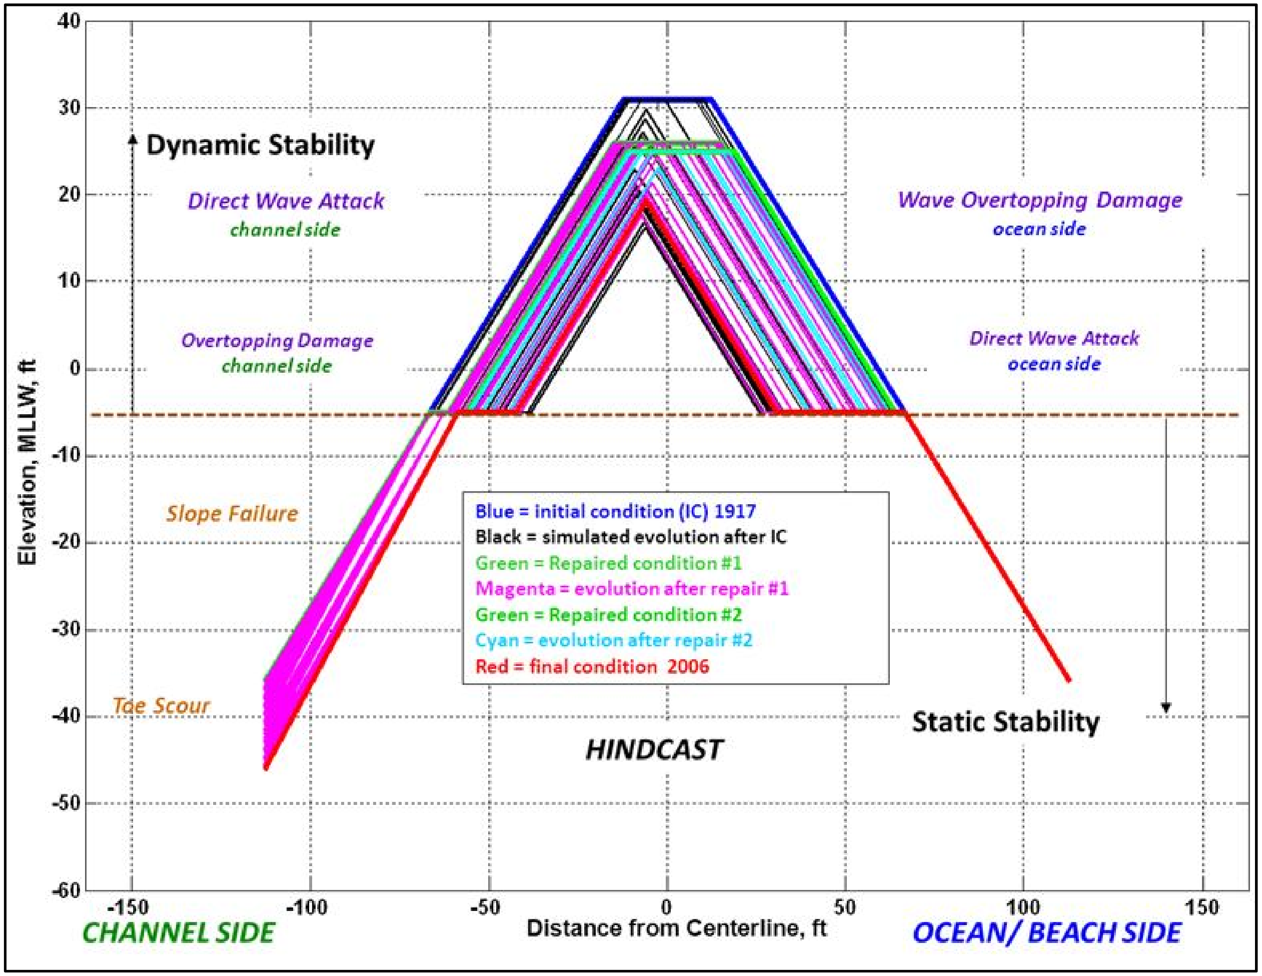
Currently, the MCR SRB model outputs include model variables and files in MATLAB *.mat format, ASCII text files in *.dat format, and various figures illustrating results of the hindcast and Monte Carlo forecast simulation. The lists of the current figures and data files that can be exported from the model can be found in Appendix A3. A description of the modeling results is presented in Section 3.9, *Engineering Evaluation and Life-cycle Model Results for the Range of Alternatives*.

The SRB model evaluates the cumulative structural response of the jetty cross section in 1-year time steps for a given 50-year life cycle. Figure 3-29 illustrates a typical jetty cross section evolution with identified damage zones. The structure is represented as a system of interacting components. Performance modes are used to describe head recession, foundation erosion, slope stability, and wave-induced damage. Considerations used in developing the model include: (1) existing condition of structure, (2) previous repairs of structure, (3) foundation conditions, (4) failure modes, (5) structure function, and (6) exposure to changing morphology and wave conditions.

The model is stochastic in that environmental loading is defined by specific probability density functions and structure response and life-cycle outcomes are expressed as random variables. The risk-based portion of the model portrays the *structural* and *functional* performance in terms of reliability and the life-cycle dredging volumes and stone quantities are based on probabilistic outcomes of negative consequences. The model uses Monte Carlo techniques to stabilize the variance of random variables and stabilize expected value estimates. In short, the model defines the initial conditions, simulates structure response and variable forcing and produces an end-state.

Figure 3-29 illustrates the modeled simulation of cross section evolution at station 79.5 on the North Jetty. The blue outline represents the initial construction and the green outlines represent repair efforts which restored the damaged jetty cross section to an improved condition. The magenta, black and cyan outlines provide estimated cross section evolution that occurs in response to a given year's storm cycle. The red outline is the final condition of the cross section at the end of the simulation. The figure and the model application are divided between dynamic stability modes, direct wave attack and overtopping damages. The static stability modes include scour at the toe and slope failures along the below water portion of the cross section. The representative elevation used to delineate between these two stability categories (dynamic and static) is -5 feet MLLW.

Figure 3-29. North Jetty Cross-section Life-cycle Evolution (1917-2006) at Station 79.5



Typical simulation using the SRB model is as follows:

1. Simulate Structure's Previous Life Cycle – Hindcast: Calibrate model to ensure the model replicates observed life-cycle quantities and timing and location of observed repairs. Key inputs include actual repair history, location, timing, and frequency.
2. Simulate Future Life Cycle – Forecast: Establish base condition to evaluate potential maintenance/rehabilitation scenarios against. A base condition is selected that is most likely to be implemented in a "non-intervention" framework.
3. Simulate Future Life Cycle – Alternative Analysis Forecast: Evaluate alternatives by life-cycle dredging and stone quantities and other metrics.
4. Select the alternative which achieves best reliable life-cycle performance.

For this project, the SRB model provides estimates, not definitive answers and is useful in comparing consequences for alternatives, but is not the only basis for plan selection in that alternatives that were deemed environmentally unacceptable were ruled out.

The SRB model was used to hindcast the life-cycle performance of each jetty from initial construction (early 1910s) to the present (2010). Accurate hindcasting of jetty performance served as a basis for model verification. Metrics provided by the SRB model, which were used to evaluate life-cycle performance include:

- Jetty cross section evolution;
- Time-varying structural and functional reliability and residual risk;
- Jetty repair occurrence – expected frequency and location of jetty repairs;
- Jetty breach occurrence – expected frequency and location of jetty breaches;
- Potential for loss of jetty function to impact navigation function of the inlet; and
- Jetty end-state condition.

The SRB model was used in forecast mode to formulate an optimal plan for rehabilitating each jetty, predicated on the need to minimize life-cycle costs or maximize reliability (see *Components and Processes of the SRB Life-Cycle Model* in Appendix A2 for additional details). Appendix A1 discusses the optimization of various jetty repair and rehabilitation scenarios.

3.6.4. **Calibration of Life Cycle Performance Model**

Before performing hindcast simulations for a given structure, it is essential that a structure's as-built condition be established to match the actual post-construction condition of the prototype. Fortunately, the historical record for the MCR jetties is good and data was available to define the initial conditions for jetty toe elevation, jetty cross-section geometry, armor/core stone attributes, and historical scour rates for MCR jetties. (Refer to Appendix A1 for historical jetty repair details). The SRB model hindcast jetty maintenance strategy was set at "interim repair" to emulate the maintenance conditions actually undertaken during the historical life-cycle of each jetty.

A detailed discussion of the model calibration, including the hindcast calibration parameters and simulated historical performance for the three jetties, is provided in Appendix A2, Section 7. The hindcast modeling results indicate that the SRB model can accurately portray the historical life-cycle for the three MCR jetties in terms of the following performance metrics: jetty repair location, timing, and frequency, and jetty profile end state. Hindcast reliability clearly illustrates the emergent cyclical behavior of each jetty as it is damaged through time, becomes vulnerable, and is then repaired. As such, the SRB model was considered to be calibrated and verified to perform future life-cycle simulations for evaluation of optimal life-cycle investment strategies for the MCR jetties.

3.7. CATEGORIES AND FEATURES OF ALTERNATIVES

Repair and rehabilitation options comprise the general categories of alternatives considered and evaluated for the MCR jetty system, as described below.

3.7.1. Repair Alternatives

Repair alternatives involved adding limited amounts of stone to trunk and root features. Under repair options, stone placement is generally limited to above-water sections and remains within the existing jetty and relic stone structures. Repair alternatives also considered differing degrees of repair. Repair alternatives were considered to occur either on the basis of a scheduled, predetermined time and place, or on an interim basis for which a stochastic model predicted both jetty repair and/or breach scenarios. For the North and South jetties, the repair alternative included repair combined with and without engineering features.

3.7.2. Rehabilitation Alternatives

Rehabilitation alternatives generally incorporate engineering components which may extend beyond the current footprint of jetty and relic stone structures and could entail both above and below-water fill. Certain engineering features were incorporated as common components present in all rehabilitation alternatives considered. These engineering features included stabilization of the jetty heads, constructing additional spur groins. Rehabilitation strategies were evaluated as both immediate and scheduled. The scheduled rehabilitation alternative constructs at specific locations along the jetty at specific time periods in order to maximize the effectiveness of the federal investment.

3.8. EVALUATED REHABILITATION AND REPAIR PLANS

3.8.1. General Alternative Approach

Rehabilitation was considered as an alternative when it could significantly extend the physical life of the feature and could be economically justified. Reliability is a measure of a facility to perform its intended function under specified operating conditions for a given period of time, in this case 50 years. In the case of the MCR jetty system, an adverse event is described as a jetty breach which has the potential to impact navigation at the entrance. Consequences are evaluated in three general categories: jetty repairs, dredging, and potential navigation impacts. In the execution of this major rehabilitation study, the assumption was made that all attempts to avoid navigation impacts would be employed by the USACE. Therefore, navigation impacts were not evaluated quantitatively.

The alternatives investigation was conducted in phases. The first phase involved a detailed analysis and summary of the base condition for the jetty system. This phase is essential and provided the standard to which all of the other plans would be compared. An extensive hindcast analysis was conducted to simulate past performance of each jetty so that future performance could be projected with a level of confidence. Additionally, lagoon fill behind the North Jetty root was analyzed.

The second phase investigated actions for the larger system-based degradation processes which impact the project as a whole and over the long-term. Those actions were discussed in Section 3.5.3. These features were evaluated individually and incrementally in the life-cycle analysis model using the minimum cross section repair plan. Engineering features included head stabilization through a robust jetty head construction, construction of spur groins at key locations along each jetty to promote foundation stabilization.

The third phase evaluated graduated levels of cross section repair or improvements. The conceptual cross sections for the three jetties can be seen in Figure 3-20 through Figure 3-22. Each of these cross sections was applied along the full length of each jetty to identify resiliency and performance of general design concepts along the jetty's length. Variability of segment-by-segment cross section resiliency is typically driven by existing condition of the structure, degree of exposure to wave attack, directions of wave attack, and foundation condition. Each of these plans was also evaluated using the life-cycle analysis model as previously discussed. The fourth and final phase evaluated the feasibility of phasing the jetty repair to minimize project failure and maximize construction efficiency. Through this phase, a plan to conduct a scheduled rehabilitation effort was developed.

Appendix A2 provides further discussion of the key selection criteria, alternative comparison and selection process, and environmental considerations.

3.8.2. Range of Alternatives Considered

The alternatives under consideration ranged from the interim repair approach of the base condition to increasingly higher levels of repair or rehabilitation action to prevent cumulative jetty damage and possibility of jetty failure and impacts to project function. Not all of the plans address the full range of structure and project degradation and each of the plans has varying levels of risk, as well as need for repair and emergency action readiness associated with it. The alternatives considered included scheduled repairs, immediate rehabilitation, and scheduled rehabilitation:

Scheduled Repair

- Scheduled Repair without engineering features (North Jetty, South Jetty, Jetty A)
- Scheduled Repair with engineering features (North and South jetties)

Immediate Rehabilitation

- Using minimum cross section
- Using small cross section (South Jetty and Jetty A)
- Using moderate cross section
- Using large cross section
- Using composite cross section

Scheduled Rehabilitation

- Using minimum cross section (North and South jetties)
- Using composite cross section (North and South jetties)

Each of these repair alternatives were evaluated with the option of retaining the jetty heads at their current locations utilizing the simulated repair alternative or allowing the jetty head locations to fluctuate based on the stability of the jetty heads. The two options with and without stabilizing the head locations were simulated in order to provide guidance on costs for the two options with all other variables being held equal. In addition, as previously discussed, there is a high likelihood that the functional performance of the jetties will be substantially degraded if the head is allowed to recede any further than they already have.

The importance of engineering features (spur groins, jetty head stabilization, lagoon fill) that target damaging long-term degradation processes of the inlet was discussed earlier in this chapter. These features have been incorporated in all of the above plans except for scheduled repair for the North Jetty and Jetty A. For the alternatives where the head locations were maintained at the current locations, the head stabilization feature was not incorporated. In the case of the South Jetty, scheduled repair with engineering features was evaluated. In addition, scheduled repair uses a minimum cross-section repair cross-section that addresses only above-water jetty structure degradation processes.

Two types of repair strategy were used to realistically assess the life-cycle performance of each plan. A great deal of work went into defining the necessary damage threshold which would trigger a repair and/or a failure (additional information on this work is provided in Appendix A2). Two general categories were utilized: (1) interim repair strategy, and (2) scheduled repair strategy (allowing for the programming of the repair). The interim repair strategy, which is only used in the base condition plan, allows the jetty to degrade at each 100-foot segment until only 30-40% of the cross-section is remaining above -5 MLLW. Since the model measures this damage with a probability density function, for purposes of discussion in this report, 30-40% is averaged to 35% (the fix-as-fails probability density function is averaged to 20%). Once that threshold is reached, a repair action is triggered. The repair action does not always repair the structure before a breach happens. The scheduled repair strategy monitors each 100-foot segment for current cross section and degradation rate. When a threshold occurs (calculated separately for each 100-foot segment and for each repair plan), which represents approximately 4 years prior to a failure, a jetty repair action is triggered. This scheduled repair strategy is used for all of the alternative plans.

The intent of a full rehabilitation of the jetties is three-fold: (1) to improve the stability of the foundation (toe) of each jetty affected by scour; (2) to improve the side-slope stability (above and below water) of each jetty; and (3) to improve the stability of each jetty to withstand wave impact. Two different methods were used to apply the full rehabilitation alternatives: immediate and scheduled. Under the immediate rehabilitation, actions would begin at a given year and continue annually until the entire jetty is completed. Under a scheduled approach, the timing of the rehabilitation would be staged throughout time applying the rehabilitation to only the portion of the jetty when it was needed, postponing the federal outlay of funds throughout the 50-year project life.

Full rehabilitation plans would all include the engineering features and would also address, in some manner, the full length of each structure. The sheer size of the MCR jetties along with the limited construction window available at the project would require that any rehabilitation effort would result in scheduling the construction over a number of years. Construction of a full rehabilitation plan on the North and South jetties is projected to take a minimum of 5 and 8 years, respectively. Due to the length of time required to implement a full rehabilitation on the South Jetty and the extent of that jetty's exposure to extreme conditions, scheduling the construction over a broader time window was not found to be effective. On the North Jetty, the scheduling of rehabilitation efforts was assessed due to vulnerability and was spaced out over about a 12 year time frame. Repair strategies that do not include full rehabilitation can be initiated and completed over a shorter period of time, but may have a shorter life span and require additional repairs in the 50 year life cycle timeframe.

The modeling performed to assess the project alternatives assumes that Jetty A is in place and fully functioning. This is because Jetty A, as originally constructed, protects the North Jetty and helps to train the Columbia River main stem. In addition, Jetty A is believed to play an important function for the Columbia River plume. The plume is an important food source for the 13 Columbia River salmonid evolutionarily significant units (ESUs) listed under the Endangered Species Act (ESA). Jetty A will be treated as the first added increment for the North Jetty and because of this, only one plan was developed and analyzed for each of the alternative categories. The three alternatives (scheduled repairs, immediate rehabilitation, and scheduled rehabilitation) for Jetty A will be evaluated against each other in the same manner as the North and South jetties.

The alternatives analyzed are:

1. Scheduled Repair without Engineering Features
2. Scheduled Repair with Engineering Features
3. Immediate Rehabilitation using Minimum Cross Section
4. Immediate Rehabilitation using Small Cross Section
5. Immediate Rehabilitation using Moderate Cross Section
6. Immediate Rehabilitation using Large Cross Section
7. Immediate Rehabilitation using Composite Cross Section
8. Scheduled Rehabilitation using Minimum or Composite Cross Section

A summary of the alternatives evaluated is provided in Table 3-7 through Table 3-9 for the North Jetty, South Jetty, and Jetty A, respectively. These alternatives are described in detail in Section 16 of Appendix A1.

3.8.3. Base Condition Development

FY 2011 MRR base condition assumed that no action would be taken to slow down the large-scale physical processes that are negatively affecting the structural stability of the MCR jetty system (the current 2012 MRR base condition is discussed in **3.8.4**). Those larger physical processes include landward recession of the jetty head, shrinking of the ebb tidal shoal, foundation erosion, and adjacent shoreline erosion. The heads of each jetty would continue to recede landward with the expected response of the surrounding morphology including continued shrinking of adjacent underwater shoals and the overall shrinking of the ebb tidal shoal. Much of the material eroded from the inlets shrinking shoals would be transported into the MCR inlet, thereby adding the requirement for maintenance dredging. The underwater sand shoals upon which the jetties are built would continue to erode, leaving deeper water depths along the jetties. The deeper water (over the eroded shoals) would allow larger waves to attack the jetties resulting in a greater rate of jetty deterioration and foundation erosion. Wave and current action within the MCR inlet would increase. The eroded lagoon area behind the north jetty would remain, allowing tidal flow and wave surge through the jetty trunk which de-stabilizes the structure and negatively impacts jetty foundation.

Due to the level of construction and the high mobilization costs, the base condition does not include any jetty head re-construction. Only the trunk and the root of the jetty are maintained, and the jetty head is allowed to recede landward. Maintenance of the trunk and root of the jetty is minimized by deferring repair activities into the future for as long as possible. Jetty repairs are initiated only when a failure of the upper portion of the jetty cross section seems to be progressing. For the fix-as-fails base condition, the level of damage that initiates a repair action is measured by the model as a jetty reach having been reduced to 20% of the cross-section remaining above -5 MLLW. A rubble-mound structure can incur a certain level of damage before the whole cross section fails resulting in a functional impact; however, a complete breach through the above water portion of the structure can result in rapid deterioration. The base condition is identified as an interim repair approach because the upper portion of the cross section is allowed to be damaged to approximately 20% remaining prior to repair actions being taken. In this way, the jetty is maintained close to the margin of functional loss.

Depending on the percentage of lost cross section which results from the deferred action, maintenance actions may need to be conducted on an expedited or emergency basis. In some cases, the repair occurs before the complete failure of the upper part of the cross section and in some cases, depending on the severity of the intervening storm climate, an actual failure of the upper cross section occurs resulting in a breach of the jetty. If a jetty breaches, adjacent segments would have a high probability of also breaching or incurring additional damage. In addition, depending on the location of the breach, sediment from adjacent land or underwater shoals can move through the breached jetty toward the navigation channel, requiring an emergency mobilization of dredges to prevent impacts to navigation.

The interim repair approach carries an elevated risk for incurring added costs either through expediting repairs (to prevent functional loss of a jetty) or responding to a breached jetty. Consequently, there is an elevated likelihood that jetty repairs may be more expensive (cost/ton of repair stone placed) when they do occur, In order to maintain navigability of the federal channel, emergency repairs would be performed on the breach and/or emergency dredging of the federal navigation channel would occur.

3.8.3.1. North Jetty Base Condition

The North Jetty has receded approximately 2,100 feet in length since original construction in 1916. The jetty head will continue to deteriorate at a rate of about 20 to 50 feet per year. In 50 years, it is estimated to reach stations 76-90 (or about 1,800 feet lost), in very close proximity to where the existing shoreline is today. Under the base condition, the jetty head is not repaired or rebuilt during the 50-year period. Peacock Spit and Benson Beach are expected to continue to erode shoreward at a similar rate to the jetty length deterioration. Much of the sediment loss associated with shoreline retreat will migrate into the federal navigation channel and routine maintenance dredging of the entrance will increase over time. The maintenance dredging volume could be greater than present by an amount of 0.5 to 1 MCY per year (or by a rate up to 25% greater). The resulting head loss would have moderate effect on wave climate and navigability. Erosion of the surrounding shoal would expose more vulnerable areas of the jetty to increased damages. Continued loss of jetty length (and Peacock Spit) could potentially expose the seaward half of the South Jetty to higher wave conditions.

The trunk of the jetty is expected to degrade by three distinct processes: direct wave impact, wave overtopping (affecting the above water level of the jetty) and scour at the base of the jetty (affecting the below water portion until it fails and destabilizes the above water portion of the jetty).

In the event of a significant breach event, approximately 2-3 MCY of material could move from Peacock Spit and Benson Beach into the navigation channel. A shoal within the navigation channel would begin to form. In the absence of emergency dredging, it is expected that the depth of the navigation channel could be reduced from -55 feet to -40 feet in about 2 to 4 months. In order to maintain navigability of the navigation channel, the USACE would perform emergency repairs on the breach and attempt to mobilize sufficient dredges to maintain the authorized channel depth. During the 50-year project life, approximately 2 to 5 planned repairs would be expected to occur along the North Jetty.

To perform emergency repairs to the breached area, a contractor would truck in readily available stone to the North Jetty, build a haul road on top of the jetty, and place jetty stone in the breached area with a track mounted excavator or similar piece of equipment to stop the volume of material migrating into the navigation channel. Not only will the breach allow for sand to move through the jetty opening, but also sea water may flood low-lying Benson Beach park areas complicating access to the repair. The contractor may need to pioneer a road into a jetty access point for breach repairs.

The Columbia River Bar can only be maintained with the use of a hopper dredge. These types of dredges have two drag arms that extend to the river bottom and hydraulically remove material. The material is temporarily stored within the ship in a hopper, and then transported to a disposal location.

Once at the proper location, doors on the bottom of the ship open or the hull of the ship opens and the material falls from the hopper through the water column to the disposal site. To perform emergency dredging, one or two dredges would be mobilized. Production rates for the dredges would be approximately 20% to 25% of normal due to weather conditions and storm events. The dredges would rely on weather windows and favorable sea conditions to remove as much of the shoal as possible with a goal of maintaining navigation. Due to the physical limitation of the dredges, it is unlikely they could achieve the -55 feet of depth of the outbound lane with swells of 10 to 16 feet.

It should be noted that this course of action would present high risks to the dredges and their crew. Given the winter wave conditions that the dredges would be performing in, it is highly likely that damage would occur to the drag arm of the dredge while working. Environmental concerns regarding loss of hydraulic fluid or oil spills may result if the dredges are damaged. Dredged material will be disposed of at an approved in-water disposal site. Because it is predicted that 2 to 3 MCY of material will enter the navigation channel, the dredges are not expected to be able to remove all of the material that has migrated into the channel; therefore, the following dredging year could require up to three dredges to work the entrance to remove twice the amount of material of a normal maintenance year. During the last 23 years, there were about 7 years when the wave climate would have been too severe to do emergency dredging. Under those circumstances, there would be more risk of not being able to do emergency dredging with the potential impacts to navigation.

3.8.3.2. South Jetty Base Condition

The South Jetty has receded approximately 6,200 feet in length since original construction in 1885-1913. Under the base condition, the jetty head is not capped and no spur groins are constructed to control foundation scour. The jetty head continues to recede back at a rate of 5 to 20 feet per year until the concrete monolith collapses at which point the head recession is projected to be more rapid. In 50 years, it is expected to reach approximately station 292 (or about 2,100 feet lost). The jetty head would not be repaired or rebuilt during the entire 50-year period. Continued loss of the jetty length (and Clatsop Spit) under the base condition would expose the seaward half of the South Jetty to higher wave conditions. Loss of jetty length would contribute to continued loss of the underwater shoal, exposing the jetty to increasing wave action and the shoreline at the root of the jetty to higher wave forces. The shoreline would continue to erode and recede, resulting in a shoreline breach into Trestle Bay in about 8-16 years. Based on the present condition of the concrete monolith, it is expected to slump into the ocean and basically be non-existent within 12-20 years adding additional deteriorating forces to the seaward half of the jetty. The remaining rubble mound portion of the South Jetty would then begin to deteriorate in an accelerated way.

The trunk of the jetty is expected to degrade by three distinct processes discussed above. During the 50-year project life, about 3 to 6 repairs would be expected to occur along the South Jetty. Unlike the North Jetty, emergency dredging would not occur because the material is not anticipated to affect the federal navigation channel in the short term. Increased dredging would occur during the summer maintenance months. The breach would not be repaired by emergency actions; rather repairs would be performed during the following summer.

Shore Area along South Jetty

The shore area along the South Jetty root has experienced profound changes since the time of jetty construction. Before construction, the nearshore area immediately south of the jetty was dominated by a broad shallow ebb tidal shoal, exhibiting relatively shallow water depth. Construction of the South Jetty dissipated this shoal, resulting in a rapid trend of increasing water depth through time. As the water depth along the south side of the jetty increased, wave action along the jetty root and adjacent shore area increased. The increased wave environment motivated rapid deterioration of the entire South Jetty and culminated with the significant breaching event along the jetty root in the late 1920s. During the 1930s, extensive efforts were undertaken to rebuild the South Jetty and re-establish the shore-land interface along the south side root of the jetty. The effort was successful; however, the result has been subjected to an increasingly harsh environment of wave action and related circulation since the 1930s.

Currently, the coastal shore interface along the South Jetty is in a condition of advanced degradation. The foredune separating the ocean from the backshore is almost breached. The backshore is a narrow strip of low elevation, accretionary area, separating Trestle Bay from the ocean by hundreds of yards. The offshore area along the South Jetty (and to the south) continues to erode, promoting larger wave action to affect the shoreline along the jetty root. The shoreline at the jetty root will continue to erode and recede, resulting in a possible shoreline breach into Trestle Bay in approximately 8-16 years. If this sand spit breach occurs, the resulting scenario would be catastrophic. The MCR inlet would establish a secondary flow way from the estuary to the ocean along this area (south of the South Jetty). This condition would profoundly disrupt navigation at the MCR and bring lasting changes to the physical nature of the inlet. Augmentation of the foredune along the South Jetty root is required to prevent the above realization.

Augmentation of the foredune would consist of placing 60,000 to 70,000 cy of cobble material to fortify the toe of the foredune and improve the foreshore fronting to resist wave induced erosion/recession. The augmentation material would be composed of a well graded mixture spanning the size range of large gravel (3-inch diameter) to large cobble (12-inch diameter.). The material would likely be delivered by truck and placed by earth moving equipment. There is the possibility that MCR sand or coarse-grained sand from the lower Columbia River could be hydraulically placed to enhance the foredune augmentation effort. However, use of sand-sized material would require a significantly large volume (200,000 to 400,000 cy) to produce the equivalent resilience as the cobble material augmentation evaluated. The timing of this action is expected to be within first 8 years of jetty rehabilitation. Note that the nearshore placement of MCR dredged material within the evaluated South Jetty Site would mitigate the erosion of the South Jetty root area. The South Jetty Site is a potential nearshore dredged material placement site located in a water depth of 40-50 feet approximately 1 mile south of the South Jetty. This would complement the foredune augmentation evaluated and help ensure balance of the sediment budget south of the South Jetty. However, this action should not be viewed as a replacement for foredune augmentation.

3.8.3.3. Jetty A Base Condition

Jetty A has receded approximately 900 feet in length since original construction in 1939. The head of the jetty will continue to deteriorate at a rate of about 5 to 20 feet per year. In 50 years, it is estimated to reach stations 78-86 (or about 1,500 feet lost). Under the base condition, the jetty head is not repaired or rebuilt during the 50 year period. There will be increases in dredging as Jetty A recedes. Clatsop Spit will prograde northward toward the navigation channel. The bathymetry in front of Sand Island will be cut back, mobilizing that additional material. The shallower area between Jetty A and the North Jetty will also be impacted allowing movement of that material toward the channel. The deepening which will be expected to happen in the vicinity of the North Jetty will further destabilize the foundation of that structure impacting its long-term reliability. The primary purpose of Jetty A is to direct river currents away from the North Jetty. It is expected that a one-time increase in dredging will occur on the order of 800,000 to 1.6 MCY followed by incremental increases in dredging that will depend on changes in channel shoaling patterns and spit movement.

The trunk of Jetty A is expected to degrade by three distinct processes: direct wave impact, wave overtopping (affecting the above water level of the jetty) and scour at the base of the jetty (affecting the below water portion until it fails and destabilizes the above water portion of the jetty). During the 50-year project life, it is predicted that Jetty A will breach, destabilizing more of the jetty and allowing significant amounts of sand to move through the jetty. Breaching typically occurs during severe winter storms. Modeling suggests that during the 50-year project life, breaching will occur between 2 and 5 times along Jetty A. If a segment breaches, adjacent segments have a high probability of also breaching. It is estimated that 2 to 4 repairs would occur along Jetty A. Unlike the North Jetty, emergency dredging would not be needed because the material is not expected to affect the navigation channel in the short term. Increased dredging would occur during the summer maintenance months. Also, repairs to the breach would occur the following summer.

3.8.4. Modification of the Base Condition

In FY 2010-11, a 90% draft of the MRR underwent District Quality Control (DQC) and Agency Technical Review (ATR). The underlying tenets of that report included a base condition involving a fix-as-fails approach where each jetty was allowed to degrade as low as 20% of the originally authorized cross-section remaining above MLLW -5, resulting in forecasted breaches. The hypothetical breaches would release material into the navigation channel, leading to emergency dredging. Breaches were forecasted to primarily occur in the winter, thus emergency dredging was high-risk and very expensive, and reliability of the navigational channel became questionable. Moreover, potential breach volumes entering the navigation channel were difficult to predict. In an attempt to model these effects, the SRB model code became more complex as the analysis was developed and the timing of the runs became very long and the economics was embedded within the model code. NWP also developed a qualitative numeric scoring of alternatives that included several factors beyond average annual cost.

The IEPR was conducted from December 2010 through April 2011. At the same time, the SRB model underwent substantial review, including ATR approval and DDN-PCX model certification in January 2011. This documentation was then forwarded to HQUSACE for final approval where it was disapproved in June 2011 because the IEPR panel raised concerns about the predicted frequency and severity of breaching and sediment transport in the base condition.

After consultation with NWD, it was decided that a Major Maintenance Report (MMR) should be produced for the most critical portions of the North Jetty for inclusion in the FY 2013 budget submission. The MMR included two actions on the North Jetty: lagoon fill between STA 20 to 60 and critical repairs between STA 86 to 99. Both were removed from the MRR alternatives and included in the revised base condition.

The district decided to revise the SRB model, MRR and appendices per the IEPR comments to show compliance with current technology and Corps policy; providing additional documentation.

The new base condition assumes the upper portion of the jetty is allowed to be degraded until approximately 35% of the cross-section is remaining prior to repair action being initiated. This change in the base condition allows for repair actions to take place prior to a breach event, and thereby eliminates breaching and sediment transport through the jetty, affecting the navigational channel and significantly reduces winter emergency dredging.

The above series of events resulted in a change in the selected plans for the three jetties.

3.9. Engineering Evaluation and Model Results for Alternatives

The SRB model allows one to review the simulated future life-cycle dredging and repair stone quantities. Forecasted dredge quantities are associated with incremental dredging requirements, above normal outlays quantities. Metrics provided by the SRB model that can be used to evaluate life-cycle performance include time-varying structural and functional reliability, jetty repair occurrence, jetty breach occurrence, cross-section evolution, and jetty end-state condition. The SRB model is used to help formulate an optimal plan for rehabilitating each jetty, predicated on the need to minimize life-cycle costs or maximize reliability. A detailed description of the SRB model and its application to the MCR jetties can be found in Appendix A2.

The paragraphs and tables below summarize the SRB model results for each base condition and alternative for each jetty. The focus is on the following output parameters:

- Degree to which larger system degradation processes are addressed.
- Final projected position of the jetty head.
- Number of large scale repair efforts expected over the project life.
- Expected jetty repair costs over the project life.
- Initiation and frequency of jetty repairs expected.
- Expected increases in dredging quantities over project life.
- Extent to which emergency dredging may be expected.
- Estimated number of significant breach events with the potential to impact navigation.
- Average projected structural and functional reliabilities.
- Additional comments on expected jetty maintenance program and potential environmental and inlet effects.

3.9.1.1. North Jetty

The base condition takes no action to address the larger system degradation processes. The North Jetty head continues to recede at a rate of 20-50 feet per year. The modified head position at the end of the life-cycle analysis is estimated at station 92 (about 900 feet shorter than current head position). Potential repairs are expected to begin immediately and extend for the life of the project, as needed. The base condition is expected to result in significant changes to the navigation entrance.

Figure 3-30 illustrates the simulated North Jetty crest profile evolution over the project life. In this figure, the blue line depicts the originally constructed North Jetty showing both the authorized length and crest elevation. The green line shows the 2006 condition of the jetty and the red line depicts the changes predicted to occur in the jetty over the next 50 years if the jetty is maintained as described in the base condition. The second graph illustrates the estimated repair and breach frequency per 100-foot segment along the jetty for the base condition. The abbreviation “FF” refers to the fix-as-fails repair scenario. The pink line refers to breach frequency and the blue line refers to repair frequency. The dotted black vertical line identifies the head position at the beginning of the simulation. The solid black line shows the head position at the end of the simulation. The third graph shows the functional and structural reliability over the project life.

Figure 3-30. North Jetty Base Condition

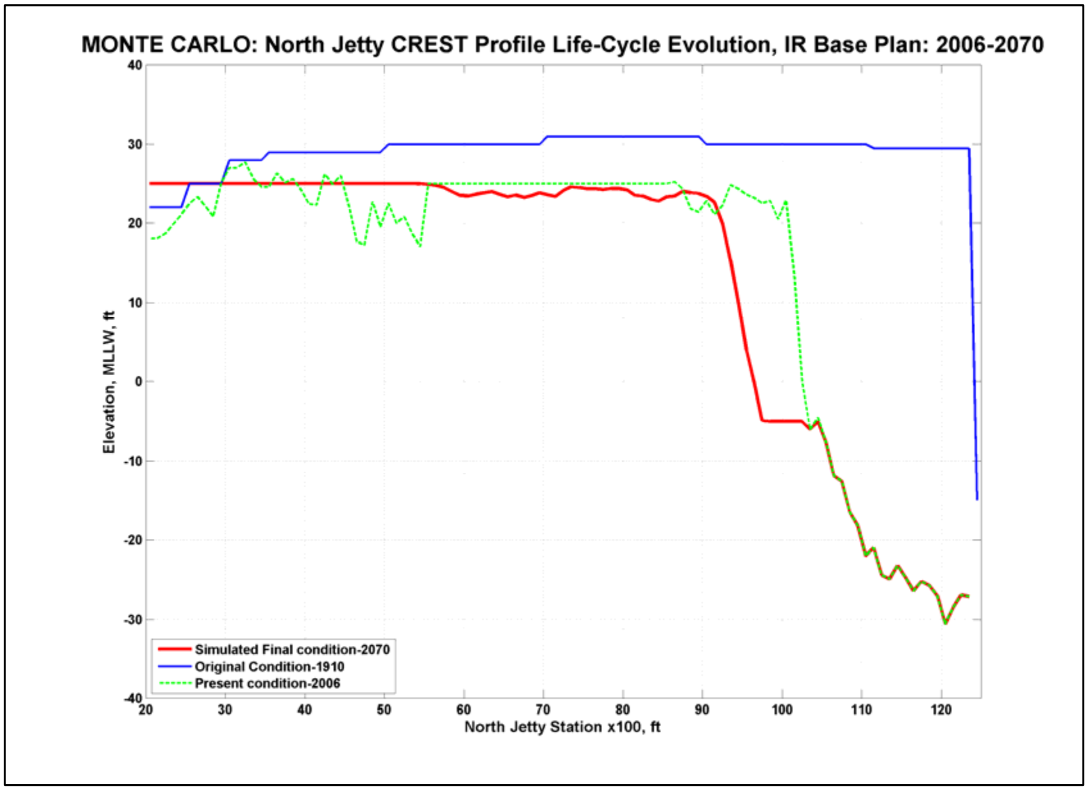

Figure 3-31, continued

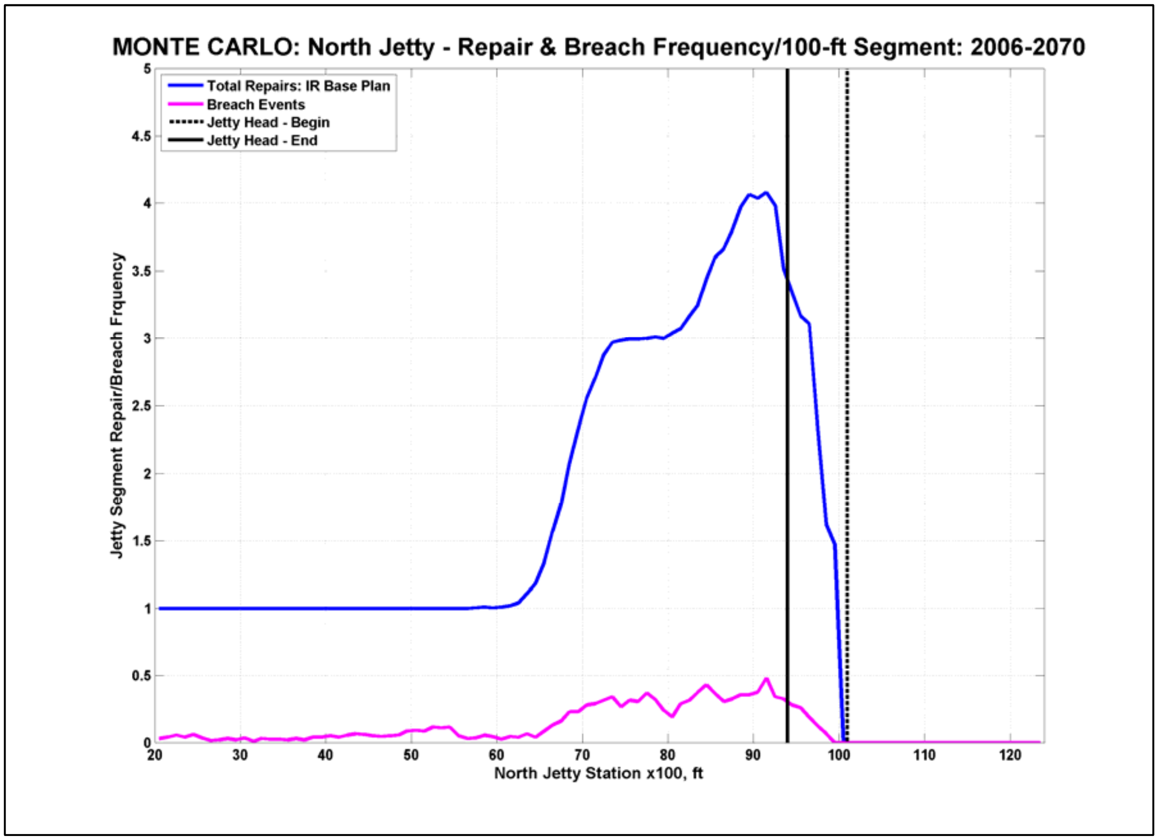

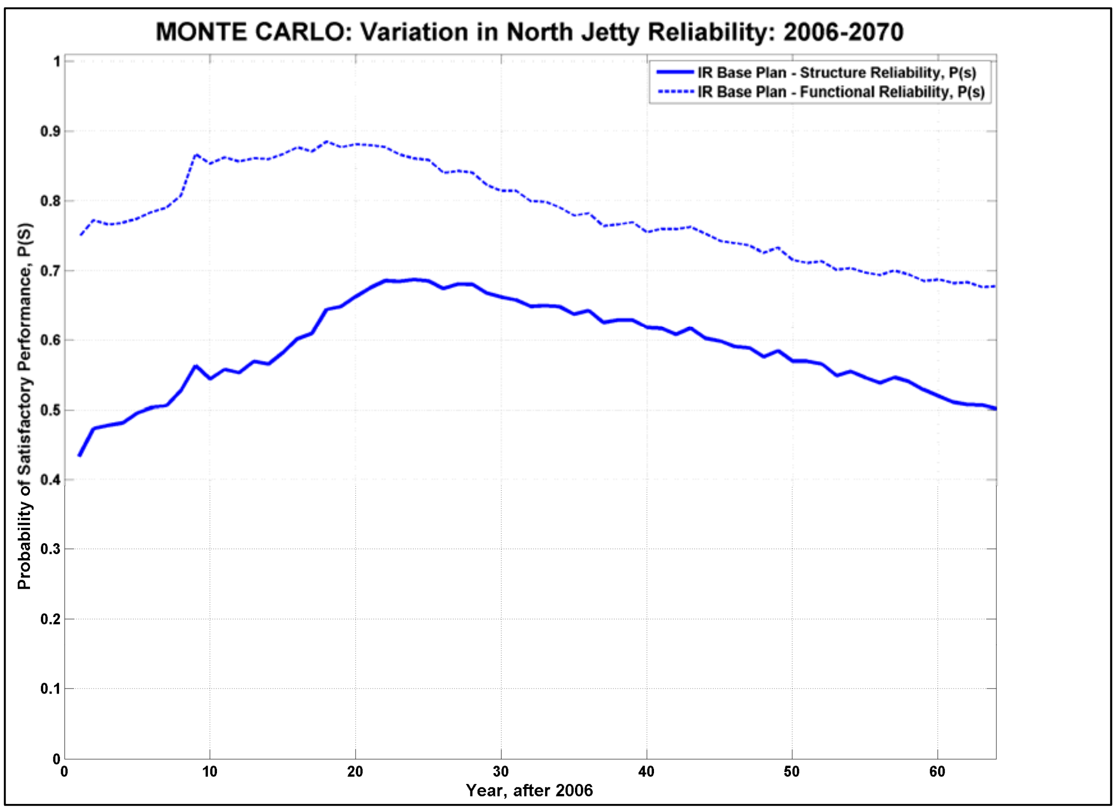

3.9.1.2. South Jetty

The base condition takes no action to address the larger system degradation processes except for some shoreline stabilization work at the root of the jetty. Initial construction costs to address the South Jetty root work are estimated at $10 million. The South Jetty head continues to recede back at a rate of 5 to 20 feet per year. The modified jetty head position at the end of the life-cycle analysis is estimated to occur at approximately station 298 (about 1,500 feet shorter than the current jetty head position). The base condition is expected to result in significant changes to the navigation entrance.

Figure 3-32 illustrates the simulated South Jetty crest profile evolution over the project life. In this figure, the blue line depicts the originally constructed South Jetty showing both the authorized length and crest elevation. The green line shows the 2006 condition of the jetty and the red line depicts the changes that are predicted to occur in the jetty over the next 50 years if the jetty is maintained as described in the base condition. The second graph shows the expected breach and repair frequency and the third graph shows the functional and structural reliability over the project life.

Figure 3-31. South Jetty Base Condition

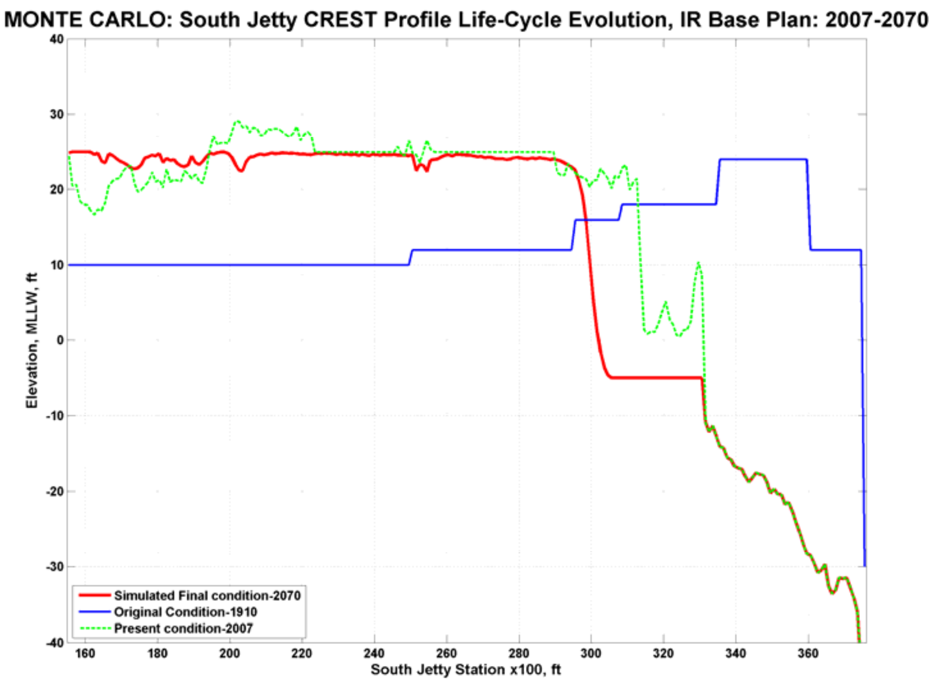

Figure 3-32, (continued). South Jetty Base Condition

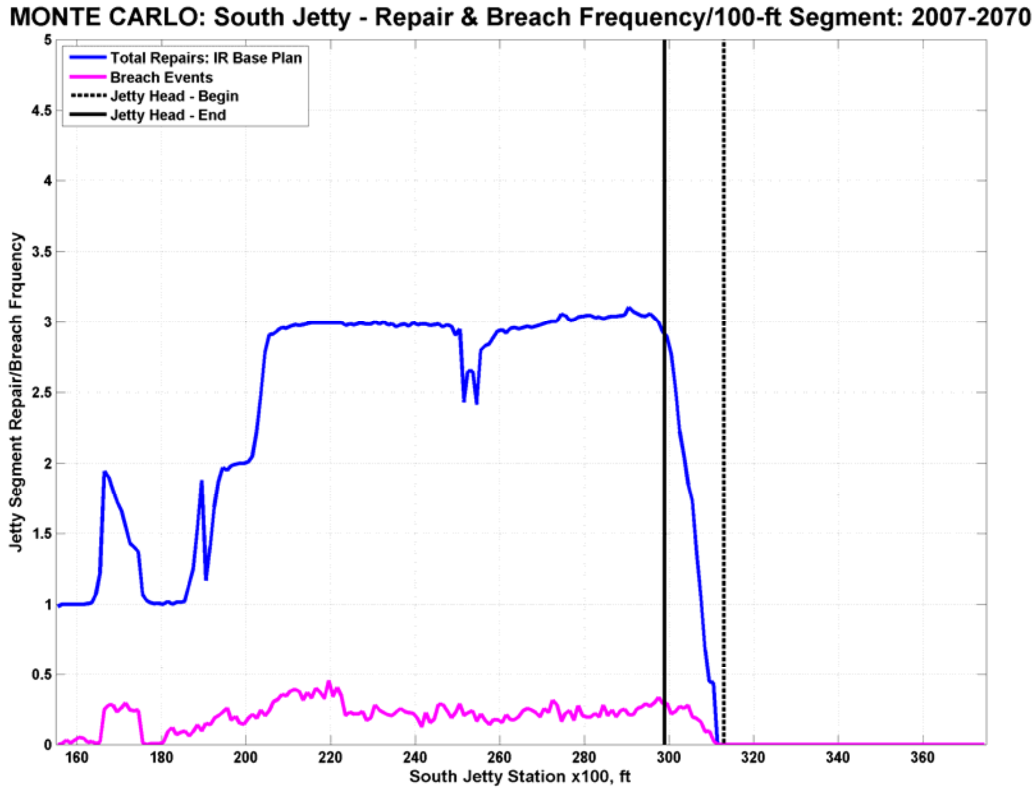

Figure 3-32 (continued). South Jetty Base Condition

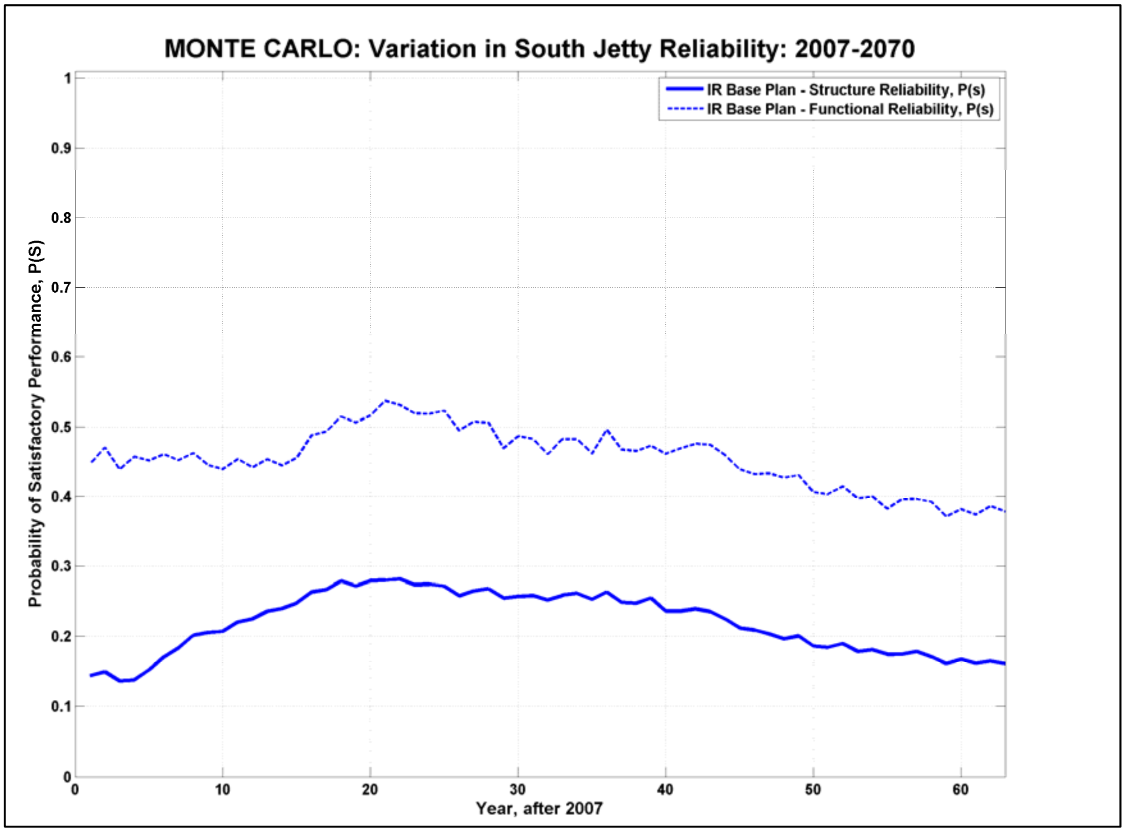

3.9.1.3. Jetty A

The base condition takes no action to address the larger system degradation processes. The jetty head continues to recede back at a rate of 5 to 20 feet per year. The modified jetty head position at the end of the life-cycle analysis is approximately at station 82 (about 600 feet shorter than the current jetty head position). The base condition is expected to result in significant changes to the navigation entrance.

In Figure 3-32, the blue line depicts the originally constructed Jetty A showing both the authorized length and crest elevation. The green line shows the 2006 condition of the jetty and the red line depicts the changes that are predicted to occur in the jetty over the next 50 years if the jetty is maintained as described in the base condition.

3.10. SUMMARY OF ENGINEERING EVALUATION OF ALTERNATIVES

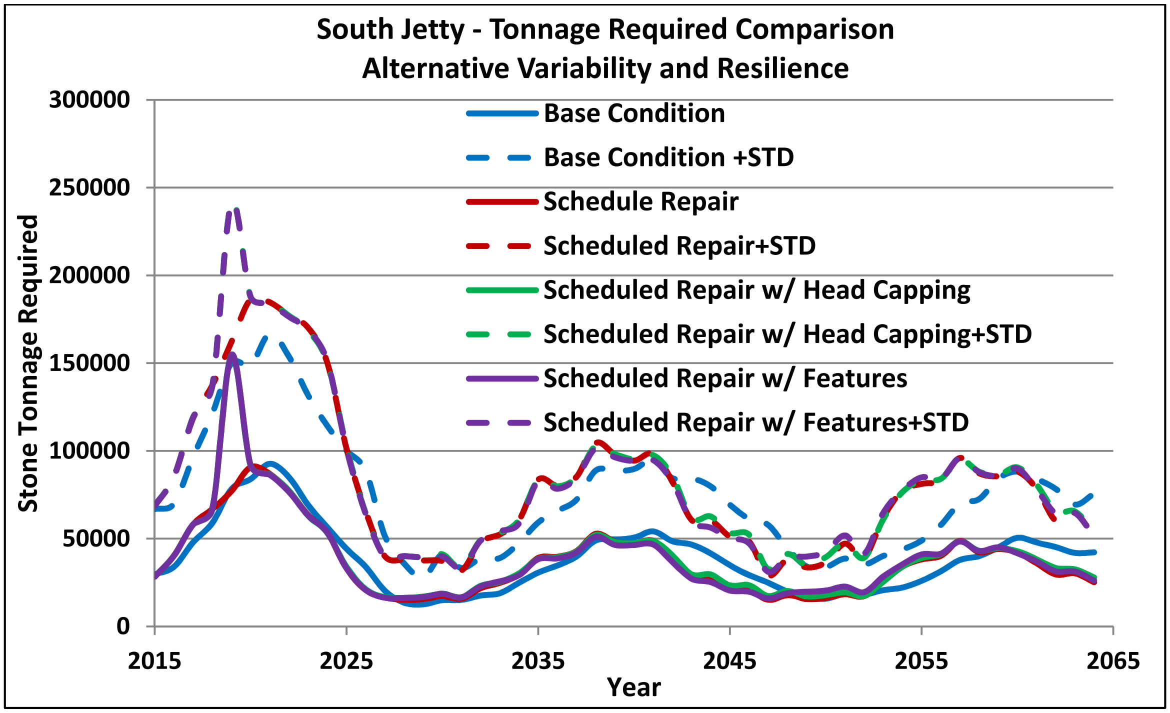
The purpose of this rehabilitation study was to identify and recommend a course of action that would minimize future life-cycle costs and maintain deep-draft navigation for the MCR jetty system. While this was a least cost analysis, various additional elements including project reliability, constructability and access, and potential navigation risk also were considered in the alternative comparisons and rankings. The complexities of major jetty repair in challenging conditions, as well as the feasibility of emergency winter dredging at the MCR, were considered in the final evaluation. Only four contract dredges are capable of dredging at the MCR during winter conditions, and they are normally scheduled for work in milder climates during the winter months. Contract dredges are typically working at projects on the east and gulf coast where work is limited to an environmental window and not expected to be available to mobilize to the west coast. The Corps' dredge ESSAYONS is also generally in repair status and not likely to be available during the winter months.

In short, dredges are typically not available for dredging at the MCR during the winter months when a breach and sudden infill are likely to occur and the risks of dredging at the MCR during that period are very high, so channel depths will likely be lost for an extended period. There typically are two dredges working at MCR for a total of 80-100 days per year to dredge 4-5 MCY during favorable weather each year. The ability to dredge an additional 2-3 MCY (during the winter) is highly unlikely. The best-performing alternative for each jetty was selected by optimizing the initial cost of structure rehabilitation, optimizing future maintenance costs, and considering the time-varying reliability of the jetty.

The alternative plans evaluated spanned the full range of potential actions from the Base Condition which does not include any attempt to slow down the larger, destabilizing processes acting upon the jetties (head recession, toe scour, backside erosion) to a Composite plan rehabilitation, a substantial and robust rehabilitation of the structure in addition to the construction of the stabilizing engineering features. Figure 3-36 through Figure 3-38 below illustrate, using tonnage required over time, how those general types of plans compare over a typical life cycle for the South Jetty, the North Jetty, and Jetty A for the base condition and the 3 least cost alternatives. Results are plotted for the cases with and without holding the jetty heads at their current location. The dashed line shown for each plan indicates the potential variability of the estimate of the mean shown by the solid line. The plans with a lower upfront action (Base Condition and Scheduled Repairs) result in a higher variability for much of the life cycle. The rehabilitation plan, as expected, provides more resilience and less need for repair actions in the near future. These figures combined with the figures that indicate reliability over time for each plan illustrate the trade-offs between a rehabilitation strategy versus a repair strategy.

This section summarizes the results for each MCR jetty and compares the engineering performance of the alternative plans that performed best in each category. Metrics used to assess future jetty performance and compare the alternatives included reliability, constructability and access, potential impacts to larger inlet system, and environmental effects. A summary of the engineering evaluations described above for the best-performing alternatives is provided in the following figures and tables for each MCR jetty.

Figure 3-36. South Jetty – Comparison of variability and resilience of alternative types



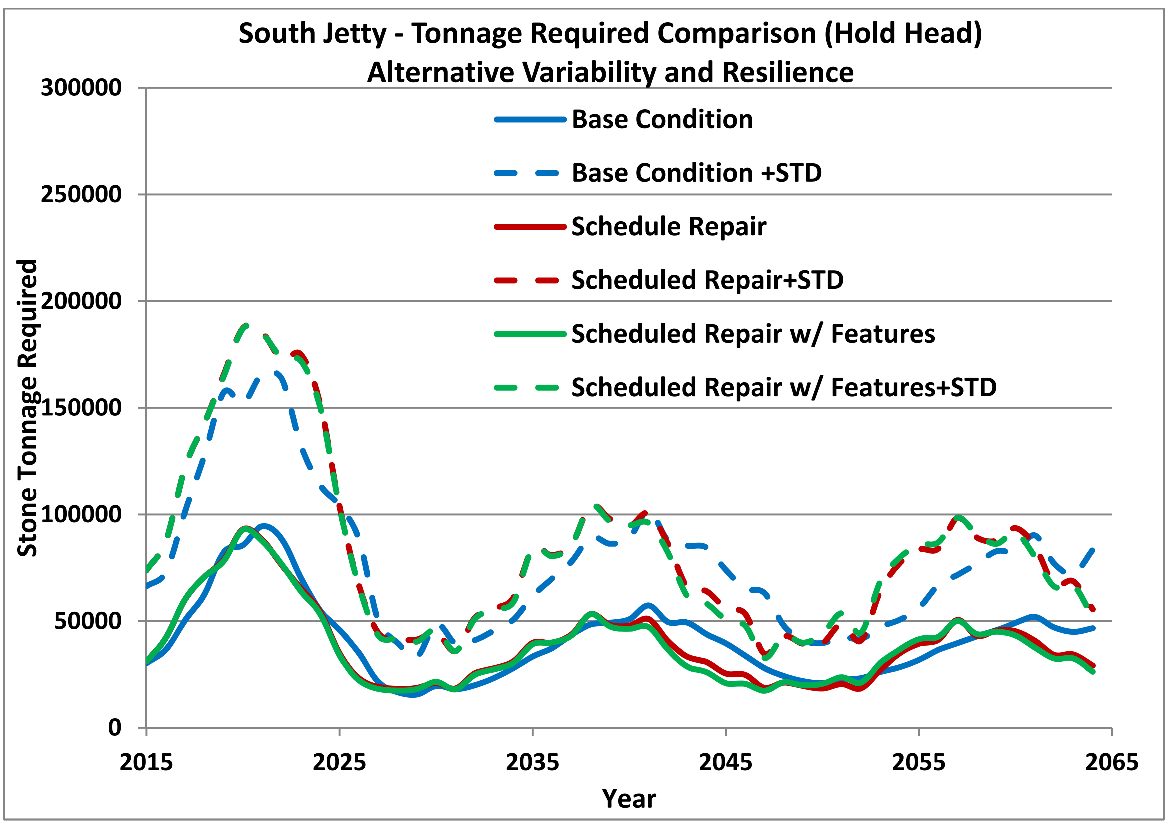


Figure 3-37. North Jetty – Comparison of variability and resilience of alternative types

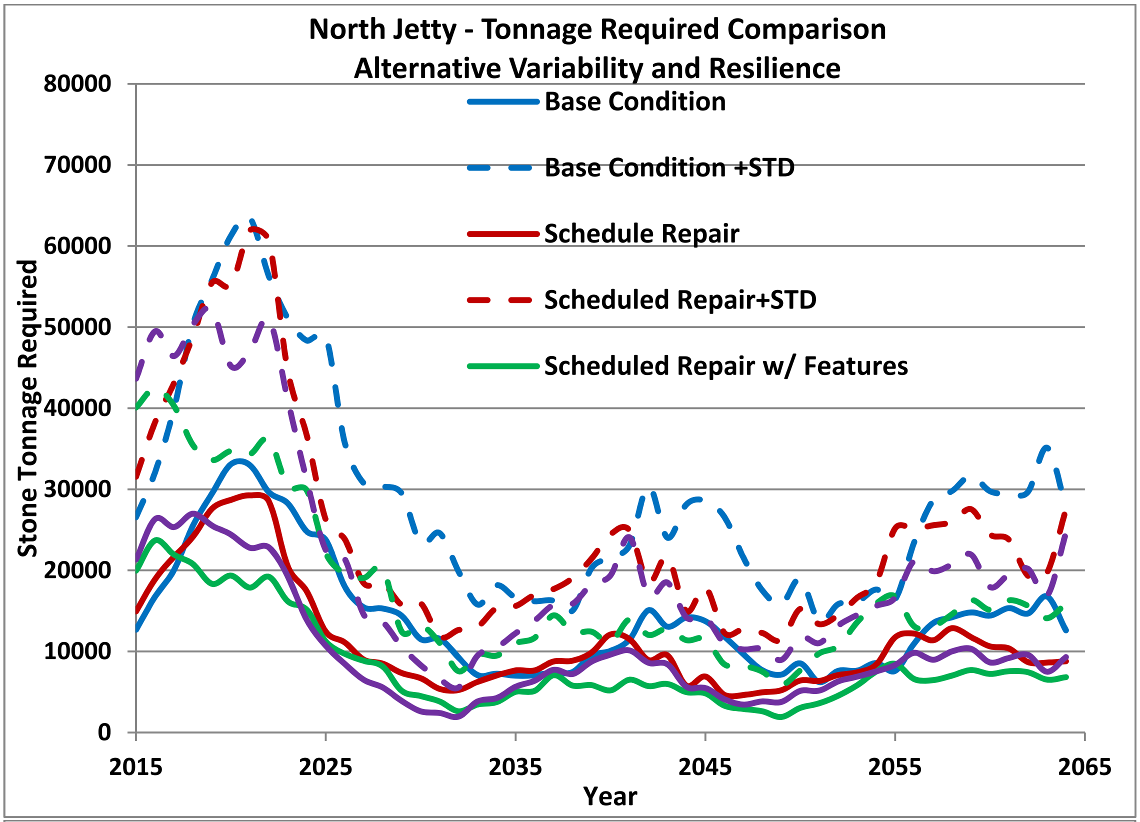

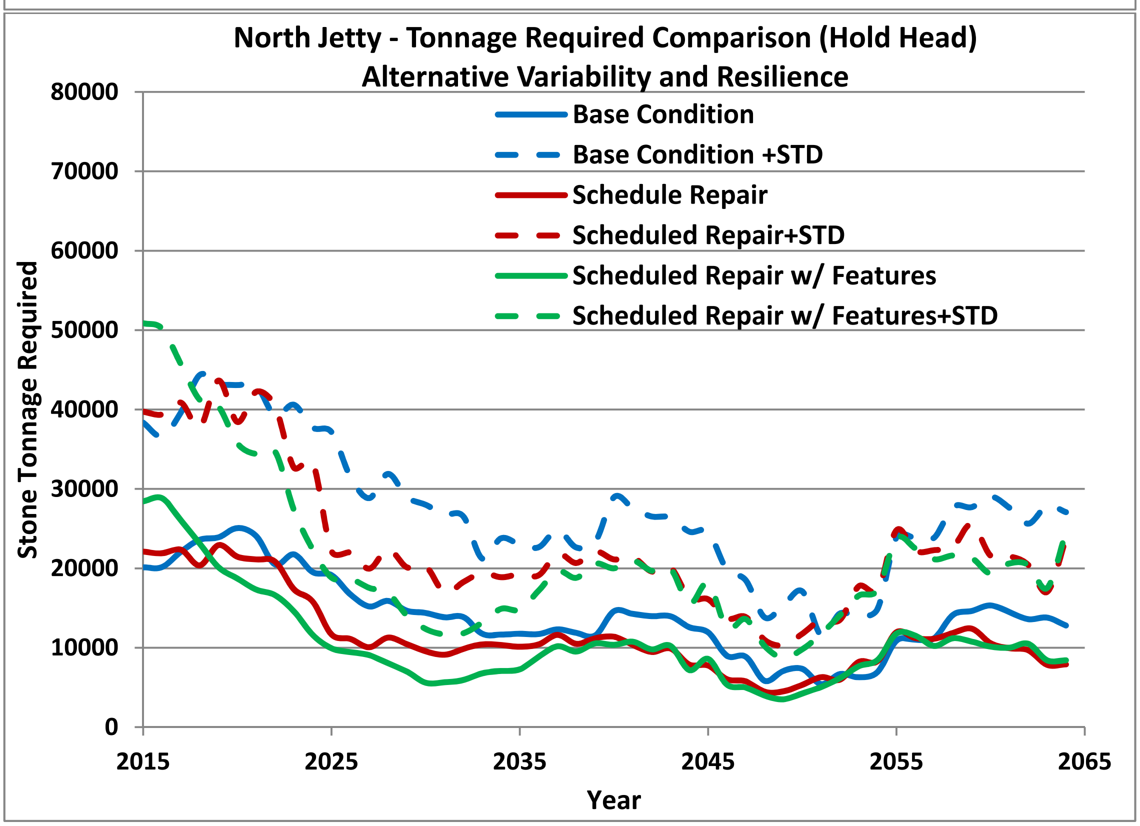

Figure 3-38 Jetty A – Comparison of variability and resilience of alternative types

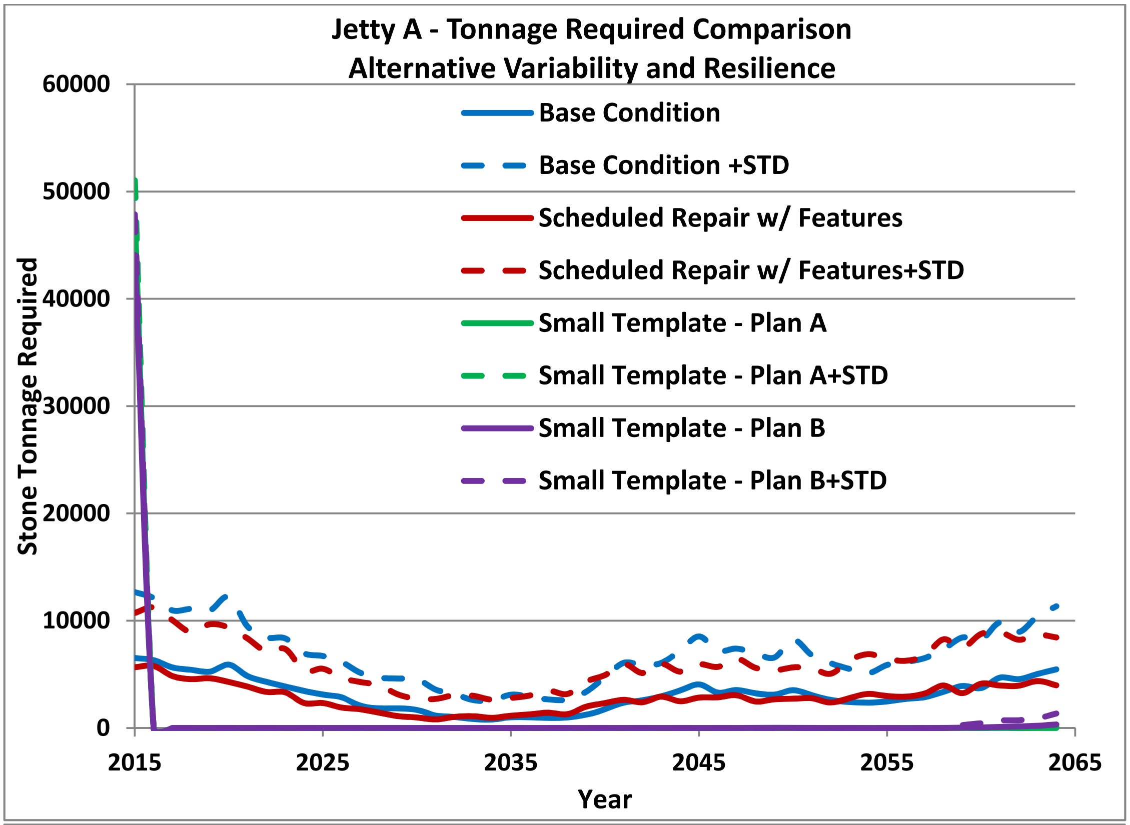

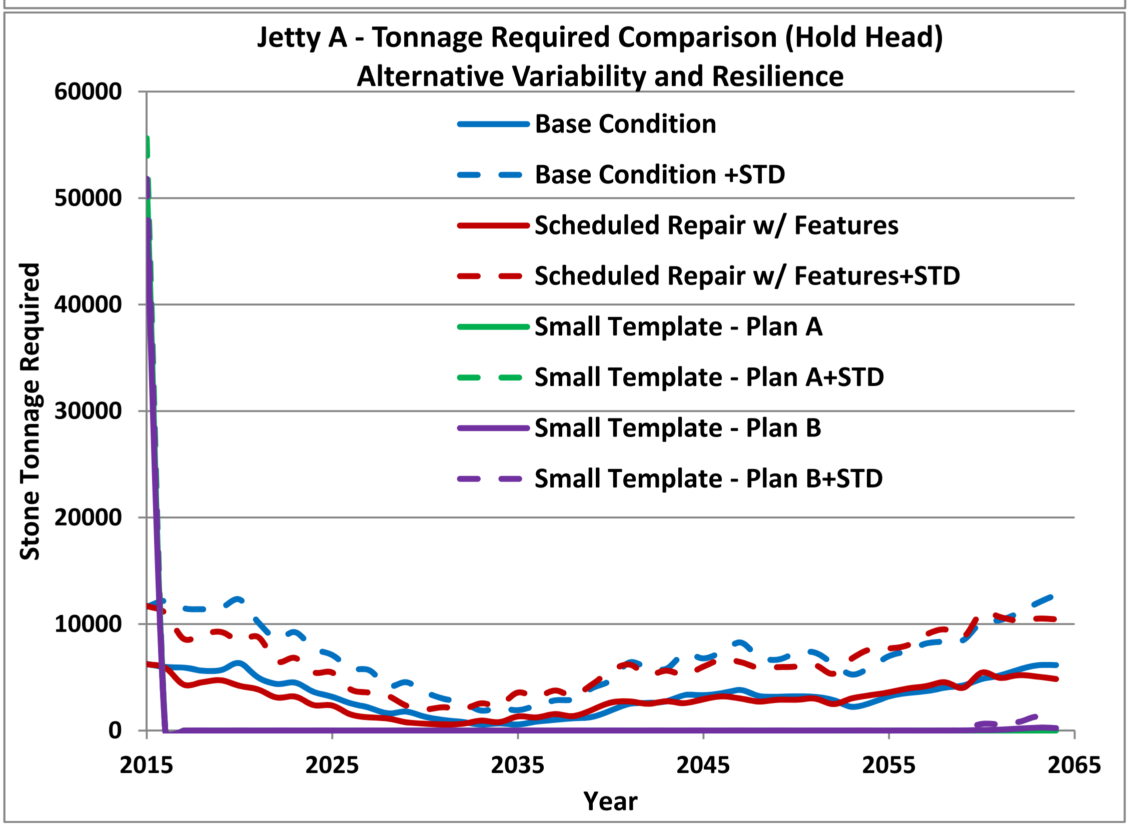

3.10.1. North Jetty

The North Jetty is distinctive in that it is closest to the navigation channel and serves to hold back very large subaerial and subaqueous sediment features in the form of Benson Beach and Peacock Spit. The existence of this large shoal has served as protection for the ocean side of the North Jetty for a good portion of its life. A major breach along this jetty has the potential to impact navigation if emergency repairs cannot be instituted quickly and/or emergency dredging cannot be conducted for the resulting sediment infill in the channel. For this reason, a major breach along this jetty would result in emergency repairs being instituted immediately, regardless of the time of year or the cost of the repairs. Another significant difference for the North Jetty is the 60- to 80-foot depths on the channel side of the seaward half of the structure, and the rapid loss of jetty length (two to three times the jetty length loss as for the South Jetty and Jetty A).

Figure 3-39 summarizes the best performing alternatives in terms of cost, which will be economically evaluated in Section 4, in comparison to the base condition. Structural and functional reliabilities are plotted as black and orange markers, respectively. All of these plans include jetty head stabilization, lagoon fill, and spur groin construction. Figure 3-40 shows the estimated structural and functional reliability over the period of analysis of the project for the best performing alternatives.

Should the repair alternative not be executed, the identified reliabilities and project performance would be impacted. The scheduled-repair-with-features alternative and the minimum cross-section alternative address the stability of the cross section only above water.

On the other end of the spectrum are the full rehabilitation composite plans that address above and below water damage processes along the full length of the North Jetty (composite 3 and composite 4). Each of these attempted to optimize resilience and cost using the graduated levels of cross-section repair along the jetty length. Cross section application increases toward the seaward end of the structure to address the increased forces. All of the plans utilize the minimum cross-section cross section (above-water repair only) for the landward half of the jetty. This portion of the jetty has the lowest exposure to waves in addition to a lower potential impact if failure occurs. All engineering features are included in these plans. Composite 4-small modified applies a more robust cross section from approximately stations 55 to 98 due to increasing damaging wave exposure, increasing foundation depths, and the potential damaging effects of a breach.

The functional and structural reliability scores of the top economic performing alternatives are presented in Figure 3-40.

3.10.2. **South Jetty**

The South Jetty is very important to the MCR inlet by serving as a type of anchor to aid in controlling the overall shape of the ebb tidal shoal which ultimately impacts sediment pathways as well as wave approach patterns. The South Jetty is also distinctive in that it extends for over 4 miles out into the ocean and is exposed to the greatest wave forces of any of the structures. The exposed nature of the South Jetty makes it difficult to repair quickly since fall through spring construction on the jetty is too hazardous. Access to the outer half of the jetty is particularly problematic and results in extreme exposure of any equipment being used. The South Jetty is located further from the navigation channel than the North Jetty and a major breach would not immediately impact the channel. Due to a slower potential impact to navigation response and the hazardous access, the South Jetty would not be repaired following a major breach until the following summer.

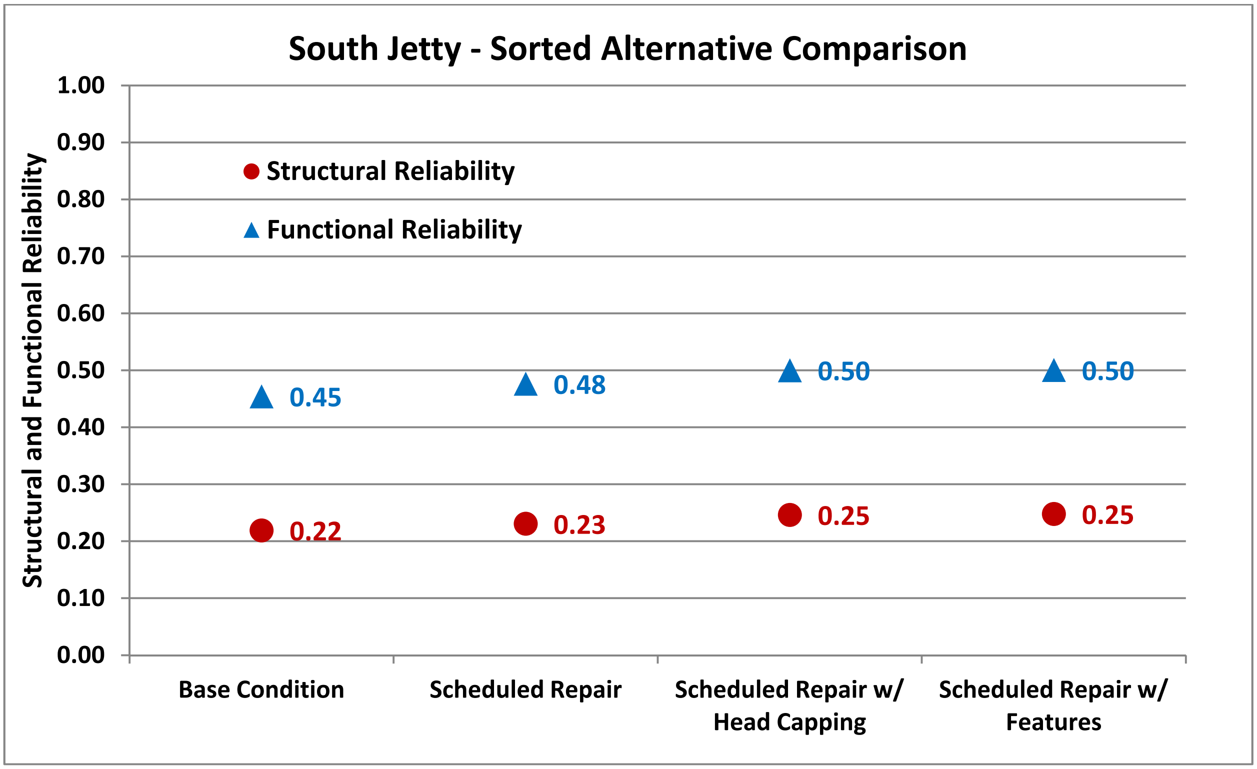
Figure 3-41 summarizes the South Jetty results for the best performing alternatives. These alternatives illustrate the key differences in approach to long-term jetty maintenance. Scheduled repair with features achieves a structural and functional reliability of 0.3 and 0.5, respectively (Figure 3-42).

The two composite alternatives are ranked next. Each of these attempted to optimize resilience using the graduated levels of cross section repair along the jetty length. These alternatives are between the low action plans and the larger full rehabilitation plans.

Because the South Jetty has such extreme exposure and challenging construction conditions, a more robust application of repair/rehabilitation has the potential to optimize life-cycle performance. Two composite alternatives, composite 1-large and composite 4-medium performed over the period of analysis with functional reliabilities of 0.72 and 0.68.

Both composite alternatives utilize the minimum cross section (above water repair only) for the portion of the jetty out to approximately station 175. This portion of the jetty has the lowest wave exposure and a lower potential impact if failure occurs. Composite 1-large applies the largest cross section repair along the jetty length. The small cross-section is placed out to station 180. From stations 180 to 260, the more resilient moderate cross section is constructed. From station 260 to the head, the larger cross section is constructed. The moderate and large cross sections provide a more resilient seaward slope and the large cross section provides a robust toe berm feature. Since the outer half of the South Jetty is most exposed to extreme wave conditions and is the most difficult to access for repair, some discussion centered around the practicality or reasonableness of implementing a smaller cross section along that reach, which would result in multiple repair actions over the life of the structure. All engineering features are included in these alternatives. The top economic performing alternatives are presented in Figure 3-41 and Figure 3-42 in terms of functional and structural reliability. None of the full rehabilitation alternatives were economically competitive, see chapter 4.

Figure 3-41. South Jetty Sorted Alternative Comparison



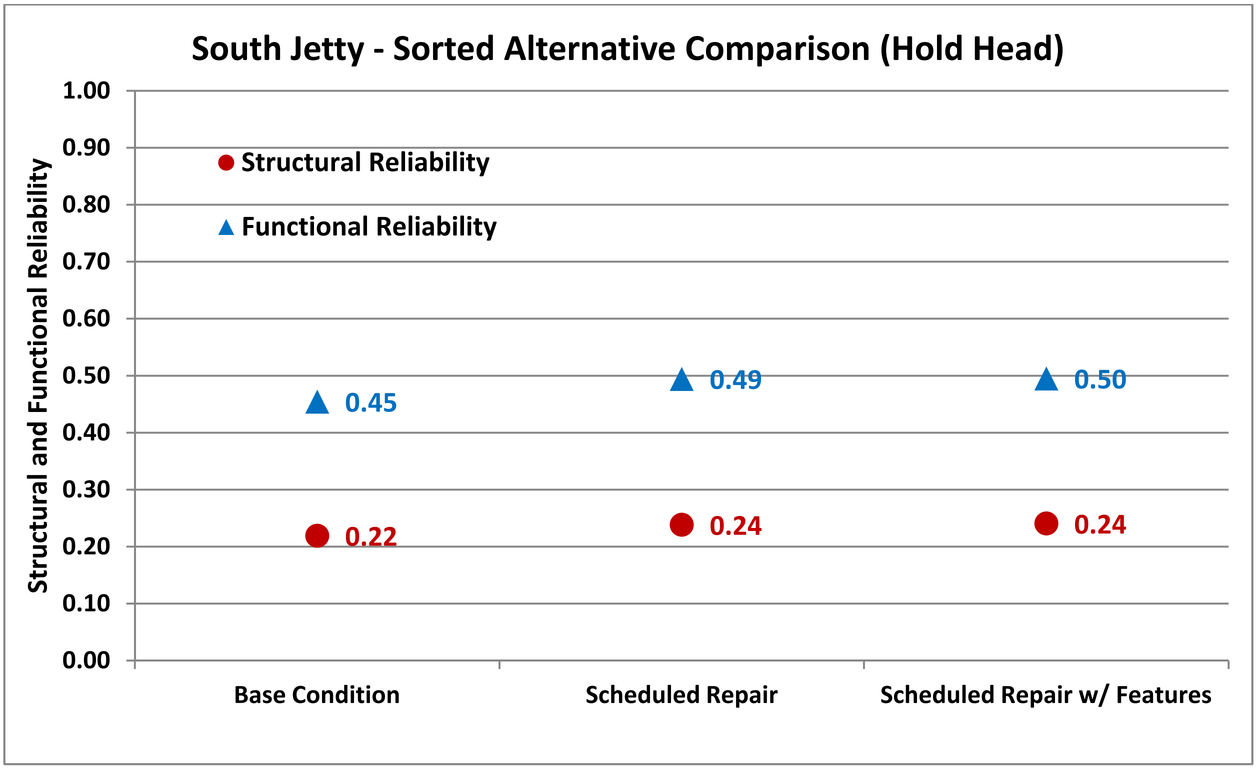


Figure 3-42. South Jetty Reliabilities for Sorted Alternative Comparison

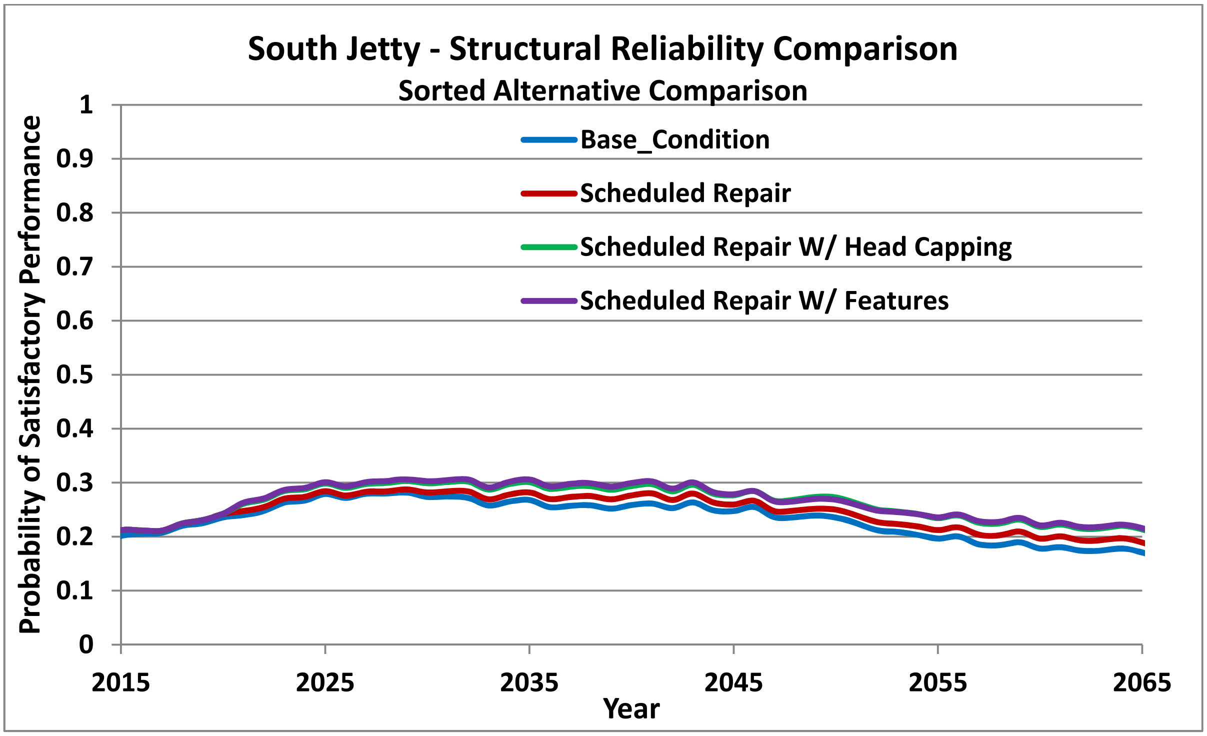

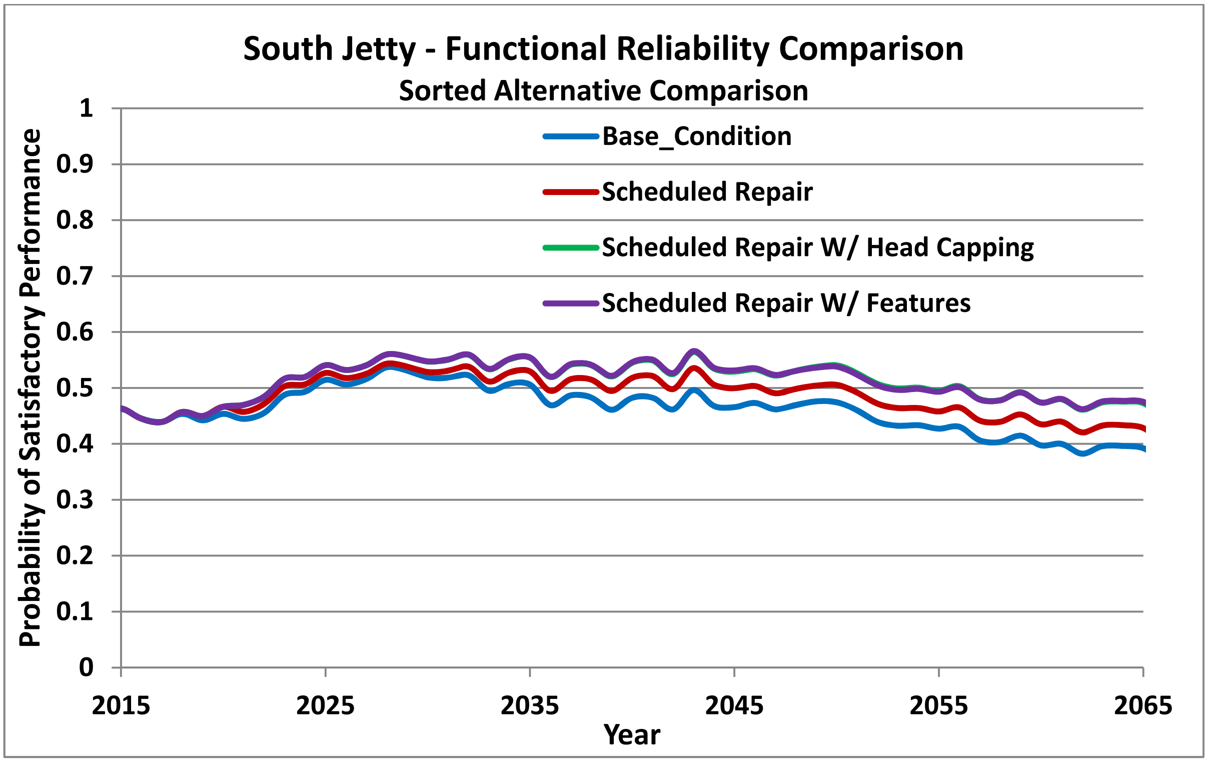

Figure 3-42. South Jetty Reliabilities for Sorted Alternative Comparison (Continued)

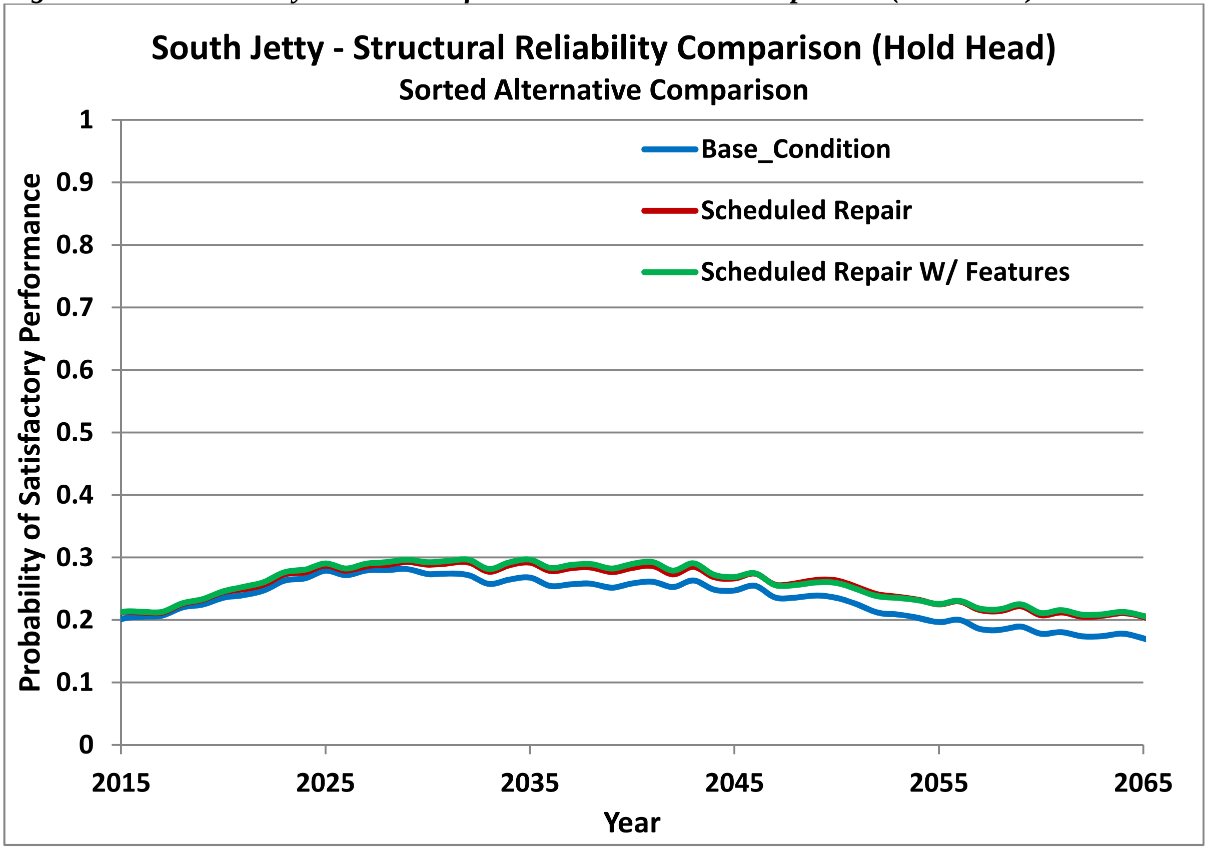

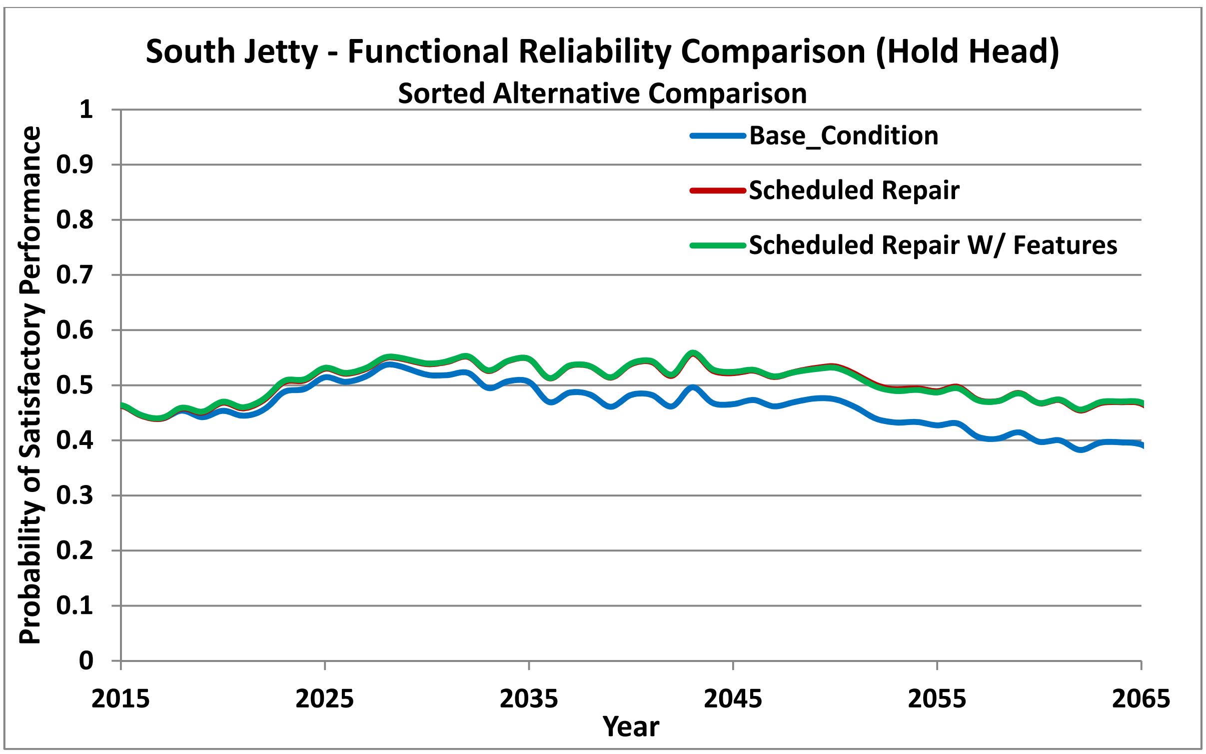

3.10.3. **Jetty A**

Jetty A is less exposed to storm waves than either the North Jetty or the South Jetty. It also is oriented perpendicular to the navigation channel, making a breach in Jetty A less likely to have an immediate impact on the navigation channel. The evolution of Jetty A over time, however, has been impacted by a large +100-foot-deep scour hole that developed off of the south end of the jetty head. The rehabilitation/repair of Jetty A is primarily to maintain a robust cross section and stable jetty length, so that the forces along the length of the North Jetty are controlled and the alignment of the navigation channel remains centered in the inlet.

Figure 3-43 summarizes the Jetty A results for the best performing alternatives. Both the functional and structural reliability values decrease from immediate rehabilitation to scheduled repair to base condition (Figure 3-44). Structural reliability decreases from 0.87 to 0.44 from immediate rehabilitation to scheduled repair, and functional reliability decreases from 0.98 to 0.92. The immediate rehabilitation plan was shown to provide the best life-cycle results for Jetty A.

4. ASSESSMENT OF ALTERNATIVES

4.1. INTRODUCTION

This chapter builds upon the previous two chapters to provide a comparison of the alternatives based on initial and life-cycle costs, reliability, and environmental considerations. Based on these comparisons, a recommended plan for each jetty is developed.

The primary function of the MCR project is to maintain the navigation channel for deep draft shipping. The secondary function evaluated in the structure rehabilitation effort is to significantly extend the life and reliability of the jetties in order to reliably maintain the primary function.

An analysis and optimization of the alternatives was performed using a stochastic (probability) risk-based (SRB) life-cycle model developed for the MCR jetties. Each jetty was analyzed separately. The evaluation addressed the following study objectives:

- Maintain deep-draft navigation at the MCR.
- Minimize jetty life-cycle costs.
- Extend the functional life of each jetty, as a system of structural elements.
- Improve the reliability of the three MCR jetty structures.

Analyses were performed pursuant to the following applicable guidance for life-cycle analyses and rehabilitation of coastal navigation infrastructure:

- Coastal Engineering Manual (2006). Engineering Manual 1110-2-1100. U.S. Army Corps of Engineers, Washington, D.C.
- Engineering and Design: Life-Cycle Design and Performance (1997). Engineering Regulation 1110-2-8159. U.S. Army Corps of Engineers, Washington, D.C.
- Engineering Regulation ER-1105-2-100 (2000). Planning Guidance Notebook. U.S. Army Corps of Engineers, Washington, D.C.
- Guidelines for Risk and Uncertainty Analysis in Water Resources Planning, Volume I and II (1992). U.S. Army Corps of Engineers, Institute for Water Resources, Report 92-R-1. Ft Belvoir, VA.
- Reliability and Risk Engineering for Existing Infrastructure (2008). Chapter 3: Basic Features and Methodologies for Reliability Analyses. Engineering Circular 1110-2-6062. U.S. Army Corps of Engineers, Washington, D.C.

4.2. DISCUSSION OF BASE CONDITION AND ENGINEERING CONSIDERATIONS

The MRR base condition reflects three separable actions:

(a) The previous (FY 11) base condition involved a fix-as-fails approach where each jetty was allowed to degrade to as low as 20 percent of the originally authorized cross section and therefore breaches were forecasted. An IEPR comment stated that this assumption was not consistent with historic maintenance practices. As a result, the district changed the base condition to reflect the most likely future jetty maintenance strategy, one that did not allow breaches: interim repair, with the jetty head receding. This assumption reflects that an effective jetty monitoring program can reasonably be expected to recognize any substantial loss of cross section, and that the process of failure, in the case of a large rubble-mound jetty, occurs over a period of years, rather than months.

Due to the level of construction and the high mobilization costs, the revised (FY 12) base condition does not include any jetty head re-construction. Only the trunk and the root of the jetty are maintained, and the jetty head is allowed to recede landward. Maintenance of trunk and root of the jetty is minimized by deferring repair activities into the future for as long as possible. Jetty repairs are initiated only when a failure of the upper portion of the jetty cross section is progressing. The base condition is identified as an interim repair approach because the upper portion of the cross section is allowed to be damaged to approximately 35 percent remaining prior to repair actions being taken. In this way, the jetty is maintained close to the margin of functional loss without breaching.

(b) The South Jetty dune augmentation and stabilization at its root is part of the without-project condition and is funded in the FY 13 Presidential budget for $5.5M.

(c) North Jetty Major Maintenance Report (MMR) actions: Lagoon fill between STA 20 to 60; and critical repairs between STA 86 to 99.

A more detailed discussion of the Base Condition is in Section 3.8.3 and Section 16 of Appendix A2.

4.3. KEY ASSUMPTIONS

The purpose of this rehabilitation study was to identify and recommend a course of action which minimizes the future life-cycle costs and maintain deep-draft navigation for the MCR jetty system. The starting point for this evaluation was to formulate alternatives that met the project purpose, and met acceptable levels of project reliability, constructability, and potential navigation risk. Alternatives varied by jetty geometry, including crest-width and -height, side slope, benching, and whether or not they included engineering features (spur groins and capping). The alternatives were further distinguished by holding the head location through reconstruction of cross-section, or through capping. These alternatives were evaluated using the SRB model providing required repair volumes through time and by reach. The required repair volumes were converted to life-cycle cost and ultimately to an average annual cost for each alternative. The life-cycle costs included initial construction cost, repair cost, and their timing after rehab. The average annual cost of each alternative was put in ranked order and the recommended plan was chosen based on least-cost.

Alternatives including rebuilding submerged sections of each jetty were screened out in the early phases of the study. These alternatives included rebuilding up to the full authorized length, constructing jetty heads on currently submerged relic stone, rebuilding the cross-section off of the existing footprint, and realigning the jetties. Hence, these alternatives were unacceptable and eliminated from further consideration because they were either outside of the authorized project, or deemed unacceptable from a constructability standpoint. The current length of each jetty is generally deemed to result in an acceptable level of navigation access and maintenance dredging, meaning that rebuilding submerged sections of the jetty would have limited potential benefit. Although it was conclusively demonstrated that use of extremely large, dense stone in larger cross sections will reduce future maintenance costs, none of the rehabilitation alternatives proved to be cost effective.

The recommended plan will identify the optimum investment both in terms of proposed actions and timing of proposed actions, given the risk and uncertainty identified during the study. This plan will offer the greatest benefit to the project with respect to cost while still meeting the project goals.

4.4. ALTERNATIVE PLAN SELECTION SCREENING

4.4.1. Screening Level 1

The Corps began looking at applying a system approach to the MCR entrance in 1999, had an interruption from study to conduct interim repairs on the North Jetty in 2005, and the South Jetty in 2006 and 2007. In 2006 the major rehabilitation study continued, evaluations began with an analysis of where the end of each of three jetties should be at the mouth of the Columbia River and developed three jetty length options:

- rebuild the jetties beyond their authorized lengths
- rebuild the jetties to their authorized lengths
- rebuild the jetties to the midpoint between the authorized length and the existing jetty end station
- rehabilitating the jetties to the current end stations

Consideration was given to alternatives that re-aligned the jetties off of the existing footprint and alternatives that included cross-sections that extended well beyond the relic stone. Table 4-1 displays the alternatives that were formulated and removed from further consideration and reasons why these alternatives were screen out.

Table 4-1 Alternatives Formulated and Removed From Further Consideration

Alternative	Currently Authorized	Environmental Concerns	Justification for Removal
Jetty Lengths			
Extending Jetties beyond their authorized length	No	Numerous	Not brought forward due to cost and authorization.
Rebuilding Jetties to their authorized length	Yes	Some	Not brought forward due to high cost, concerns on constructability due to scour holes at the end of N. and S. Jetties; and therefore not cost effective.
Rebuilding Jetty head at midpoint between authorized length and existing length	Yes	Some	Numerical modeling did not conclude a change to circulation patterns; therefore, it was determined there was no benefit to the navigation channel for the investment cost.
Jetty Alignment			
Reconstruct North and South Jetty alignment to improve inlet conditions, reduce O&M dredging	No	Not likely to be acceptable to the resource agencies and the public	Not brought forward due to authorization issues and significant environmental concerns. The improvements to the navigation channel were uncertain and not justified when compared to cost of construction.
Cross-section			
Increasing the cross-section of the jetty beyond the relic stone for foundation and structural stability	No	Numerous	Not brought forward due to authorization issues and numerous environmental concerns. The improvements to the navigation channel were uncertain and not justified when compared to cost of construction.

4.4.2. Screening Level 2

Based on this screening effort project alternatives were developed on the basis that the end of the jetties would not extend past their existing length. The alternatives developed in Chapter 3 were compared using the SRB model with the results being displayed below for each of the three jetties. Alternatives in Table 4-2, 4-3 and 4-4 are those that remain for consideration. The table displays average annual costs (AAC) and demarcated based on benefit to cost ratios (BCR) greater than unity and for the South Jetty near unity, because the South Jetty had no alternatives above unity when costs are compared to the base condition. Those alternatives that are shaded in the table were removed from further consideration.

Table 4-4 Jetty A Alternatives Remaining For Consideration

Alternative	**Alternative Description**	**Average Annual Cost ($1,000)**	**Benefit Cost Ratio**	**Rank**
JA-06	Scheduled Repair (Hold Head)	913	1.42	1
JA-05	Base Condition (Hold Head)	1,000	1.30	2
JA-08	Small Cross-section Rehab (Plan B) - Immediate (Hold Head)	1,086	1.19	3
JA-04	Small Cross-section Rehab (Plan B) - Immediate	1,114	1.16	4
JA-07	Small Cross-section Rehab (Plan A) - Immediate (Hold Head)	1,164	1.11	5
JA-02	Scheduled Repair	1,192	1.09	6
JA-03	Small Cross-section Rehab (Plan A) - Immediate	1,200	1.08	7
JA-01	Base Condition	1,297	-	8

No alternatives were screened at this level using the level 2 methodology of removing all alternatives with BCRs lower than unity.

4.4.3. Screening Level 3

This section takes the above-the-line portion from screening level 2 for the North and South Jetties and Jetty A from Tables 4-2, -3 and -4 respectively.

Additional screen will be applied, with the actions bulletized below each table for screening level 3.

Table 4-5 North Jetty Alternatives Remaining For Consideration

Alternative	Alternative Description	Rehab Cost ($1,000)	O&M Repair ($1,000)	Expedited Repairs ($1,000)	Dredge Costs ($1,000)
NJ-17	Scheduled Repair (Hold Head)	0	52,625	8,227	1,263
NJ-02	Scheduled Repair	0	52,578	5,687	5,059
NJ-04	Scheduled Repair w/ Spur	6,529	50,833	4,564	1,756
NJ-16	Base Condition (Hold Head)	0	45,581	17,239	1,297
NJ-18	Scheduled Repair w/ Engineering Features (Hold Head)	6,529	52,657	5,917	1,080
NJ-19	Scheduled Repair w/ Spur (Hold Head)	6,529	52,657	5,917	1,080
NJ-01	Base Condition	0	43,483	18,294	5,745

Level 3 Screening occurred as below:

- Alternatives NJ-0 4, NJ-18 and NJ-19 were removed from consideration because the upfront rehabilitation costs did not appreciably reduce O&M repair costs over time as compared with North Jetty alternatives.
- Alternatives NJ-01 and NJ-16 were removed from further consideration due to their high expedited repair costs and the higher inherent risk to life safety and channel function.

Table 4-6 South Jetty Alternatives Remaining For Consideration

Alternative	Alternative Description	Rehab Cost ($1,000)	O&M Repair ($1,000)	Expedited Repairs ($1,000)	Dredge Costs ($1,000)
SJ-01	Base Condition	0	124,369	65,319	15,825
SJ-04	Scheduled Repair	0	155,249	38,803	13,263
SJ-16	Base Condition (Hold Head)	0	133,035	70,856	3,448
SJ-18	Scheduled Repair w/ Spur Groins (Hold Head)	3,560	159,571	44,264	1,005

Level 3 comparison occurred as below:

- SJ-08 was removed from consideration because the upfront rehabilitation costs did not appreciably reduce O&M repair costs over time as compared with South Jetty alternatives.

Table 4-7 Jetty A Alternatives Remaining For Consideration

Alternative	**Alternative Description**	**Rehab Cost ($1,000)**	**O&M Repair ($1,000)**	**Expedited Repairs ($1,000)**	**Dredge Costs ($1,000)**	**Added Costs to NJ ($1,000)**
JA-06	Scheduled Repair (Hold Head)	0	15,289	4,078	251	0
JA-05	Base Condition (Hold Head)	0	11,674	9,551	249	0
JA-08	Small Cross-section Rehab (Plan B) - Immediate (Hold Head)	23,034	188	127	-5	-8
JA-04	Small Cross-section Rehab (Plan B) - Immediate	26,994	113	112	164	22
JA-07	Small Cross-section Rehab (Plan A) - Immediate (Hold Head)	24,721	165	123	-5	-8
JA-02	Scheduled Repair	0	14,806	4,058	5,717	1,022
JA-03	Small Cross-section Rehab (Plan A) - Immediate	28,868	93	109	164	22
JA-01	Base Condition	0	10,981	9,948	5,884	1,053

Jetty A was constructed to help train the Columbia River as well as provide added protection to the channel side foundation of the North Jetty. As a result, Table 4-7 has a column labeled “Added Costs to the North Jetty” to account for this relationship as measured in the model.

Level 3 comparisons occurred as below:

- Jetty A alternatives 1, 2, 3 and 4 were removed from consideration because they put the North Jetty at risk; therefore, not satisfying Jetty A’s purpose.

4.4.4. Alternative Selection

All of the remaining alternatives maintain deep-draft navigation at the MCR, extend the functional life of each jetty as a system of structural elements, and improves the functional reliability of the three MCR Jetty structures. The final objective is to minimize jetty life cycle costs.

Table 4-8 Comparison of Remaining Alternatives for North Jetty, South Jetty and Jetty A

Alternative	Alternative Description	Structural Reliability	Functional Reliability	AAC
NJ-17	Scheduled Repair (Hold Head)	0.62	0.82	2,891
NJ-02	Scheduled Repair	0.60	0.79	2,948
SJ-01	Base Condition	0.22	0.45	9,567
SJ-04	Scheduled Repair	0.23	0.48	9,650
SJ-16	Base Condition (Hold Head)	0.22	0.45	9,652
JA-06	Scheduled Repair (Hold Head)	0.34	0.90	913
JA-05	Base Condition (Hold Head)	0.33	0.89	1,000
JA-08	Small Cross-section Rehab (Plan B) - Immediate (Hold Head)	0.82	0.96	1,086
JA-07	Small Cross-section Rehab (Plan A) - Immediate (Hold Head)	0.84	0.96	1,164

Table 4-8 displays the structural and functional reliability with the AACs for each of the alternatives remaining. Table 3-6 defines acceptable levels of reliability for a rubble-mound structure the functional reliabilities shown for the North Jetty and Jetty A show a low likelihood for minor structural degradation in response to extreme waves.

ER 1105-2-100, Appendix G (pp. 7-8), states: "Identification of the NED plan is to be based on consideration of the most effective plans for providing different levels of output or service. Where two cost-effective plans produce no significantly different levels of net benefits, the less costly plan is to be the NED plan, even though the level of outputs may be less."

It is important to note that the purpose of the authorized project is to maintain a reliable, functioning, deep-draft navigation channel through the Columbia River entrance. It is not to compare the structural components of each of the alternatives so that if two alternatives still result in no impact to the navigation channel, their benefit is treated as the same. Therefore, the alternatives were evaluated based on least cost as long as they still provided for a usable channel.

Alternatives are selected as below:

- Both plans for the North Jetty have acceptable levels of Functional Reliability. Alternative NJ-17 was selected over alternative NJ-02 because holding the head stabilizes the adjacent geomorphology, protects Benson Beach from further erosion and is least cost. Because NJ-17 has a lowest AAC it is the selected alternative.
- All three plans for the South Jetty have similar values for structural and functional reliability. Because SJ-01 has a lowest AAC it is the selected alternative.
- The high functional reliability and comparatively low structural reliability for JA-06 and JA-05 indicate that the jetties will continue to function with degradation. Structural reliability is

not the determining factor for Jetty A; the functional reliability ranges from 0.89 to 0.96 for all Jetty A alternatives in Table 4-8. Increased AACs provide no benefit to the channel. Because JA-06 has a lowest AAC it is the selected alternative.

4.5. DESCRIPTION OF NED RECOMMENDED PLANS

As discussed in Chapter 2, the National Economic Development (NED) plan compares the average annual costs (AAC), net benefit, and the benefit-to-cost ratio (BCR) for the alternatives developed for each jetty structure. Each alternative was compared to the base condition. Based on this comparison, the NED plan for each jetty structure is shown below:

- **North Jetty** (BCR: 1.09) – Scheduled repair with head stabilization at or near STA 101, (less extensive than the previously proposed capping). These repairs will be conducted after the base condition maintenance repairs to stations 86-99 and lagoon fill to stop erosion of the jetty root. It does not include spur groin construction.

- **South Jetty** (BCR: 1.00) – Base condition (interim repairs) allowing head recession. It does not include spur groin construction. Dune augmentation near the jetty root will be implemented in FY 13 as a separate action and not included in the cost estimate. Although the base condition is the NED plan, the interim repair, hold head alternative is very close in AAC, differing by 0.9 percent. When conditions are appropriate (i.e., repairs of the South Jetty allow for a haul road to be established to the end of the jetty approximately FY 2019), head stabilization could be re-evaluated—using parameters such as least cost, environmental acceptability and engineering feasibility.

- **Jetty A** (BCR: 1.42) – scheduled repair and head stabilization at approximately STA 89. It does not include spur groin construction.

The project has a combined BCR of 1.1 for the system (all three jetties).

The NED plan for each jetty structure was selected as the recommended plan for the MCR jetty system. Additional information on the recommended plan is provided in Chapter 5, *Environmental Considerations*, in Chapter 6, *Construction and Cost Estimate*, and in Appendix A1, *Coastal Engineering*.

4.6. FUTURE DESIGN CONSIDERATIONS

During the DDR phase, the district will develop the least cost head-stabilization plan for the North Jetty and Jetty A. While the South Jetty NED plan is the base condition—allowing head recession—the average annual costs only vary by 0.9% from the base condition alternative holding at STA 313. Consequently, during the DDR phase, the district will also analyze head stabilization alternatives for the South Jetty. The district will survey all three jetties and adaptively manage each. Furthermore, spur groins will be reassessed to prevent ongoing erosion to the surrounding shoals.

It should be noted that this a planning analysis used to support the selected plan. In practice the following will be done to assess actual locations for repair: a biennial monitoring program where photogrammetric surveys of each of jetties will be executed to track cross-sectional degradation and head recession; annual visual inspections; and reporting by the Coast Guard and commercial ship traffic. Consequently, actual jetty repairs may not follow the exact locations identified by the predictive planning model used to develop the seven-year construction sequence on all three jetties.

5. ENVIRONMENTAL CONSIDERATIONS

This section summarizes the anticipated environmental effects of the proposed rehabilitation of the MCR jetty system, and the coordination undertaken related to environmental compliance issues. The associated EA provides a full evaluation of the project and associated environmental compliance considerations. Additional discussion and pertinent correspondence is included in Appendix D, *Environmental Documentation.* Any citations in this chapter can be found in the References section of the EA.

The following discussion is pulled directly from the EA which evaluates the effects of the Major Rehabilitation actions, the Major Maintenance Report actions, and South Jetty dune augmentation actions.

5.1. ENVIRONMENTAL EFFECTS

5.1.1. Physical Characteristics

The proposed action will enable the jetty structures to continue protecting the MCR inlet, adjacent morphology, shore lands, and side channels from becoming destabilized by the intense forces of waves and currents. The proposed action would have no calculable effect on nearshore or shore land areas beyond 1-2 miles north or south of the MCR inlet. Stabilizing the jetty heads would stop the migration of littoral sediment into the navigation channel. Because jetty lengths will be about the same as the existing jetty head locations, a negative impact on the sediment budget in the littoral cell, or on Clatsop or Peacock spits is not expected. Likewise, there would be no changes to salinity or plume conditions.

5.1.2. Water Quality

Effects of the proposed action to water quality could occur by increasing suspended sediments, increasing the potential occurrence of spills and leaks, and increasing the potential for contamination. However, the Corps expects these effects to be negligible.

Placement of rock by heavy equipment, jetty access road construction, dredging, disposal, and pile installation and removal could all cause temporary and local increases in suspended sediment. This is expected to have minimal and limited effects on the environment. Previous tests have confirmed that material to be dredged will be primarily sand with little or no fines, which does not stay suspended in the water column for an extended length of time. During infrequent and limited duration dredging and disposal which could occur for a few days annually or less often, depending on use of the facilities, suspended sediments may increase locally for a short time. These increases will dissipate quickly due to the sandy nature of the sediment, and inwater activities will be further constrained to conditions in the State 401 Water Quality Certification that limit the duration of such exceedences. Light attenuation and water quality effects from increased suspended sediments are expected to be minimal and fleeting. Pile driving is also expected to occur in sand and therefore have similar transient and minimal effects to water quality. Jetty roads could also contribute suspended sediments that would create turbidity during stormy seasons or overtopping events, but since they are above MHHW this will likely be an infrequent occurrence. When erosion of roads does occur, the background turbidity and wave climate is likely to also be in a state of increased turbulence and turbidity such that any additional roadway runoff will be a minimal contribution to the dynamic ocean and channel-forming processes churning the waters during overtopping events. Small increases in turbidity from construction activities on the jetties will likely occur on a nearly daily basis but will be of limited extent and duration, as rock placement will involve clean fill of large, individual boulders with a majority of the placement actions occurring above MLLW. Turbidity monitoring and compliance with expected likely conditions of the 401 State Water Quality Certification would also ensure protection of aquatic life and other beneficial uses in the vicinity of the inwater work. Wave and current conditions in the action area naturally contribute to higher background turbidity levels; and such conditions also preclude the effective use of isolating measures to minimize turbidity. However, other BMPs described for the proposed action would further reduce effects of turbidity from the proposed action. Effects from potential stormwater runoff were addressed in the Construction Staging and Stockpile section. Therefore, impact from suspended sediments should be inconsequential.

The Corps will require the contractor to provide a spill prevention and management plan that will include measures to avoid and minimize the potential for spills and leaks and to respond quickly to minimize damages should spills occur. Good construction practices, proper equipment maintenance, appropriate staging set-backs, and use of a fast fueling system would further reduce the likelihood of leak and spill potential and exposure extent and its associated effects.

Test results on dredge material described earlier further indicated that materials in the area are approved for unconfined in-water disposal and do not contain contaminants in concentrations harmful to organisms occupying the action area. The prohibition of treated wood will also avoid contamination from the migration of creosote and its components (e.g., copper and PAHs) from treated wood in the lotic environments.

Temporally, effects to water quality from suspended sediment and turbidity could occur on a daily basis, but are not expected to be continuous throughout the day. Clean, large boulders are not expected to create much discharge, and the substrate on which they are being placed also includes large, weathered boulders. Any other inwater work such as construction or dredging of offloading facilities will involve sandy materials that settle out very quickly. Turbidity levels and durations will be limited to conditions required in the State Water Quality Certifications which will likely include exceedence windows that are protective of beneficial uses such as salmonids and other aquatic life. Spills or leaks are expected to be infrequent and unlikely. Although the repetition of disturbance may be greater, it is still expected to remain within safe ranges that would not have long-term or deleterious effects. Furthermore, effects are expected to be geographically limited, short term, and minor.

5.1.3. Anadromous and Resident Fish Species

5.1.3.1. Federally Listed Fish Species

The threatened and endangered fish species listed under the Endangered Species Act (ESA) that may occur in the MCR project area are shown in Table 5-1. A description of these species is provided below.

Anadromous Salmonids

Adult salmonids use the MCR area as a migration corridor to spawning areas throughout much of the Columbia River Basin. They are actively migrating and are not expected to use the area for resting or feeding, although they would spend time in the MCR to physiologically acclimate to freshwater.

Chum, coho and Chinook salmon and steelhead populations spawn in tributaries to the Columbia River, and chum and Chinook salmon spawn in the mainstem Columbia River in appropriately sized gravels. No spawning would occur in the vicinity of the MCR for these species because of the lack of tributaries and appropriate spawning substrate.

Juvenile salmonids occur in the MCR area during their out-migration to the ocean. Juveniles that have already become smolts are present in the lower river for a short time period. Juveniles that have not become smolts, such as Chinook salmon subyearlings, spend extended periods of time rearing in the lower river. They normally remain in the lower river or estuary until summer or fall, or even to the following spring when they smoltify and then migrate to the ocean. Rearing occurs primarily in shallow backwater areas. Most juveniles out-migrate in late spring and early summer, although fall Chinook salmon typically have a more extended outmigration period and commonly out-migrate in late summer.

Table 5-1. Federally Listed Anadromous Fish Species

Listing status: 'T' means listed as threatened; 'E' means listed as endangered. FR = Federal Register

Species	Listing Status	Critical Habitat	Protective Regulations
Chinook salmon (*Oncorhynchus tshawytscha*)			
Lower Columbia River	T 6/28/05; 70 FR 37160	9/02/05; 70 FR 52630	6/28/05; 70 FR 37160

Columbia River Bull Trout	T 6/10/98; 63 FR 31647	10/18/10; 75 FR 63897	Not applicable

In 2005, critical habitat was designated for all Columbia River steelhead and Columbia River salmon evolutionarily significant units (ESUs), with the exception of lower Columbia River coho salmon ESU. General run-specific life history descriptions for the salmonid ESUs are provided below.

<u>Snake River Spring and Summer Run Chinook Salmon</u>. Fish from this ESU occur in the mainstem Snake River and subbasins including the Tucannon, Grande Ronde, Imnaha, and Salmon Rivers. Adults migrate in late winter to spring and spawn from late August to November. Spawning occurs

in tributaries to the Snake River. Juveniles remain in freshwater from 1-3 years and outmigrate from early spring to summer.

<u>Snake River Fall Run Chinook Salmon</u>. Fish from this ESU occur in the mainstem Snake River and sub basins including the Tucannon, Grande Ronde, Imnaha, and Salmon Rivers. Adults migrate from mid-August to October and spawn from late August to November. Spawning occurs in the Snake River and lower reaches of tributaries to the Snake River. Juveniles rear in freshwater from 1-3 years and out-migrate from early spring to summer.

<u>Lower Columbia River Chinook Salmon</u>. Fish from this ESU occur from the MCR upstream to Little White Salmon River, Washington and Hood River, Oregon and including the Willamette River upstream to Willamette Falls. Adults migrate in mid-August through October (fall run) and late winter to spring (spring run). Spawning occurs from late August to November in the mainstem Columbia River to upper reaches of tributaries. Juveniles out-migrate from early spring to fall.

<u>Upper Columbia River Spring Run Chinook Salmon</u>. Fish from this ESU occur in Columbia River tributaries upstream of the Rock Island Dam and downstream of Chief Joseph Dam in Washington, excluding the Okanogan River. Adults migrate from late winter to spring and spawn from late August to November. Spawning occurs in the mainstem Columbia River to upper reaches of tributaries. Juveniles out-migrate from early spring to summer.

<u>Upper Willamette River Chinook Salmon</u>. Fish from this ESU migrate upstream from late winter to spring and spawn from late August to November. Juveniles migrate from early spring to summer, some rearing in the Columbia River estuary and some in freshwater.

<u>Lower Columbia River Coho Salmon</u>. It is believed that the majority of fish from this ESU return to the lower Columbia River to spawn between early December and March. Spawning occurs in tributaries to the Columbia River. Young hatch in spring, rear in freshwater for one year, and out-migrate to the ocean the following spring. Most juveniles out-migrate from April to August, with a peak in May. Coho salmon occur in the Columbia River estuary as smolts and limited estuarine rearing occurs (more extensive estuarine rearing occurs in Puget Sound).

<u>Oregon Coast Coho Salmon</u>. Fish from this ESU are found in Oregon coastal streams south of the Columbia River an North of Cape Blanco. They generally migrate up spawning streams from August through November, and spawning takes place from late September through January in shallow tributaries with gravel bottoms. Fry emerge from redds in May or June and remain in fresh water from one to four winters before going to sea. Coho salmon smolts tend to stay close to shore at first, feeding on plankton. As they grow larger, they move farther out into the ocean and switch to a diet of small fish. Coho salmon can stay at sea for 2 to 3 years.

<u>Southern Oregon/N. California Coasts Coho Salmon</u>. The SONCC coho ESU includes all naturally spawned populations of coho salmon in coastal streams between Cape Blanco, Oregon, and Punta Gorda, California. Spawning runs occur throughout the year, varying in time by species and location. Depending on temperatures, eggs incubate for several weeks to months before hatching. Juveniles may spend from a few hours to several years in freshwater before migrating to the ocean. En route to the ocean the juveniles may spend from a few days to several weeks in the estuary. Juveniles and subadults typically spend from 1 to 5 years foraging in the ocean before returning to freshwater to spawn.

Columbia River Chum Salmon. Fish from this ESU are distributed from Bonneville Dam to the MCR. Adults migrate from early October through November and spawning occurs in November and December. Spawning habitat includes lower portions of rivers just above tidewater and in the side channel near Hamilton Island below Bonneville Dam. Juveniles enter estuaries from March to mid-May and most chum salmon leave Oregon estuaries by mid-May. Most juveniles spend little time in freshwater and rear extensively in estuaries.

Snake River Sockeye Salmon. Fish from this ESU occur in the Salmon River, a tributary to the Snake River. This population migrates in spring and summer and spawning occurs in February and March. Spawning occurs in inlets or outlets of lakes or in river systems. Juveniles rear in freshwater and out-migrate in spring and early summer, out-migrating primarily between April and early June. They spend little time in estuaries as smolts and are guided to ocean waters by salinity gradients.

Snake River Basin Steelhead. Fish from this ESU occur in all accessible tributaries of the Snake River. Upstream migration occurs in spring and summer and spawning occurs in February and March. Spawning habitat includes upper reaches of tributaries. Juveniles spend from 1-7 years (average 2 years) in freshwater and out-migrate during spring and early summer.

Middle Columbia River Steelhead. Fish from this ESU are distributed from Wind River, Washington and Hood River, Oregon upstream to the Yakima River, Washington. These fish migrate in winter and summer and spawning occurs in February and March. Spawning habitat includes upper reaches of tributaries. Juveniles spend from 1 to 7 years (average 2 years) in freshwater and out-migrate during spring and early summer.

Upper Willamette River Steelhead. Fish from this ESU are a late-migrating winter group, rearing 2 years in freshwater and 2 years in the Pacific Ocean before returning to spawn. The run timing appears to be an adaptation to ascending Willamette Falls at Oregon City.

Lower Columbia River Steelhead. Fish from this ESU are distributed from Wind River, Washington and Hood River, Oregon downstream to the MCR. They migrate in winter and spring/summer and spawning occurs in February and March. Spawning habitat includes upper reaches of tributaries. Juveniles spend from 1-7 years (average 2 years) in freshwater and out-migrate during spring and early summer.

Upper Columbia River Steelhead. Fish from this ESU are distributed from the Yakima River upstream to the Canadian border. These fish migrate in spring and summer and spawning occurs in February and March. Spawning habitat includes upper reaches of tributaries. Juveniles spend from 1-7 years (average 2 years) in freshwater and out-migrate during spring and early summer.

Green Sturgeon

Green sturgeon is a widely distributed, marine-oriented sturgeon found in nearshore waters from Baja California to Canada. They spawn in the Sacramento, Klamath and Rogue rivers in the spring. Spawning occurs in deep pools or holes in large, turbulent river mainstreams. Critical habitat for southern DPS green sturgeon includes all tidally-influenced areas of the Columbia River to approximately RM 46 and up to MHHW and includes adjacent coastal marine areas. Green sturgeon congregate in coastal waters and estuaries, including non-natal estuaries, where they are vulnerable to capture in salmon gillnet and white sturgeon sport fisheries.

Information from fisheries-dependent sampling suggests that green sturgeon only occupy large estuaries during the summer and early fall in the northwestern United States. Commercial catches of green sturgeon peak in October in the Columbia River estuary, and records from other estuarine fisheries (Willapa Bay and Grays Harbor, Washington) support the idea that sturgeon are only present in these estuaries from June until October. Green sturgeon enter the Columbia River at the end of spring with their numbers increasing through June. The greatest numbers are caught in the estuary in July through September. The majority of green sturgeon were caught in the lower reaches of the Columbia River based upon harvest information from 1981-2004. There are no known spawning populations in the Columbia River and its tributaries.

Eulachon

The southern DPS of Pacific eulachon (smelt) consists of populations spawning in rivers south of the Nass River in British Columbia, Canada, to and including the Mad River in California. The Columbia River and its tributaries support the largest known eulachon run. The major and most consistent spawning runs return to the mainstem Columbia River (from just upstream of the estuary at RM 25 to immediately downstream of Bonneville Dam) and in the Cowlitz River. Eulachon typically spend 3-5 years in saltwater before returning to freshwater to spawn from late winter through early summer. Spawning occurs in January, February, and March in the Columbia River. Spawning occurs at temperatures from about 39° to 50°F (4° to 10°C) in the Columbia River and tributaries over sand, coarse gravel, or detrital substrates. Shortly after hatching, the larvae are carried downstream and dispersed by estuarine and ocean currents. After leaving estuarine rearing areas, juveniles move from shallow nearshore areas to deeper areas over the continental shelf. Larvae and young juveniles become widely distributed in coastal waters and are found mostly at depths up to about 49 feet.

Bull Trout

Bull trout are endemic to western North America and were more widely distributed historically. The Columbia River may have provided important historical rearing and overwintering habitat for bull trout. Currently, the occurrence of bull trout downstream of Bonneville Dam appears to be incidental, and their occurrence upstream of Bonneville Dam appears to be limited. However, there are resident populations in rivers and creeks both in and east of the Cascades. Historic records have documented bull trout passing the fish ladder at Bonneville Dam in 1941, 1947, 1982, 1986, and 1994, as well as in the lower Columbia River near Jones Beach. High quality bull trout habitat is characterized by cold water temperatures; abundant cover in the form of large wood, undercut banks, boulders, etc; clean substrate for spawning; interstitial spaces large enough to conceal juvenile bull trout; and stable channels. The Columbia River downstream of Bonneville Dam does not typically achieve water temperatures suitable for bull trout.

5.1.2.2. Effects of the Proposed Action

Possible effects of the proposed action on anadromous and resident fish species include:

- Temporary and permanent interruption/alteration of adult and juvenile migration pathways.
- Temporary and permanent loss of shallow water habitat.
- Juvenile predator attraction to the jetty substrate and habitat type.
- Temporary disruption and displacement from piling installation and barge offloading traffic.
- Temporary loss of benthic organisms.
- Temporary displacement from dredging and rock placement activities.

- Temporary water quality impacts from construction activities and potential spills.
- Temporary increase in turbidity.
- Temporary and permanent insignificant changes to salinity, velocity, and bed morphology.

Rock Placement. Rock placement is not expected to cause mortality to adult or juvenile anadromous and resident fish. Fish could be displaced during rock placement by disturbance from rocks entering the water. Some benthic habitat will be permanently lost due to rock placement. Adjacent benthic areas will suffer relatively insignificant and temporary effects due to settling of suspended sediments. Because much of the rock will be placed above MLLW on existing relic rock, most benthic habitat should not be adversely affected. Because the jetties are in a high energy environment and are relatively unproductive near the structures, this habitat loss is not considered significant.

Jetties and Causeways. Juvenile salmonids, especially sub-yearling Chinook salmon, out-migrate in close proximity to the North Jetty, and may out-migrate in close proximity to the South Jetty as well. The length of the North Jetty forces fish that are bound for waters near the surf zone along Benson Beach farther offshore. They swim a farther distance and are potentially exposed to increased risks from predation before reaching preferred shallow-water nearshore habitat. With scheduled repairs of the North Jetty, it is expected that Benson Beach will halt its recession and resume accretion, which over time will lessen the distance that sub-yearling juvenile Chinook salmon must swim to reach preferred nearshore waters. It is possible that juvenile salmonid outmigration occurs in close proximity to the South Jetty as it does at the North Jetty. Offloading facilities and turn-outs on the channel side with elevations at or above MLLW are expected to be capable of altering outmigration routes by forcing juvenile salmonids away from the shallower waters along the jetty proper and into deeper waters as they swim around the barge offloading facilities.

Barge Offloading Facilities and Dredging. Barge offloading facilities are a potential method of delivery for stone and other construction materials. If barge offloading facilities are used, this would create the largest impacts to 404 waters of the US. Therefore, these represent the worst-case scenario for spatial effects. Pilings will be constructed out of untreated wood or steel. After installation, the presence of the barge facilities would not likely cause disturbance to salmonids in the vicinity, except for the coming and going of barges that could induce movement in fish. The construction and eventual removal of these facilities, including dredging and pile driving, would temporarily disturb fish and temporarily and permanently convert aquatic habitat (changes to depth and substrate). Because of the soft substrates, it is expected that vibratory drivers can be used effectively to install piles. The impacts from pile driving would be intermittent and would not be expected to adversely affect fish.

Material to be dredged for barge offloading facilities is primarily sand with little or no fines. Disposal of dredged material is expected to occur at approved in-water disposal sites. A clamshell dredge will be used for most dredging. Fish would likely be forced into moving to other nearby suitable habitat during dredging. There also would be a loss of benthic invertebrates in areas dredged, but only negligible losses to food resources for juvenile salmonids and aquatic species would be expected to result.

Potential Spills. Operation of heavy equipment requires use of fuel and lubricants that would kill or injure aquatic organisms if spilled into the water. The Contractor will provide a spill prevention plan to include measures to minimize the potential for spills and to respond quickly should spills occur. Due to preventative and response measures required, it is unlikely that spills would adversely affect aquatic resources because of their low chance of occurrence.

According to the Lower Columbia River Geographic Response Plan (GRP) (WADOE 2003), routes for major shipping traffic keep super tankers 50-60 Nautical Miles (NM) offshore, minimizing potential coastal effects from a catastrophic spill. Up until 2003, the GRP also quantified the volume of potential spilled material as follows. Refined product in barges and small tankers transported closer to the shoreline and up the Columbia River averaging 160 tank barge movements as well as 50-60 bunkering operations by barge to a variety of vessels per month. The majority of these bunker barges had a capacity of 15,000 barrels. Annually, self propelled tankers made approximately 100 port calls to the Portland area. The majority of the tank vessels were approximately 39,000 deadweight tonnage, having had capacity of approximately 275,000 barrels, although the largest had a capacity of 400,000 barrels. Supertankers in ballast also transited the river enroute the Portland Ship yard for routine inspections and maintenance. Approximately 2,000 general cargo, bulk, and container vessels entered the river annually, carrying bunker fuels of approximately 15,000 barrels capacity (WADOE 2003).

According to information in the Oregon Department of Environmental Quality's spill tracking database, between 1998 and March 2011, 63 spills were reported in Clatsop County in the vicinity of the Columbia River from Astoria downriver (DEQ 2011). Of these 63 spills, 43 were less than 50 gallons and were mostly the result of equipment malfunctions and minor spills and vessel leakage. Five spills were between 50 and 100 gal; 6 between 100 and 200 gallons; 2 between 200 and 800 gallons; then up to 6 at 1000 gallons; and one over 10,000 gallons (DEQ 2011). The incidents with the highest level of spill discharge generally involved storm sewage overflows or sewage release, followed by the sinking, grounding, or capsizing of fishing vessels, then land to surface water releases from other facility malfunctions (DEQ 2011). Washington Department of Ecology's Environmental Reports Tracking System (ERTS) shows about 145 incidences between January 200 and December 2010, with the majority of the sources indicated from various size vessels (WADOE 2011). Of these, most were petroleum products in the following quantities: 63 incidences were under 5 gallons; 11 were between 6-30 gallons; 9 were between 50-100 gallons; 3 were 101-300 gallons; and the largest quantified was 1 at 1500 gallons; 57 incidences did not have any associated quantities (WADOE 2011). The GRP also further describes several of the most prominent spills on the Columbia prior to 2003, including: the1984 T/V Mobiloil spill of 200,000 gallons; the 1991 discharge of 11,000 gallons of Intermediate Fuel Oil (IFO) 380 from the M/V Tai Chung at the Columbia Aluminum Facility; two similar bunkering mishaps within six months of each other at Longview Anchorage; the 1993 M/V Central spill of approximately 3,000 gallons of IFO 180; and the 1994 M/V An Ping 6 spill of a similar amount of product at the same location as M/V Central (WADOE 2003). It is notable that none of the identified spills occurred in the vicinity of the MCR, but rather further inland and upriver.

This limited spill history further indicates that spill releases from the project are very unlikely, and a spill that reaches catastrophic levels is even less likely. The required spill prevention and response plan along with additional BMPs will help avoid any significant impacts from spills.

Turbidity. Placement of rock and dredging/pile driving for barge offloading facilities will be conducted and are not likely to require measures to minimize turbidity. Placement of clean fill and pile installation in sandy substrate is not anticipated to create significant turbidity plumes. Increased turbidity from construction activities will be intermittent over the projected 8-year construction timeframe, but individual, localized increases should be of limited extent. These turbidity increases would likely not result in a reduction in feeding rates and growth, physiological stress, and increased mortality of juvenile and adult salmonids and other fish because of rapid dissipation of turbidity in the high-energy MCR environment and the mobility of fish. Movement from turbid areas and behavioral avoidance of turbid areas by fish would likely result. Sediment suspension is not thought to be an issue with respect to aquatic resource impacts because the sediments that would be suspended are mostly sand.

<u>System Effects - Permanent Changes to Velocity, Salinity, Bed Morphology</u>. Modeling results show that no appreciable permanent changes to velocity, salinity, and bed morphology at the MCR would be expected from implementation of the proposed action. Any changes to water velocities resulting from the proposed action would not likely adversely alter aquatic habitat or affect the organisms that use the MCR area.

<u>Salmonid Critical Habitat</u>. Increases in suspended sediment and resultant turbidity from driving piles and/or placement of jetty stones may impact aquatic habitat. The increases in suspended sediment and turbidity will generally be limited to the construction areas along the jetty bases and will be intermittent over the projected 6-year construction timeframe. No contaminated material would be suspended because sediment is nearly pure sand. The course-grained characteristic of the sand will cause it to settle relatively quickly.

Rock placement will occur for jetty repair and for construction of barge offloading facilities. Alteration of bottom habitat would occur from dredging, which will create temporary disturbance and greater depths that could affect the composition of benthic communities. These effects are not anticipated to be measurable, as the character of the area is naturally dynamic and prone to extreme energy conditions, and benthic organisms are adapted for such conditions and usually rapidly re-colonize. Alteration of bottom habitat by pile driving or placing additional rock to expand the bases of the jetties should not adversely affect aquatic habitat. The MCR is an active migration corridor and it is unlikely that salmon are feeding to any extent in the area. Consequently, effects on salmon feeding habitats are not anticipated.

The permanent removal or conversion of some shallow water, nearshore sandy habitat likely used by juvenile salmonids for migrating, foraging, or rearing habitat would result from previously described rock placement for turnouts, set-up pads, causeways and stone docks for offloading facilities. In addition, some shallow water, nearshore sandy habitat likely used as migrating, foraging, or rearing habitat by juvenile salmonids would be unavailable for the projected 6-year construction timeframe. Some causeway structures would be removed upon project completion and others will remain.

In-water aquatic habitats, both shallow intertidal and deeper subtidal areas will also be affected by the project. Habitat conversions and temporal disturbance will occur from maintenance dredging and placement of jetty cross-sections, turnouts, crane set-up pads, barge offloading facilities, and causeways. There will also be permanent fill lasting more than a year at the South Jetty. The biological consultation has been completed between the Corps and NMFS and the U.S. Fish and Wildlife Service (USFWS). The consultation evaluated effects from a larger project footprint than the currently selected plan. The current plan selection has further minimized impacts and the following quantities represent the worst-case scenario from effects of barge offloading facilities after minimization measures have been implemented to the maximum extent practicable.

- North Jetty – 4.36 acres, 404 waters
- South Jetty – 13.84 acres, 404 waters
- Jetty A – 6.62 acres, 404 waters

For further detail, please see both Biological Opinions (NMFS, USFWS) in Appendix D.

Shallow-water habitat is especially important to several species in the estuary; therefore, specific initial estimates were also calculated regarding shallow-water habitat (shallow here defined as -20-ft or -23-ft below MLLW). About 21 acres of area at these depths will be affected by, maintenance dredging, and construction of the causeways and barge offloading facilities. However, this shallow-water footprint estimate does NOT including any expansion of the jetty's existing footprint. For this analysis, there was no distinction drawn between periodically exposed intertidal habitat and shallow-water sandflat habitat. As with wetland estimates, these approximations will be updated and may be reduced as project designs are refined and as additional analyses and surveys are completed to quantify changes in jetty and dune cross sections.

Consequently, these conversions and disturbances could result in disturbance of benthic invertebrates and a possible conversion of biological communities. Within an estimated 3-mile proximity of the MCR jetties, about 19,575 acres of shallow water habitat (anything -20 ft or shallower) exists, of which 33 acres represents a difference of much less than 1%. Therefore, these effects of habitat conversion are expected to be minimal, and unlikely to appreciably impact food resources or foraging behavior of juvenile or adult salmonids. Spawning does not occur in the areas of habitat conversion, so effects from the proposed action will not impact spawning substrate or behavior.

<u>Green Sturgeon</u>. The federally listed green sturgeon (southern DPS) occurs in the Columbia River estuary. Its distribution and habitat use in the estuary is not well known, though the area was recently listed as critical habitat (74 FR 52300). Green sturgeon would be expected to occur in the more tranquil estuary proper to a greater extent than in the vicinity of the MCR jetties. Though sandlance provide one food source for the green sturgeon, the proposed project is not expected to have any considerable impact on this supply. Given the existing relic rock substrate resulting from the current jetty structures, it is unlikely that the area in the vicinity of the jetty repairs provides much suitable habitat for sandlance. Therefore placements of the jetty stone on top of or near the existing footprint will not likely result in any measurable impact to the green sturgeon's food availability. There is a slightly higher likelihood of affecting sandlance habitat in the vicinity of the proposed barge off-loading sites, but these impacts are also anticipated to be negligible relative to the habitat available, and new ephemeral shallow-water habitat will likely be created as sand is accreted behind the repaired jetty structures. During construction, rock placement and dredging (turbidity) could disturb green sturgeon in the area. Some sand habitat in close proximity to the jetties that green sturgeon could potentially use would be permanently removed by placement of rock for off-loading facilities, jetty and stabilization stone.

The Corps and USGS have recently been working on a green sturgeon study in the Coos and Columbia River estuaries. Though results are preliminary and sample sizes are relatively small, acoustic receivers detected green sturgeon presence several times off the tip of Jetty A, near the North Jetty, and in the area of Social Security beach off the Clatsop Spit (USGS Preliminary 2009-2010 data). Information about specific use in the action area is still under development, but activities at Jetty A and North Jetty could cause some avoidance behavior by green sturgeon present during construction.

<u>Eulachon</u>. Impacts to federally listed eulachon are anticipated to be temporary and minimal. Eulachon occur in nearshore ocean waters and to 1,000 feet in depth, except for the brief spawning runs into their natal (birth) streams. After leaving estuarine rearing areas, juvenile eulachon move from shallow nearshore areas to deeper areas over the continental shelf. Larvae and young juveniles become widely distributed in coastal waters and are found mostly at depths up to about 49 feet. Though substrate likely to be impacted by dredge and fill activities may be similar to eulachon spawning habitat, the likely timing for work in late summer/early fall are outside of the typical

eulachon spawning season. Further, eulachon are planktonic feeders, so minimal losses of benthic invertebrates would not affect their foraging behaviors. Finally, the Biological Review Team further identified dredging activities as low to moderate threats for eulachon (NOAA 2009).

Bull Trout. Federally listed bull trout are known to have occurred in the Columbia River historically but now appear to occur only incidentally in the lower river. Water temperature and lack of spawning substrate likely limits their use at the MCR to migratory passage. Only sporadic records of bull trout in the Columbia River downstream of Bonneville Dam or passing through the dam have been documented dating to 1941. The proposed action will occur in the area designated as bull trout critical habitat, mostly serving as a migratory corridor. For these reasons, the proposed action is not likely to adversely affect bull trout.

Pacific Lamprey. Pacific lampreys are likely present in the vicinity of the MCR as juveniles out-migrate from February to June, adults return to freshwater from July to October. During the likely construction period between April and October, either end of the age distribution may be present during project activities. However, the project is not anticipated to impact their food sources or habitat, as the jetty system is not expected to discernibly alter the current distribution of predator or prey species, and the rocky substrate may provide some resting habitat on which lampreys could attach.

Resident Fish Species. The proposed action will directly affect species such as English sole, sand sole and starry flounder from the permanent loss of sandy bottom habitat preferred by these species from jetty and spur groin construction. Impacts to groundfish habitat are likely to be insignificant because the jetties do not provide highly productive rocky habitat due to low benthic productivity, unstable bottoms, and high current/wave action in the jetty areas. There may be a long term, intermittent impact from disturbance to some groundfish species that use the jetty habitat over the projected 6-year construction timeframe. Effects on groundfish migratory habitat are likely to be insignificant since disturbed areas will be small relative to the amount of available migratory habitat at the MCR. It is unlikely that disturbing this small amount of migratory habitat would impact the population levels of groundfish. On the other hand, construction of the spur groins would create a substantial amount of additional rocky habitat that would provide a permanent, long-term benefit to many groundfish species. Groundfish species should quickly recolonize the jetty areas once construction for a particular jetty is completed.

Essential Fish Habitat (EFH). The Columbia River estuary and the Pacific Ocean are designated as EFH for various groundfish and coastal pelagic and salmon species. The proposed action will directly affect EFH for Chinook salmon, coho salmon, English sole, sand sole and starry flounder from the permanent loss of sandy bottom habitat from jetty and spur groin construction. Short-term disturbances to EFH would result for lingcod, English sole, sand sole, starry flounder, black rockfish, brown rockfish, China rockfish, copper rockfish, and quillback rockfish. However, the addition of rock would increase EFH for lingcod, black rockfish, brown rockfish, China rockfish, copper rockfish, and quillback rockfish.

5.1.4. **Macrophytes and Invertebrates**

The mobile sand community at the MCR provides habitat for invertebrate species such as polychaetes, clams, amphipods, and crabs. This is a high-energy zone and generally less productive than other areas of the estuary. The jetties provide rocky intertidal and subtidal habitat. Dominant macrophytes include brown and green seaweeds and sea lettuce that are attached to the jetty rocks. Invertebrate species include sponges, hydroids, sea anemones, crabs, tubeworms, limpets, and mussels that live on the rocks or in crevices. There would be some loss of invertebrates with construction; however, those species occupying rocky habitats would colonize newly placed rock. No permanent, adverse effects to macrophyte and invertebrate populations are expected.

5.1.5. Dungeness Crab

Crabbing occurs in river between the jetties. Extensive use by crabs occurs on sandy bottom areas on the south side of the North Jetty and to a lesser extent on the north side of the South Jetty. Crabs move out of the estuary in large numbers (as 1+ aged crabs) along the northern part of the channel (south side of the North Jetty) in the fall and move into the estuary as megalops in the spring. Megalops enter the estuary passively by current mainly along the north side of the entrance (on the south side of the North Jetty) where current is strongest and salinity highest. No adverse impacts to adult and juvenile Dungeness crabs would be expected from the proposed action because modeling shows no appreciable permanent changes to velocity, salinity, and bed morphology at the MCR. The insignificant changes to water velocities from adding spur groins would not likely adversely alter the migration paths of young crabs moving in or out of the estuary.

5.1.6. Marine Mammals and Sea Turtles

Federally listed marine mammals and sea turtles that could occur in the vicinity of the vicinity of the MCR project are shown in Table 5-2.

Table 5-2. Federally Listed Marine Mammals and Sea Turtles

Listing status: 'T' means listed as threatened under the ESA; 'E' means listed as endangered. FR = Federal Register

Species	Listing Status	Critical Habitat	Protective Regulations
Marine Mammals			
Steller sea lion (*Eumetopias jubatus*)			
Eastern	T 5/5/1997; 63 FR 24345	8/ 27/93; 58 FR 45269	11/26/90; 55 FR 49204 10/1/09; 50 CFR 223.202
Blue whale (*Balaenoptera musculus*)	E 12/02/70; 35 FR 18319	Not applicable	ESA section 9 applies
Fin whale (*Balaenoptera physalus*)	E 12/02/70; 35 FR 18319	Not applicable	ESA section 9 applies
Humpback whale (*Megaptera novaeangliae*)	E 12/02/70; 35 FR 18319	Not applicable	ESA section 9 applies
Killer whale (*Orcinus orca*)			
Southern Resident	E 11/18/05; 70 FR 69903	11/26/06; 71 FR 69054	ESA section 9 applies

Sperm whale (*Physeter macrocephalus*)	E 12/02/70; 35 FR 18319	Not applicable	ESA section 9 applies
Marine Turtles			
Green turtle (*Chelonia mydas*)			
Excludes Pacific Coast of Mexico & FL	ET 7/28/78; 43 FR 32800	9/02/98; 63 FR 46693	ESA section 9 applies
Leatherback turtle (*Dermochelys coriacea*)	E 6/02/70 ; 39 FR 19320	1/5/10; 75FR319	ESA section 9 applies
Loggerhead turtle (*Caretta caretta*)	T 7/28/78; 43 FR 32800	Not applicable	7/28/78; 43 FR 32800
Olive ridley turtle (*Lepidochelys olivacea*)	ET 7/28/78; 43 FR 32800	Not applicable	ESA section 9 applies

Steller sea lions breed along the West Coast from California's Channel Islands to the Kurile Islands and the Okhotsk Sea in the western North Pacific Ocean. They are year-long residents along the Oregon Coast. Steller sea lions are not known to use the North Jetty or Jetty A. A major haul-out area for Steller sea lions occurs at the head of South Jetty, where the monthly averages between 1995 and 2004 ranged from about 168 to 1106 animals at the South Jetty. They primarily use the concrete block structure that has become an island with the erosion of the rubble mound structure landward.

This concrete block structure is the farthest ocean-ward, above-water portion of the South Jetty. Their use of the South Jetty is concentrated more in the winter months and is least during the May-July breeding season when adults disperse to rookeries. Placing jetty rock near or at the head will disturb Stellar sea lions by forcing them to move off haul out areas; however, they will be able to haul out elsewhere in the vicinity. Prey resources for sea lions are not expected to be affected. The proposed action is not likely to adversely affect Steller sea lions.

The whale species listed in Table 5-2 are all federally endangered and occur as migrants off the Oregon Coast in waters typically much farther from shore than the nearshore MCR area. Blue whales occur off the coast in May and June, as well as in August through October. Blue whales typically occur offshore as individuals or in small groups and winter well south of Oregon. Fin whales also winter far south of Oregon and range off the coast during summer. Sei whales winter south of Oregon and probably occur in southward migration off the Oregon Coast in late summer and early fall. Sperm whales occur as migrants and some may summer off the coast; they forage in waters much deeper than those in the nearshore area. Humpback whales primarily occur off the Oregon Coast from April to October with peak numbers from June through August. Humpback whales are particularly concentrated in Oregon along the southern edge of Heceta Bank and are found primarily on the continental shelf and slope. North Pacific right whales may occur off the coast during winter and summer in cool waters north of 50 degrees north latitude. During winter, killer whales have moved into Pacific coastal waters and are known to travel as far south as central California. Sightings of killer whales off the coast of Washington, Oregon, and California indicate that they are utilizing resources in the California current ecosystem. These whale species are migratory in the vicinity of the MCR, generally are not found close to shore, and are highly mobile. Moreover, MCR is likely not the preferred habitat for these species, they are unlikely to feed in the vicinity of the jetties, and jetty rehabilitation work would have inconsequential impacts on their prey base. The proposed action is not expected to adversely affect these whale species.

The sea turtle species listed in Table 5-2 are migratory in the vicinity of the MCR, are generally are not found close to shore, and are highly mobile. The loggerhead sea turtle, green sea turtle, leatherback sea turtle, and olive Ridley sea turtle have been recorded from strandings along the Oregon and Washington coasts. The occurrence of sea turtles off the Oregon Coast is associated with the appearance of albacore. Albacore occurrence is strongly associated with the warm waters of the Japanese current. Because these warm waters generally occur 30 to 60+ miles offshore from the Oregon Coast, these sea turtle species do not typically occur in the nearshore MCR area. In 2010, the NMFS proposed a revised critical habitat designation for leatherback turtles that includes the vicinity of the MCR project (*Federal Register* 75:319). However, the project area is not likely preferred habitat for the species, they are unlikely to feed in the vicinity of the jetties, and rehabilitation work will have inconsequential impacts on their prey base. The proposed action is not expected to adversely affect these sea turtle species.

5.1.7. **Terrestrial Wildlife and Seabirds**

Federally listed wildlife and seabird species that could occur in the vicinity of the MCR project are shown in

Table 5-3. A description of these species is provided below.

Table 5-3. Federally Listed Terrestrial Wildlife and Seabirds

Listing status: 'T' means listed as threatened; 'E' means listed as endangered. FR = Federal Register

Species	Listing Status	Critical Habitat
Marbled Murrelet *(Brachyramphus marmoratus)*	T 10/01/92; 57 FR 45328; 2/11/09 74 FR 6852	5/24/96; 61 FR 26255; 2/11/09; 74 FR 6852

Northern Spotted Owl *(Strix occidentalis caurina)*	T 6/26/90; 55 FR 26114	1/15/92; 57 FR 1796; 8/13/08 73 FR 47325
Columbian White-tailed Deer *(Odocoileus virginianus leucurus)*	E 3/11/67; 68 FR 43647	Not applicable
Oregon Silverspot Butterfly *(Speyeria zerene hippolyta)*	T 07/02/80; 45 FR 44935	7/02/80; 45 FR 44935

Marbled Murrelet

The marbled murrelet is a near-shore marine bird that is most frequently observed within 1.5 miles of shore. Marbled murrelets forage just beyond the breaker-line and along the sides of river mouths where greater upwelling and less turbulence occurs. Marbled murrelets nest in old growth/mature coniferous forests. The low incidence of marbled murrelets at coastal locations is probably related to the loss of old growth coniferous forest from harvest and/or fire (*Federal Register* 56:28362). Marbled murrelets are expected to occur in the general vicinity of the MCR, specifically on the Columbia River bar and nearshore waters. Their numbers are anticipated to be low throughout the general project area. Cape Disappointment State Park is located about 1.6 miles northeast of the North Jetty at Benson Beach and contains suitable habitat for marbled murrelet nesting. While nesting has not been documented in this area, birds have been noted in flight during the nesting season. Periodic minor disturbance may occur to marbled murrelets due to noise generated from trucks on haul roads through Washington State Parks property adjacent to possible nesting habitat, although all truck traffic would occur only during daylight hours. The following measures would be employed during the marbled murrelet nesting season (April 1 to September 15) to reduce impacts from noise to nesting murrelets:

- Trucks will only be allowed to use roads through Cape Disappointment during daylight hours.
- Trucks will not unnecessarily stop along the roads through Cape Disappointment.
- Trucks will be prohibited from using compression brakes (jake brakes) on roads through Cape Disappointment.

No adverse impacts on feeding by marbled murrelets would be expected from the proposed action because modeling shows no appreciable permanent changes to velocity, salinity, and bed morphology at the MCR. Because the proposed action is located approximately 1.6 miles from potential nesting areas, periodic disturbance may occur to marbled murrelets in project vicinity because of noise generated from construction and from trucks on the haul roads through Washington State Parks property. Conservation measures will further avoid and minimize disturbance to marbled murrelets.

Western Snowy Plover

Western snowy plovers historically occurred in the vicinity of Clatsop Spit although no breeding or wintering plovers have been reported from these beaches in recent years. This evidence was supported by a survey completed by the USFWS and Corps representatives in May 2010 when no plovers were observed. However, two birds were sighted in recent surveys (Blackstone 2012). Benson Beach and Clatsop Spit are not designated as critical habitat, although a Habitat Conservation Plan (HCP) has been developed for Clatsop Spit by Oregon Parks and Recreation Department (OPRD). Most of the land-based construction activities will occur above the MHHW levels in the near and immediate vicinity of the jetties. Thus, this limits the geographical extent of the disturbance effects from construction clearing, and reduces the likelihood that actions would occur in foraging areas preferred by snowy plover. According to USFWS, European beachgrass reduces the amount of open, sandy habitat and contributes to steepened beaches, and increases habitat for predators. These conditions are problematic at the Spit, and may actually be improved by the proposed foredune augmentation, clearing for stockpiling and construction staging, and eventual replanting of native dune plants.

A draft Habitat Conservation Plan (HCP) for western snowy plovers was prepared (Jones and Stokes 2007 and 2009) and included restoration activities at various locations along the Oregon Coast including Clatsop Spit. The Snowy Plover Management Area identified on Clatsop Spit included 0.62 mile of beach along the Columbia River within the park and is located north of the South Jetty. This area is owned by the Corps and leased by the OPRD. The OPRD manages the natural resources, facilities, and visitors within the leased area. Activities that OPRD are interested in include predator management, symbolic fencing, public outreach and education, habitat restoration and maintenance (which could include grading of vegetated areas), and monitoring. On December 17, 2010, the Corps joined the USFWS, other federal agencies, and the State of Oregon in signing a statewide HCP for snowy plovers. The area proposed for construction, storage, and staging is mostly outside of the area on Clatsop Spit identified in the HCP. Thus, the proposed action is not likely to adversely affect snowy plovers. The Corps is implementing best management practices (BMPs) that are in alignment with our efforts under the HCP.

The Corps is investigating opportunities to create western snowy plover nesting habitat on Clatsop Spit within Fort Stevens State Park. As staged areas could be attractive to plovers, the Corps will consider creation of habitat after use of the Spit for rock storage is completed to avoid potential limitations to rock storage and transport on the Spit if plovers begin to nest in staging areas. The Corps will also consider options to create plover habitat concurrently with rock storage if it is certain that plover use of the created habitats and beaches would not interfere with the Corps' ability to use Clatsop Spit throughout the life of the project. This habitat area would be implemented with the intention to create more preferable nesting areas such that plover are lured away from the potential attractive nuisance of the cleared staging areas. In other words, the Corps is creating bare sand areas that would attract birds away from construction site impacts. Habitat maintenance each year after creation would be required to preserve functional habitat. The Corps would maintain these sites during construction, but maintenance would not be Corps responsibility after completion. The Corps has had initial discussions with the USFWS and OPRD regarding snowy plover habitat creation.

Short-tailed Albatross

There have been three confirmed sightings of short-tailed albatross off the Oregon Coast. The closest sighting to the project was 20 miles southwest of the MCR (Marshall et al., 2003). This species would not be expected to occur in the vicinity of the MCR.

Northern Spotted Owl

Northern spotted owls are nocturnal predators that generally prey primarily on small forest mammals and nest from February to June, with parental care of the juveniles lasting into September. Spotted owls live in forests characterized by dense canopy closure of mature and old-growth trees, abundant logs, standing snags, and live trees with broken tops; they prefer older forest stands with variety multi-layered canopies of several tree species of varying size and age, both standing and fallen dead trees, and open space among the lower branches to allow flight under the canopy. Benson Beach and Clatsop Spit have large areas of land that have accreted since the construction of the MCR jetty system and are not old enough to have evolved these forest characteristics. These habitat conditions do not exist in the immediate vicinity where the majority of the construction activities will occur. Benson Beach and Clatsop Spit are not designated as critical habitat.

Columbian White-tailed Deer

Columbian white-tailed deer occur on the Oregon and Washington mainland and instream islands primarily from Skamokawa, Washington upstream to Port Westward, Oregon. Their closest location to the MCR jetties project vicinity is 34 miles upstream at the Julia Butler Hansen National Wildlife Refuge near Cathlamet, Washington. This species does not occur in the vicinity of the MCR.

Oregon Silverspot Butterfly

The Oregon silverspot butterfly occupies coastal headlands or Coast Range peaks that provide specific habitat features, primarily because of the presence of its host plant, the early blue violet (*Viola adunca*). The closest populations of this butterfly to the project area occur at Camp Riles in Clatsop County, Oregon to the south and at Long Beach, Washington to the north. No Oregon silverspot butterfly populations are known to occur in the project area, and suitable viola habitat was not observed during the plant community surveys on Clatsop Spit. The proposed project would not be expected to have any effect on this species.

Waterfowl

Common loon, Clark's grebe, western grebe, horned grebe, red-necked grebe, Brandt's cormorant, bufflehead, rhinoceros auklet, Cassin's auklet, tufted puffin, black oystercatcher, harlequin duck, fork-tailed storm petrel, and peregrine falcon are species of concern in the states of Oregon and/or Washington and could occur in the vicinity of the MCR. The proposed action is not expected to significantly affect these species because they could readily avoid the construction areas.

Pelagic and Brandt's cormorants nest on the cliffs of Cape Disappointment. Three species of terns occur in the Columbia River or over nearshore waters. Caspian terns are present from April to September and have established a large colony on East Sand Island within the estuary. Common and arctic terns occur off the Oregon and Washington coasts from April to September principally during migration. Shorebirds found on coastal beaches at the MCR and estuarine flats include sanderlings and various species of sandpipers, dunlins, and plovers. Various species of gulls are common in the vicinity of the MCR. Shearwaters, auklets, murres, fulmars, phalaropes, and kittiwakes are occasionally noted in the vicinity of the MCR but more commonly offshore. Again, the proposed action is not expected to significantly affect these species because they could readily avoid the construction areas, and impacts to shallow intertidal habitat is minimal relative to the availability of adjacent foraging habitat, and the short temporal loss is likely to be replaced with accreted habitat that is captured and formed behind the new and repaired structures. Furthermore, wave and current action at the jetty features likely limits shorebird use of these areas.

It is unlikely that bald eagles would be impacted by the proposed action because they can readily avoid the construction areas while foraging. The Cape Disappointment bald eagle pair nests in close proximity to roads through the park, but use of haul roads is less of a concern for nesting bald eagles because they appear to be acclimated to traffic and noise.

Overall, the proposed action is not expected to significantly affect terrestrial wildlife and seabird species. These species could readily avoid the construction areas, any impacts to shallow intertidal habitat would be small relative to the availability of adjacent foraging habitat, and the short temporal loss is likely to be replaced with some accreted habitat that is formed behind the repaired jetty structures. This habitat will likely be ephemeral and will not provide a long-lasting benefit. At the jetty structures, wave and current action likely limits seabird and shorebird use of these areas.

5.1.8. Vegetation

Federally Listed Plant Species

Nelson's Checker-mallow (*Sidalcea nelsoniana*), a federally threatened species (*Federal Register* 58:8235), is a perennial herb with tall, lavender to deep pink flowers. Critical habitat has not been designated. Flowering occurs as early as mid-May and extends into September. This plant most frequently occurs in Oregon ash swales and meadows with wet depressions, or along streams. It also grows in wetlands in remnant prairie grasslands or along roadsides at stream crossings where non-native plants, such as reed canarygrass, blackberry, and Queen Anne's lace, also are present. Most sites where the species occurs are in the Willamette Valley in Oregon; the plant is also found at several sites in the Coast Range of Oregon and at two sites in the Puget Trough of southwestern Washington. The proposed action would not occur in or significantly affect habitat for this species.

5.1.9. Wetland and Waters of the U.S. Mitigation

The process used to determine mitigation was to first maximize avoidance of the impacts. However, some impacts to wetlands and waters remain unavoidable. Mitigation for unavoidable impacts was then based on the extent and quality of the habitat affected.

Impacts associated with wetlands have a known and quantified footprint and are the same under all the construction alternatives. Specific wetland mitigation sites and methods have been identified and developed. A cost effective incremental cost analysis was done on this mitigation.

The exact extent of impacts to 404 waters of the US is unknown because they are contingent upon the delivery method of the rock which will be determined during contract bidding. Impacts associated with method of delivery are unknown, therefore the extent of mitigation is uncertain and variable based on the mode of stone delivery and placement. Impacts will be greater if the contractor chooses to use offloading facilities; hence, the maximum potential effects were evaluated in the EA. Because of this, maximum mitigation requirements were also assumed for 404 waters, and the cost associated with mitigating these impacts was estimated based on this scenario. The costs were estimated using a similar representative mitigation project. Mitigation requirements will be further coordinated with the adaptive management team (AMT) which is described below. A cost effective incremental cost analysis will be completed on the refined mitigation requirements during design development.

Wetland mitigation options for Jetty A and the South Jetty are very limited. No land is available near Jetty A; therefore, it's most cost effective to use lands near the North Jetty because construction mobilization costs are much lower there. Also, it is environmentally preferable to use lands near the North Jetty.

The selected plan design and construction methods for repair and rehabilitation of the MCR jetties have been developed and refined to take advantage of opportunities to avoid and minimize to the maximum extent practicable the project's ecological impacts to wetland, aquatic habitats, and species per requirements under the Clean Water Act and Executive Order (EO) No. 11990. Efforts were made to reduce the project footprint and to locate staging areas away from wetland and waters areas. However, there will be unavoidable effects to wetlands and waters as aquatic habitat will be filled and converted as a result of the project.

Staging and rock stockpile areas are required to work with the large stone and to construct the repairs. A balance was struck to provide and locate such staging areas that allowed project completion in an efficient and timely manner while minimizing both the areal and temporal extent of project impacts to wetlands and waters. This also includes siting offloading facilities in areas that minimize the extent of dredging and impacts to critical shallow water habitat. To avoid and reduce shallow-water impacts, the Corps determined that offloading facilities would avoid locations within Baker Bay as well as in the small bay area along the north shore of Clatsop Spit. Further, by potentially utilizing barging operations to supply and place the large-sized and large volume of stone, this both reduces the impacts of traffic and somewhat avoids and reduces safety issues with large trucks entering and exiting the Coast Guard and State Park facilities, respectively.

It is assumed all wetlands will be impacted for more than one year. Impacts to 404 waters of the US will also occur for more than one year with maintenance dredging and continuous use. Facilities may be removed or left in as permanent fixtures depending on hydraulic conditions at the offloading sites and along the adjacent jetties themselves, as well as costs associated with both removal and mitigation. For these reasons, impacts are considered permanent under assumptions for the worst-case scenario. Mitigation will be commensurate with the project footprint, which may be reduced further depending on whether or not the final implementation requires barge offloading facilities.

Official wetland delineations have now been completed for all three jetties. Prior to this at release of the Draft EA, preliminary available information allowed the Project Delivery Team (PDT) to initially locate construction activities and features to reduce anticipated impacts to wetlands. This information was also used to calculate initial estimates regarding potential wetland impacts. The original estimates, pre-delineation, approximated wetland acreages potentially impacted to be: North Jetty ~4.78 acres, South Jetty up to ~22 acres, and Jetty A up to ~11 acres, for an estimated total of ~38.28 acres of potential wetlands impacts. Post wetland delineations and after further minor refinement of locations for staging areas since the release of the draft EA, these impact numbers have been revised and dramatically reduced.

Ultimately, the project seeks to achieve no net loss in wetland habitat, to protect, improve and restore overall ecosystem functions, and to provide mitigation actions that are anticipated to restore affected benefits to aquatic species in the vicinity of the project. Towards that end, specific project footprints and activities described above have been identified, categorized, and quantified with conservative estimates where appropriate. Per initial consultation with regulating resource agencies and as a result of the wetland types, functional values and aquatic habitat proposed to be impacted, a preliminary ratio of 2:1 was suggested for wetland mitigation, and a ratio of 1.5:1 for waters other than wetlands to offset impacts that would occur to aquatic resources. As required, the Corps will mitigate for impacts which could not be otherwise avoided or minimized. Mitigation plans currently address three general categories: actions that create wetlands, offsetting actions for 404 impacts in-water, and actions that re-stabilize and replant construction-disturbed upland habitats. Onsite or adjacent mitigation to address impacts is preferred.

The Corps coordinated with the regulating agencies to determine appropriate mitigation ratios based on functions and typical compliance requirements. Proposed wetland mitigation is at a 2:1 ratio and mitigation for waters other than wetlands is at a 1.5:1 ratio. Though WQCs have not yet been obtained, the Corps has been working closely with the Certifying agencies to ensure it is meeting its legal responsibilities. The effects evaluated in the BA and the BiOp assumed a larger suite of actions, the effects of which have been reduced in the current plan selection. It is anticipated that through meetings and discussions with the AMT (the role of which is described in the coordination section of this chapter), the total for proposed mitigation will reflect the reduced project footprint. All agencies will be kept abreast of the project development to ensure construction and mitigation commitments are appropriate and realized.

Wetlands near South Jetty (on Clatsop Spit)

In order to acquire the 44 acres needed for staging and rock stockpiles, 2.65 acres of unavoidable wetland impacts will occur at the South Jetty. However, by slightly revising locations, maintaining hydrologic connections at wetland and lagoon crossings, and by maintaining a 50-ft wetland, shoreline, and riparian buffer for preserved areas whenever possible, these impacts have been greatly reduced and minimized relative to initial conservative impact estimates. This includes limiting the roads required to cross wetlands to a 20-ft width and requiring culverts to maintain hydrologic connectivity at crossings. In addition to wetlands, about 3.5 of the existing 5.2 acres of other waters of the US will be impacted in the form of fill in a lagoon area adjacent to and along the jetty. There will be a road and crossing over these waters, which will be culverted in order to maintain flows into and out of the marsh wetland complex; and the 40-ft wide causeway/jetty access roadway will be constructed immediately adjacent to the jetty in order to minimize interference with and impacts to the inlet of the marsh complex.

According to the Cowardin Classification system (1979), of the wetlands impacted, approximately: 0.77 acres are classified as Estuarine-Intertidal-Emergent-Persistent; 0.66 acres are classified as Palustrine-Forested-Needled-leaved-Evergreen; 0.75 are classified as Palustrine-Emergent-Non-persistent; and, 0.47 acres are classified as Palustrine-Forested-Broad-leaved-Deciduous.

As described in the South Jetty section under Landforms 2.1.3., wetlands were scored for grouped service functions as define by Oregon Rapid Wetland Assessment Protocol, 2010 (ORWAP), and the categories depressional and estuarine were identified.

It is notable that Cowardin and Hydrogeomorphic (HGM) classifications are not necessarily the same thing. For ORWAP scoring purposes, the HGM class for Estuarine appears broader than the Cowardin class. Because a portion of the wetlands preserved and impacted may be small, fringe parts of a larger wetland complex or feature (with possibly a tenuous connection to those other wetlands), therefore the dominant hydrological influence of the greater wetland area was considered. In some cases though the wetland was classified under Cowardin as Palustrine (considering landscape position and degree of connectivity of the delineated area to the greater wetland area), the greater dominating hydrologic regime was tidal (therefore the Estuarine classification in ORWAP).

Following this method in determining the types of wetland impacts, this brings the totals under the ORWAP categories to 1.15 acres of impacts to depressional wetlands at the South Jetty, which were ranked relatively as follows: low for hydrologic function and fish support group; and high for water quality, carbon sequestration, aquatic support, and terrestrial support. Alternatively, the relative scores for the grouped service values were: low for hydrologic function, terrestrial support, and public use and recognition; equal for provisioning services, and high for water quality, fish support, and aquatic support. The wetlands also ranked relatively high for ecological condition and sensitivity, and low for stressors.

In comparison to State wetland scores for grouped service functions as define by ORWAP (2010), 1.49 acres of impacts would affect estuarine wetlands at the South Jetty which are ranked relatively as follows: low for hydrologic function, aquatic support, and terrestrial support; and high for water quality, carbon sequestration, and fish support group. Alternatively, the relative scores for the grouped service values were: low for hydrologic function, aquatic support, terrestrial support, and public use and recognition; equal for provisioning services, and high for water quality and fish support. The wetlands also ranked relatively high for ecological condition, and low for stressors and sensitivity.

These wetlands will be mitigated near the impact site in an area identified in Trestle Bay near the channel entrance to Swash Lake. At a 2:1 mitigation ratio, this equals about 5.3 acres of wetland mitigation. Anecdotally, it is thought that the uplands in this area are the result of previous historic fill from the dredging the adjacent channel, so that excavation of uplands would result in restoration of wetland that are likely to be intertidal. There is also a former ODOT mitigation site that the Corps will likely abut. This is an appropriate mitigation site because it is within the same subwatershed (HUC 7), and per the ORWAP scoring and Cowardin classification, the adjacent areas have wetland types similar to those being impacted. The likelihood of successful wetland plant establishment is also higher because of proximity to already functioning native wetland communities and exisiting hydrology.

In comparison to State wetland scores for grouped service functions as define by ORWAP (2010), depressional wetlands at the South Jetty mitigation area are ranked relatively as follows: low for hydrologic function, carbon sequestration, fish support group, and aquatic support; and high for terrestrial support; and equal for water quality. Alternatively, the relative scores for the grouped service values were: low for hydrologic function, aquatic support, terrestrial support, and public use and recognition; equal for provisioning services, and high for water quality and fish support. The wetlands also ranked relatively high for ecological condition and sensitivity, and low for stressors.

In comparison to State wetland scores for grouped service functions as define by ORWAP (2010), estuarine wetlands at the South Jetty mitigation area are ranked relatively as follows: low for hydrologic function and water quality; and high for carbon sequestration, fish support group, aquatic support, and terrestrial support. Alternatively, the relative scores for the grouped service values were: low for hydrologic function, aquatic support, terrestrial support, and public use and recognition; equal for provisioning services, and high for water quality and fish support. The wetlands also ranked relatively high for ecological condition and stressors, and low for sensitivity.

Proximity of the uplands proposed for wetland conversion to the existing wetlands from both classes that had similar ORWAP scores at the mitigation site, in addition to tidal and precipitation hydrology should serve as reasonable indicators for potential success of the mitigation site. For all proposed mitigation, detailed designs, plans, and specifications will be further determined in the next stages of project development and will be constructed concurrent with wetland impacts.

Actions adjacent to or onsite of the South Jetty that were identified to mitigate wetland impacts include excavation of low and high saltwater marsh wetlands and new interdunal wetlands adjacent to existing wetlands; establishment of native wetland plant communities and removal of invasive species around a buffer zone for wetlands; restoration or provision of hydrology to newly excavated wetlands via appropriate elevation design; and/or restoration of wetland connectivity between existing fragmented wetlands. Offsite opportunities for wetland mitigation in the estuary that warranted further investigation were associated with: levee breaches, inlet improvements, or tide gate retrofits, as appropriate. However, these were not the preferred mitigation alternative as they were further away from the impacted areas and were not of similar wetland or habitat type impacted. Purchasing mitigation bank credits was considered as a possibility, though this is currently constrained by limitations of service area and availability of appropriate wetland types. Hydrology and vegetative communities are heavily influenced by elevation; therefore, providing improved hydrology combined with strategic excavation and appropriate plantings should result in a simple and self-sustaining design and outcome.

Wetlands near Jetty A

Rock storage and staging activities require a minimum of about 23 acres to meet the project need for implementation at Jetty A. This encompasses most of the area adjacent to the jetty root at the Coast Guard Station. A total of about 0.91 acres of wetland at Jetty A will also be filled due to rock storage and construction staging activities. Unfortunately, these wetlands cannot be avoided, but impacts to adjacent water of the U.S. will be minimized by implementing a 100-ft buffer beyond the Highest High Tide elevation, which is consistent with the setbacks required for lands designated as “Conservancy” by Pacific County. Of the wetlands impacted, 0.74 acres rated as a Category III Interdunal, Depressional wetlands with scores under 26. 0.17 acres rated as Category 1 Estuarine, Freshwater Tidal Fringe wetlands.

Because of onsite space constraints and site conditions, these wetlands at Jetty A will be mitigated at the North Jetty, north of the North Jetty Access Road. At a 2:1 mitigation ratio, this equals about 1.82 acres of wetland mitigation, plus the required buffer. These requirements were determined and align with joint Corps and Washington Department of Ecology, 2006 (WADOE) guidance. Reduced disturbance coupled with improved potential hydrology and adjacent functioning wetlands at North Jetty compared to at Jetty A make the success of wetland creations more likely at the location at the North Jetty compared to any creation at Jetty A. Therefore the mitigation for Jetty A is 1.82 acres. Jetty A mitigation ratios and acreages are likely close to the final amounts, they may change following further coordination with WA Department of Ecology and receipt of conditions in the Washington State Clean Water Act 401 Water Quality Certification and the determination of Coastal Zone Management Act Consistency.

Fill in Other Waters of the U.S.

In-water habitats (below MHHW), both shallow intertidal and deeper subtidal areas will also be affected by the project. These waters are also considered "waters of the US" as defined by the Clean Water Act. Habitat conversions and impact to 404 waters will occur from lagoon fill, maintenance dredging, jetty cross-sections, turnouts, barge offloading facilities, and causeways. Effects to waters and the aquatic resources residing there will occur on a temporal and spatial scale. Though dredged areas may refill over time and some facilities and fill may be removed, there will still be repeated and chronic site disturbance in these waters over the duration of the project. There will also be permanent lagoon fill at the North Jetty root and temporary, partial lagoon fill at the South Jetty for construction access. This fill will be in place for several years.

The calculated extents of impacts were strictly based on the area of habitat that was converted by fill or removal. They did not include value or functional assignments regarding the significance of the conversion, whether it was a beneficial, neutral, or detrimental effect to specific species, nor if conversions created unforeseen, indirect far-field effects. For example, acreage of conversion for shallow sandy sub-tidal habitat to rocky sub-tidal habitat was calculated in the same manner as conversion from shallow intertidal habitat to shallow sub-tidal habitat. Multiple aquatic species utilize these waters, including macro-invertebrates like crabs, benthic organisms, marine mammals, and various other fish and wildlife species. It is also notable that impacts to 404 waters of the US will occur in an area that is listed as Essential Fish Habitat (EFH) for various species as well as in Critical Habitat for several listed ESA species. This impact was described in the 404(b)(1) analysis.

In WA at MCR, the designated CWA beneficial use designations for fresh waters by Water Resource Inventory Area (WRIA) include the following general and specific uses: Aquatic Life Uses - Spawning/Rearing; Recreation Uses; Water Supply Uses; Misc. Uses - Wildlife Habitat, Harvesting, Commerce/Navigation, Boating, and Aesthetics. In OR, the following list of beneficial uses were identified: Anadromous Fish Passage; Drinking Water; Resident Fish and Aquatic Life; Estuarine Water; Shellfish Growing; Human Health; and Water Contact Recreation. These designated beneficial uses also include specific water quality criteria to protect the most sensitive uses, which includes use by salmonids for rearing and migration. For this reason, mitigation under the CWA also complements protections and conservation measures under the ESA for salmon and steelhead.

Because of these impacts, the Corps has proposed mitigation actions at a ratio of 1.5 :1 to offset temporal and spatial impacts to 404 waters and associated aquatic resources. This ratio was determined with input from the regulating resource agencies considering several factors including: beneficial use listings that involve species with EFH and critical habitat designations in the impacted areas, the duration of the construction period, the number of different beneficial uses in the area impacted by the project, and the temporal and spatial extent of the actions. These actions are not proposed to directly mitigate or compensate for any project-related impacts to ESA-listed species but will mitigate for effects to CWA 404 waters of the US. However, the 404 mitigation actions will also complement but are not driven by Conservation Recommendations in the NMFS BiOp for recovery of ESA-listed salmonid habitats and ecosystem functions and processes.

Mitigation features will be commensurate with impacts and will be designed to create or improve aquatic habitat. In-kind mitigation opportunities for impacts to 404 waters were investigated, specifically tidal marsh, swamp, and shallow water and flats habitat. Though a specific site or action has yet to be determined for mitigation of impacts to waters other than wetlands, if possible fish access to these mitigation features will be an important consideration.

Table 5-4 Possible Mitigation Features for Impacts to 404 Waters of the US

Feature/Site	Area Affected	Type and Function
Trestle Bay	5 to 8 acres with potential for additional acres	Estuarine Saltwater Marsh Wetland and Intertidal Mudflat Creation and Restoration • Create and expand estuarine intertidal brackish saltwater marsh wetland habitat • Expand and restore Lyngby sedge plant community • Expand/increase intertidal shallow water habitat, including dendritic mud flats and off-channel habitat • Remove and control invasive species and improve/restore diversity and density of native plant assemblages • Increase habitat complexity for fisheries benefit • Potentially expand floodplain terrace and improve riparian function • (Re)introduce natural tidal disturbance regime to area currently upland dunes
Wetland Creation at Cape Disappointment	Up to ~10 acres	Creation and Expansion of Interdunal Wetland Complex • Excavation of new interdunal wetlands adjacent to existing wetlands • Establishment of native wetland plant communities and removal of invasive species around a buffer zone • Restoration or provision of hydrology to newly excavated wetlands via appropriate elevation design • Restoration of wetland connectivity between existing fragmented wetlands via culvert retrofits, if feasible
Tide Gate Retrofits for Salmonid Passage	Variable	Select Tributaries from ODFW Priority Culver Repair List – Tributary Reconnection • Restore and improve existing fish passage and provide access throughout greater range of flows to off-channel juvenile rearing • Restore and increase habitat complexity for fisheries benefit • Restore and improve adult salmonid access to headwaters and potential spawning habitat
Pile Dike Removal	Variable	Remove Existing Pile Dike Fields • Restore and improve existing aquatic habitat • Restore and increase habitat complexity for fisheries benefit
Beneficial Use of Dredge Material	Variable	Beneficial Placement of Dredge Material • Restore and improve existing aquatic habitat • Restore and increase habitat complexity for fisheries benefit

From the list of possible mitigation features shown in Table 5-4, one or a combination of actions will be selected for further development and implementation in order to offset actions affecting 404 waters. Selection will occur by the Corps with input from the AMT regarding legal requirements and completion of supplementary compliance documentation, and work is anticipated to be completed concurrent with jetty repair actions. Please refer to the CE/ICA discussions in chapter 2 where estimates were based on the worst-case analysis for impacts to 404 waters. These will be refined during DDR.

General Wetland Mitigation Design and Monitoring

Materials removed from impacted wetlands will be reused in the created wetlands as appropriate to take advantage of the existing wetland seed bank and hydrologic soils constituents. Plantings, revegetation, and invasive species removal will also be implemented, including the required buffer around the new wetland area. It is anticipated that upland material removed during wetland creation will be placed as part of the lagoon fill on the South Jetty. With ample precipitation, functioning adjacent reference sites, and appropriate plantings, the likelihood of successful wetland establishment is reasonably high.

At the South Jetty, wetland mitigation will take place adjacent to an existing mitigation site further southwest of the impact area at the bottom of Trestle Bay such that there are reference elevations and hydrophytic species to facilitate design planning and vegetation establishment, respectively. The mitigation location near Swash Lake is not as close to the area of impacts as the site at the North Jetty, but the proposed location is further away from areas experiencing heavy recreation and all-terrain vehicle (ATV) use such as is occurring in the existing wetlands on Clatsop Spit itself. Therefore, the likelihood of successful wetland establishment is greater in the proposed location.

The process for creating the wetlands at the South Jetty site will be similar to that at the North Jetty, but an additional dendritic channel may also be included as appropriate such that newly created wetlands experience an estuarine connection like those that are being impacted by the project. This will also involve excavation to create hydrologic conditions based on tidal and reference site elevations

Monitoring of all mitigation sites is expected to occur prior to, during, and for three years after mitigation implementation. For wetlands, sample reference plots will be established along with a photo point, and success criteria will be based on achievement similar or better functions and values scores relative to those indicated by the delineations for those impacted by the project. Monitoring components will likely include the following elements, which may be modified as further mitigation development details are available: percent survival; percent cover; percent of native vs. non-native species; and achievement of appropriate hydrology. Hydrologic indicators will include establishment of topography and contouring/geomorphology that is similar to adjacent representative sites, and in the case of South Jetty, achievement of regular tidal inundation. Appropriate monitoring criteria will also be developed for the mitigation to waters other than wetlands.

Refinement and implementation of this overall mitigation plan will help protect species and habitats while restoring wetland, in-water, and upland functions affected by the proposed action. Monitoring and maintenance of mitigation will be required to ensure successful establishment of mitigation goals and satisfactory return on investment. These mitigation actions and monitoring results will also be recorded on the Corps mitigation website at:

https://sam-db01mob.sam.ds.usace.army.mil:4443/pls/apex/f?p=107:1:1390572094248259.

Regular coordination with the AMT will further facilitate implementation of appropriate mitigation for impacts to wetlands and waters that appropriately offset affected habitat and are complementary to the framework for successful protection and preservation of aquatic resources, ESA listed species, and high-value habitat. The mitigation action(s) for 404 waters of the US ultimately selected will be evaluated in a subsequent NEPA document(s) when further details are available.

General Aquatic Habitat Mitigation Design and Mitigation Monitoring

Specific opportunities were investigated in the Columbia River estuary and Youngs Bay and several are under consideration to mitigate for impacted aquatic functions in 404 waters of the US. Depending on further development and determination of appropriate mitigation siting for final impacts to 404 waters, a specific project or combination of projects will be designed and constructed concurrently as the proposed repair and rehabilitation options are completed over time. Proposed projects are subject to further analysis, and unforeseen circumstances may preclude further development of any specific project. In all cases, final selection, design, and completion of specific mitigation features is contingent on evolving factors and further analyses including: potential reduction in estimated impact acreage due to alterations in project implementation, hydraulic and hydrologic conditions, cultural resource issues, etc. For this reason a suite of potential proposals has been identified and subsequent selection of one or some combination of these or other projects and designs will occur during continued discussion with resource agencies participating on the AMT. The Corps will make a decision regarding the specific mitigation proposal for waters other than wetlands and then will vet the final designs through the AMT in order to obtain necessary legal clearances.

Actions considered and investigated to provide mitigation for in-water habitat impacts include levee breaches, inlet improvements, or tide gate retrofits. However, mitigation efforts must consider in-kind mitigation and are constrained by the project's O&M authority, which precludes acquisition of private property and does not authorize breaches of federal levees. Additional associated actions that were investigated and may be implemented with the wetland mitigation include: excavation in sand dunes and uplands to specified design elevations in order to create additional intertidal shallow-water habitat with dendritic channels and mud flats, and excavation for potential expansion of the floodplain terraces. Though conceptually considered, other specific opportunities for mitigation projects such as the following were not identified but warrant further investigation if none of the projects in the list is determined to be feasible: removal of overwater structures and fill in the estuary; removal of relic pile-dike fields; removal of fill from Trestle Bay or elsewhere; removal of shoreline erosion control structures and replacement with bioengineering features; beneficial use of dredge material to create shallow water habitat features; and restoration of eelgrass beds. Certain pile fields and engineering features may be providing current habitat benefits that could be lost with removal, and such actions would require appropriate hydraulic analysis coordination with engineers and resource agencies.

For potential mitigation projects located in Trestle Bay, there is additional monitoring and assessment opportunity. A separate hydraulic/engineering study under a different project authority could investigate whether or not an expansion of low-energy, intertidal habitat near Swash Lake could effectively provide additional storage capacity and affect circulation in the bay such that erosive pressure at neck of Clatsop Spit could be reduced.

Table 5-5 Summary of Estimated Acreages for 404 Wetland and Waters Mitigation

Area Affected	Impacted Acreage	Mitigation Acreage	Comment
North Jetty			
Wetland	1.14	2.28	Base Condition: MMR
404 Waters Lagoon	8.02	12.03	Base Condition: MMR
Other 404 Waters	4.36	6.54	CE/ICA during DDR phase
South Jetty			
Wetlands	2.65	5.30	CE conducted
404 Waters	13.84	20.76	CE/ICA during DDR phase
Jetty A			
Wetlands	0.91	1.82	CE conducted
404 Waters	6.6	9.9	CE/ICA during DDR phase

5.1.10. Uplands Disturbance and Re-stabilization

Rock storage and staging areas will impact uplands as well as wetlands. Best management practices (BMPs) to reduce the environmental footprint and to avoid and minimize impacts have been incorporated and will be implemented, including appropriately locating staging sites, implementing stormwater management plans, and stabilizing the site during and after construction. Post-construction upland re-stabilization would include re-establishing native grasses, shrubs, and trees where appropriate; controlling and removing invasive species like scotch broom and European beach grass in the project vicinity; and re-grading/tilling the area to restore pre-project natural contours. The Oregon Parks and Recreation Department (OPRD) has requested that the Corps utilize the State Forester as one resource for determining optimal revegetation plans.

As mentioned in the snowy plover discussions, on Clatsop Spit there is a unique opportunity to partner with USFWS and OPRD regarding creation and management of snowy plover habitat under the 2010 HCP. There may be locations in the vicinity and away from projected construction and staging areas to convert upland habitat to snowy plover habitat via invasive species removal, tilling, and application of shell hash. Newly cleared habitat would be created with the intention of luring plover to a more preferable nesting location away from the potential attractive nuisance of the disturbed staging areas. Operation and maintenance during the project via regular tilling and shell hash distribution could be coordinated between the agencies through a Memorandum of Agreement (MOA) or similar avenue. The Corps currently has a signed MOA indicating it will cooperate with OPRD in the implementation of the snowy plover management plan under development.

5.1.11. Cultural and Historic Resources

The proposed action is being conducted in an area that is highly erosive and has previously been disturbed by jetty construction. Jetty site evaluations concluded that shipwrecks or remnants of shipwrecks do not occur at the jetty locations. Although the MCR jetties are currently not listed on the National Register of Historic Places, nomination of the structures is planned. Documentation of the structures will be coordinated with the State Historic Preservation Offices. Section 106 documentation of the current condition of the jetty trestle remnants was conducted in 2006 for the repair work. Both the North and South jetties are eligible for the National Register of Historic Places because they are important historically. However, they do not retain original materials of workmanship as they have been repaired many times, but they do retain their original alignments.

Interim repair work done in 2005 and 2006 on the Washington side was coordinated with the State Historic Preservation Office; a no adverse effect determination was supported for this interim repair after remnants of the original trestle were documented by a historic architecture study in an area adjacent to the jetty rock structure in a planned staging area where trestle remnants would be impacted. Much of the area around each jetty is composed of accreted material from littoral drift with little or no potential for historic properties. The undertaking has been determined to have no effect on historic properties since the action will not affect the criteria that make the jetties eligible for the Register and the Washington and Oregon SHPOs have concurred.

5.1.12. **Socioeconomic Resources**

Construction vehicles and trucks hauling jetty rock would have an intermittent but long-term affect on local traffic patterns in the Long Beach/Ilwaco area (North Jetty/Jetty A) and in Warrenton/Hammond area (South Jetty), depending on whether barge or truck transport is used for jetty rock. The approximate number of trucks or barges to be used for rock transport is shown below (additional information is provided in Section 6.4):

Construction of the proposed action would have minor adverse impacts to recreationists at Cape Disappointment State Park and Fort Stevens State Park, both those participating in water-sports and beach activities near the jetties, and those using the jetty structures for fishing and crabbing. Heavy equipment using park roads and parking lots will delay or inconvenience park visitors and water sport and beach recreationists. Park visitors and recreationists are likely to be disturbed by construction noise. A number of restrictions would be in place near the construction zones at each jetty to protect park visitors, water sport and beach recreationists, and the public. For public safety reasons, the Corps discourages use of the jetty structures themselves, and this policy would remain in force throughout the construction period. Along the South Jetty where surfing occurs, there may be some exclusion areas near the jetty structure and during dune augmentation and portions of jetty repair. However, the bulk of vessel traffic will occur on the channel side of the jetty and repairs will be in the immediate vicinity of the structure, so the minimal and short-term effects on surfing are likely to be negligible. Some park roads and parking lots would likely be closed at times during construction. Razor clam beds in the vicinity of the jetties may be temporarily closed during construction activities, but are not expected to be negatively impacted. Access to the jetties and nearby beaches would also be closed periodically at different times during construction of the individual jetties, which would also impact water sport and beach recreationists and anglers using the immediate vicinity. However, large portions of the parks and beaches will remain open and accessible to the public, and the bulk of the construction activities are likely to be seasonally concentrated. The long-term reduction in the levels of recreational activity could also affect the local economy of the Long Beach peninsula and the Warrenton/Hammond area, which are highly dependent on tourism. However, navigation traffic transiting the MCR, including recreational vessels and cruise ships that dock at Astoria, Oregon, would not be affected during construction. Overall, the recreation and local economy impacts during construction of the proposed action are expected to be minor. Therefore, the Corps is not proposing mitigation for recreational impacts, nor is the Corps proposing to construct additional beach access points. The potential environmental impacts of creating additional beach access points outweigh the inconvenience and reduced access caused by seasonal construction activities.

After construction there would have a long-term, positive effect on navigation vessel safety, including recreation vessels and cruise ships. Maintenance of the shoreline at Clatsop Spit and Benson Beach is expected, which preserves these areas for recreational opportunities mentioned above. The proposed action would have no effect on utilities and public services in the area. The MCR is the gateway to the Columbia-Snake River system, accommodating commercial navigation traffic with an approximate annual value of $20 billion dollars a year. The proposed action would have a long-term, positive effect on maintaining this vital transportation link and associated economy for the states of Oregon, Washington, Idaho and Montana, as well as for the Nation as a whole.

5.2. COORDINATION AND CORRESPONDENCE

An agency coordination meeting was held on May 25, 2006 for the purpose of introducing the project to several agencies that will be involved with review of environmental documents. Staff from the USACE Portland District presented the current state of environmental review and engineering modeling to the National Marine Fisheries Service (NMFS), U.S. Fish and Wildlife Service (USFWS), Washington Department of Ecology, Oregon Department of Environmental Quality, and Oregon Department of Land Conservation and Development.

On April 13, 2007 the USACE met with the U.S. Geological Survey (USGS) and Portland State University regarding numerical modeling in support of the MCR rehabilitation project. Also in 2007, four resource agency meetings and presentations were held regarding the MCR project on April 27, May 30, July 11, and September 5. A public information meeting was held in Astoria, Oregon on July 31, 2006. After a presentation about the MCR jetty rehabilitation project, the public was invited to ask questions and talk to USACE staff about the project. In addition, the USACE Portland District established a web site to keep the public informed about the repair/rehabilitation of the MCR jetties, located at https://www.nwp.usace.army.mil/issues/jetty/home.asp.

An initial draft Environmental Assessment (EA) was distributed for a 30-day public review in June 2006. Six comment letters were received based on the June 2006 EA. Since the current range of alternatives and project description changed, comments received on the June 2006 EA may no longer be relevant to the current proposed alternatives. A summary of these comments is provided below.

- Interested in how rehabilitation would impact siltation in side channels and in Baker Bay and effects to coastal erosion.
- Need to analyze/mitigate losses to crab nursery habitat.
- Loss of sand from coastlines (primarily Benson Beach) needs to be analyzed/mitigated. Interested in sand placement on Benson Beach.
- Focus on Environmental Impact Statement (EIS) and evaluate all projects in the MCR vicinity cumulatively in a comprehensive context (dredging, dam regulation, disposal, etc).
- Purpose should be to get goods to market not rehabilitate the jetties. Alternative should consider other options besides shipping.
- Jetty A’s purpose should be discussed; noted that channel has moved north.
- Evaluate how existing spur groins have performed.
- Affected environment should extend to Grays Harbor.
- Role of near-jetty disposal should be evaluated in greater detail.
- The degree to which waves have changed should be evaluated with respect to jetty design.
- Discuss project impacts to Clatsop Spit and Peacock Spit and sediment budget to littoral cell.
- Sand placement alternatives should be considered to address jetty foundation shoal erosion.
- The draft EA (2006) was put out for public review too early and has deprived the public its opportunity to comment.
- Should report current rates of erosion at Peacock Spit.

- Supports rehabilitation of the MCR jetties citing navigation safety and economic benefits.
- Interested in how rehabilitation of Jetty A would affect base of North Jetty and channel entrance to Port of Ilwaco with respect to sand accumulation.
- Supports studying/planning and rehabilitating the MCR jetties citing the international/economic importance of shipping.
- Recommend that rehabilitation be accomplished from land-based work sites to minimize amount of dredging.
- Recommend that dredged material resulting from project be used to create snowy plover habitat at base of South Jetty by covering beach grass. Interested in reviewing any planting plan.
- Interested in type of wetlands to be impacted at North Jetty and location of disposal site.
- The wetlands behind the North Jetty should be categorized using the Washington State wetland rating system for Western Washington to assist in determining appropriate mitigation.
- Interested in potential impacts/mitigation to wetland north of the North Jetty access road from filling behind the North Jetty (the area is considered Conservancy Shorelands under Pacific County Shoreline Management Plan).
- Best management practices should be in place to prevent adverse impacts to wetlands from construction traffic.
- Interested in alternative routes to beach, and viewing area during construction.
- Assess impacts of barge offloading facility creation and haul routes when known.
- Interested in interactions with other planned activities about the MCR including Benson Beach project.
- Modeling should consider impacts from sediment transport/deposition at Benson Beach and whether build-out would affect ability to do the Benson Beach project.

Due to changes in the project description, a revised draft EA was prepared. A revised draft 2010 EA was informed by and revised to reflect and address the above comments, as appropriate. The revised draft EA was issued for a 30-day public review period in January 2010. The revised draft EA was provided to federal and state agencies, organizations and groups, and various property owners and interested publics. In addition, a public information meeting was held in Astoria, Oregon on February 3, 2010. After a presentation by the Corps about the MCR jetty rehabilitation project, the public was invited to ask questions and talk to USACE staff about the project. Another public information meeting to describe likely construction techniques was also held on June, 4, 2010, at Fort Vancouver, WA to solicit input from potential construction contractors and to provide additional information regarding the feasibility of the Major Rehabilitation and Repair approach.

A summary of the comments received on the January 2010 revised draft EA is provided below, followed by the Corps' response and subsequent changes to the 2011 EA and the 2012 revision, as appropriate.

1. Confederated Tribes of the Grand Ronde, email dated January 21, 2010.
    a. Requested any reviews related to the National Historic Preservation Act.
        i. No change to EA text. This will be done as part of the actions described in the Compliance section.
2. Clatsop County Transportation and Development Services, letter dated January 21, 2010.
    a. Project will affect the safety and operations of Ridge Road to be used to access the South Jetty project area; request meeting to discuss requirements for road's use.

        i. No change to EA text. This will occur later during development of the Detailed Design Report and Plans and Specifications prior to construction.

3. Oregon State Historic Preservation Office, letter (no date).
    a. Project will have no effect on any known cultural resources; no further archaeological research is needed unless cultural material is discovered during construction.
        i. No change to EA text. This will help inform part of the National Historic Preservation Act actions described in the Compliance section.
4. Columbia River Crab Fisherman's Association, letter dated February 1, 2010.
    a. Agree with findings of report/no action is unacceptable; EA and Finding of No Significant Impact (FONSI) is appropriate.
        i. No change to EA text.
    b. Just adding stone to jetties will not solve entire foundation problem, direct sand supplementation of the sand foundation is needed to stabilize jetties over coming decades.
        i. No change to EA text. Engineering staff has evaluated and designed the project as described in the EA to address the perceived problems and causes, including consideration of spur groins to accrete sand and protect the jetties' foundations.
    c. Lengthen Jetty A to full length will help stabilize natural northern migration of shipping channel and help somewhat with increasing erosion on Sand Island.
        i. No change to EA text. Engineering staff has evaluated and designed the project to address the perceived problems and causes as described in the EA, including capping or stabilization of the head of Jetty A at its current length to avoid further head loss.
    d. Routine direct placement of sand near root of jetties and north along Benson Beach will be required and must be part of the long-range stabilization plan. Consider a permanent pipe with frequent outlets for length of jetties to distribute sediment on both sides of jetties to supplement sand foundation. Consider permanent pipeline to supplement Benson Beach.
        i. No change to EA text. Engineering staff has evaluated and designed the project to address the perceived problems and causes as described in the EA, including lagoon fill and consideration of spur groins to address protection of the jetty foundation. Benson Beach littoral drift replenishment is being conducted under a separate project.
    e. In general, the Columbia River Crab Fisherman's Association supports the project.
        i. No change to EA text.
5. Public Commenter, email dated February 12, 2010.
    a. Previous jetties repairs have required a great deal of truck traffic in SW Washington; transport rock this time via barge. State is in a budget crisis cannot afford to repair roads; barges are more energy efficient and would keep roads from being compromised.
        i. As described in Section 5.5.3, the feasibility of several transportation options have been considered, and a combination of approaches may be implemented.
6. Public Commenter, letter dated January 15, 2010.
    a. During design, consider how construction will affect the surf break.
        i. No change to EA text. Wave climate and currents were modeled and considered for their impacts to the function and integrity of the jetty structures for maintaining navigation. Understanding wave formation for recreational uses was not one of the project purposes evaluated.

b. Locations of spur groins not clearly shown in the EA.
    i. Locations of spurs were clearly shown on the proposed action figure for each jetty. They are no longer proposed in this 2012 preferred alternative.
c. The EA does not adequately address impact to socio-economics of Warrenton; revise text (Sections 2.4.3 and 6.8) to acknowledge other activities like water sports (surfing, kayaking, kite boarding), clam digging, and beach activities such as walking, running, dog exercise, etc.
    i. Text of EA was revised as suggested.
d. There needs to be public access to beach immediately south of South Jetty; prohibiting access by not allowing climbing over jetty rocks is not a solution. Public beach access should be maintained during construction. Letter provides two ways to address this: (1) contractor can retain some parking at Lot C and provide safe pedestrian access through construction zone; or (2) contractor can build new or temporary parking lot/path to the beach south of jetty.
    i. As described in the Socio-economic sections of the EA, for safety reasons, the Corps prohibits climbing on jetty rocks, and to maintain safety will also have certain portions of the park closed where there is construction, equipment, or staging activities. Though there may be intermittent closures in certain areas, there are likely to be portions of the beach that remain open and unaffected. The Corps will be coordinating with the Park and construction staff to maintain the safety of park visitors.
e. Post-construction establish a permanent, safe public access from the parking area to the beach.
    i. No change to EA text. The purpose of this project is to maintain the jetties and does not include construction of additional beach access points.
f. The EA should address construction safety for surfers and other water sport enthusiasts; contractor to delineate safety zones when working in or around the water using buoys or other types of notification; provide signs or displays warning surfers when in-water work is underway.
    i. No change to the EA text. This is mentioned in Section 6.15

7. Chadbourne + Doss Architects, email dated February 4, 2010.
    a. Spends time at South Jetty and sees opportunity for interpretive center or thoughtful installation to help communicate purpose of the jetty and efforts of Corps.
        i. No change in the EA text. This does not fit with the purpose and need of the project.
8. Public Commenter, letter dated January 17, 2010.
    a. Provides information and photos of Japanese approach to sea walls and breaker barriers.
        i. No change in the EA text. Concrete armor units similar to those shared by the commenter are already under consideration for use at the jetty heads.
9. JP&M Mining, email dated January 20, 2010.
    a. Attending meeting in Astoria on February 3, wants any existing surveys on North and South jetties and information on previous quarries used.
        i. Request was forwarded to the geotechnical engineer, and a quarry list has been provided in the EA.
    b. Putting together a business plan that may include revamping a coastal port.
        i. No change in the EA text.

   c. Jetty rehab excellent way to use local workers and improve infrastructure in coastal communities.
      i. No change in the EA text.

10. Public Commenter, letter dated February 2, 2010.
    a. Provided two historical references to be added to history of MCR jetties section.
       i. These were added to reference section.
    b. Draft EA overemphasizes use of quarried armor stones; other approaches like reinforced concrete armor units and structural solutions using reinforced concrete elements should also be given emphasis in decision-making process.
11. More information was added to EA about physical model (Section 4.1.2.3). Concrete armor units are under consideration for use at the jetty heads.PND Engineers, letter dated February 12, 2010.
    a. Provided information on OPEN CELL jetty structures.
       i. No change in the EA text. Information was forwarded to the coastal engineers.
12. Northwest Environmental Advocates, letter dated February 12, 2010.
    a. USACE must prepare an EIS that complies with the purpose of NEPA.
       i. No change to the EA text. With the release of the Draft EA for solicitation of public comments, through its evaluation of impacts and alternative, and through meeting its other compliance obligations, the Corps has also been complying with its NEPA obligations. At the conclusion of the Final EA, the Corps will make its determination as to whether or not an EIS or a FONSI will be completed.
    b. Information required for public disclosure has been omitted from draft EA (disposal of dredged materials, costs and benefit-to-cost ratio for the project, meaningful discussion of impacts, etc).
       i. EA text has been revised for dredged material disposal, alternative selection, and impact discussions.
    c. Draft EA segregates connected actions; the jetties, maintenance of the MCR and Columbia River navigation channel, and dredged material disposal sites are connected actions.
       i. No change to text in the EA. The purpose and need described in the proposed action is limited to repair and rehabilitation of the existing jetty system.
    d. Biological Assessments for the Services not completed prior to public review of draft EA.
       i. The EA text has been edited to reflect updated evaluations and information, including in the ESA Compliance section. Biological Assessments have been completed, and a Biological Opinion and Letter of Concurrence have been obtained from the Services prior to completion of the final EA.
    e. Inadequate information on future conditions that will degrade the jetties, e.g., wave height changes, climate change.
       i. Text was added to the EA in section 6.11 describing hydrologic and hydraulic processes and modeling that was conducted during evaluation and design of the jetty alternatives.
    f. Draft EA does not address the impacts of filling the Trestle Bay area with cobble.
       i. As described in the alternatives discussion for the South Jetty, this alternative component has been removed as part of the selected or preferred plan. Text was added to Section 6 to discuss impacts from fill at the foredune augmentation.

g. Draft EA does not adequately analyze alternatives.
    i. Changes to the text were made for describing the selection of alternatives.
h. Draft EA does not contain a detailed mitigation plan.
    i. The wetland impacts and mitigation sections have been revised to reflect mitigation plans.
i. Draft EA fails to identify/analyze cumulative impacts of past, current and future actions; as with previous EIS or EAs for MCR and Channel Deepening projects, including deepwater site, there is no evaluation of baseline conditions and cumulative changes to issues such as salinity, ocean plume, risk of oil spills, changes in shipping, habitat loss, impacts on salmonids, and sedimentation processes.
    i. The Cumulative Effects section has been revised. The No Action and Baseline conditions, impacts, and hydrology and hydraulics have also been described.
j. Draft EA does not discuss how littoral cell and other Corps actions, such as hydrosystem operation and dredging and disposal of dredged materials, have affected sedimentation in the littoral cell and how continued maintenance of existing jetty length will continue to affect sedimentation processes.
    i. Text was added to the EA in section 6.11 describing hydrologic and hydraulic processes and modeling that was conducted during evaluation and design of the jetty alternatives.
k. Draft EA does not address possible effects of filling the dunes at South Jetty root/Trestle Bay.
    i. As described in the alternatives discussion for the South Jetty, the Trestle Bay fill alternative component has been removed as part of the selected or preferred plan. Text was added to Section 6 to discuss impacts from fill at the foredune augmentation.
l. Action area should encompass the entirety of the littoral cell.
    i. The affected environment and possible environmental consequences were both described, as were effects to hydraulics and hydrology in the project vicinity.
m. Project timing and schedule not clear – draft EA does not state how long repairs should last; timing of project is described as lasting 50 years but project actions take place in 2045 and 2069.
    i. More information has been added to EA under Construction Scheduling, and also in the description of alternatives and proposed actions. The construction schedule has also been revised here and subsequent the draft and final EA. Even with repairs and rehabilitation earlier in the project life, the model predicts that future repairs could be required given storm and wave climate at the jetties. This has been described in the No Action section.
n. A supplemental EIS for the MCR is required to address impacts of jetty rehabilitation project.
    i. No changes were made to the EA text. The Corps disagrees and has determined a separate EA for jetty repairs and rehabilitation is an appropriate path for complying with NEPA requirements.
o. Independent peer review is required by the Water Resources Development Act of 2007.
    i. No change to EA text. The 90% Major Rehabilitation Report, of which the draft EA was a part, has completed independent external peer review (IEPR).

13. United States Fish and Wildlife Service, letter received February 23, 2010.

a. Requests disposal of dredged material be used to cover European beach grass.
    i. These actions will be evaluated during construction implementation by the Corps and will also be vetted through the AMT.
b. Requests heavy equipment to remove European beach grass and to restore and enhance snowy plover nesting habitat in concert with the draft Habitat Conservation Plan and Oregon Parks and Recreation Department (OPRD).
    i. These actions will be evaluated while establishing staging areas in order to reduce the potential attractive nuisance created by these disturbance areas.
c. Requests habitat improvement in coordination with OPRD for rock storage via creation of habitat areas for snowy plover that do not interfere with use of the Spit.
    i. Habitat preferred by snowy plover will be created adjacent to the staging areas in order to reduce the potentially attractive nuisance created by the cleared staging area.

5.2.1. The Adaptive Management Team

Due to the dynamic conditions at MCR and the long duration of the MCR Jetty construction sequence, the Corps proposes formation of a modified Adaptive Management Team (AMT). The Corps suggests annual meetings, and more as needed, to discuss relevant design and construction challenges and modifications, technical data, new species listings or critical habitat designations, evolving environmental conditions, and adaptive management practices as needed. The primary purpose of the proposed AMT and its implementation is to ensure construction, operation, and maintenance actions have no greater impacts than those described in the Biological Assessments and Environmental Assessment, and that Corps obligations and terms and conditions are being met. This will also allow confirmation that any necessary construction or design refinements remain within the range and scope of effects described during Consultations and that compliance obligations are being met and efforts are being made to adjust mitigation once final impacts are fully understood. These adjustments could result in a reduction in mitigation based on actual impacts occurring. This forum will provide an opportunity for periodic evaluation as to whether or not the proposed actions, ESA listings, or environmental conditions result in any re-initiation triggers. It will also facilitate continued coordination and updating and allow the Corps to inform agency partners when unforeseen changes arise. Results regarding marine mammal and fish monitoring, mitigation monitoring, as well as water quality monitoring will also be made available to the AMT in order to fulfill reporting requirements and to address any unexpected field observations. Results of jetty monitoring surveys will also inform the AMT of the repair schedule and design refinements that may become necessary as the system evolves over time. This venue will provide greater transparency and allow opportunities for additional agency input. Final selection and design of the mitigation proposal will be determined by the Corps and will be vetted through this forum to facilitate obtaining final environmental clearance documents for this component of the MCR proposed action. Potential principal partners include federal (National Marine Fisheries Service, U.S. Fish and Wildlife Service) and State (Washington and Oregon) resource management agencies.

5.3. COMPLIANCE WITH LAWS & REGULATIONS

5.3.1. Clean Air Act

This Act established a comprehensive program for improving and maintaining air quality throughout the United States. Its goals are achieved through permitting of stationary sources, restricting the emission of toxic substances from stationary and mobile sources, and establishing National Ambient Air Quality Standards. Title IV of the Act includes provisions for complying with noise pollution standards. Section 118 (42 U.S.C. 7418) of the Clean Air Act specifies that each department, agency, and instrumentality of the executive, legislative, and judicial branches of the Federal Government (1) having jurisdiction over any property or facility or (2) engaged in any activity resulting, or which may result, in the discharge of air pollutants, shall be subject to, and comply with, all Federal, State, interstate, and local requirements respecting the control and abatement of air pollution in the same manner, and to the same extent as any non-governmental entity. Corps activities resulting in the discharge of air pollutants must conform to National Ambient Air Quality Standards (NAAQS) and State Implementation Plans (SIP), unless the activity is explicitly exempted by EPA regulations10.

Repair and rehabilitation of the MCR jetty system is anticipated to remain in compliance with the Clean Air Act and the State Implementation Plan. This is not a transportation project, it will not qualify as a major stationary source of emissions of criteria pollutants, and the project does not appear to be located in a non-attainment area for limited air quality.

There would be an intermittent but long-term reduction in air quality during construction of the proposed action due to emissions from construction equipment. Any emissions that do occur during and after construction from motor vehicles or facility functions are expected to be de minimus and will be from activities of a similar scope and operation to those of the original facility. There also would be an intermittent but long-term increase in noise levels from construction equipment. Efforts to avoid and minimize these effects have been considered when comparing and evaluating construction methods. Use of vibratory hammers will minimize some of the noise impacts during piling placement. It is also possible barging rocks verses overland trucking would result in reduced truck traffic and lower project emissions. These effects will be evaluated while taking into consideration other environmental factors during final selection of construction methods.

5.3.2. **Marine Protection, Research and Sanctuaries Act**

Prior to dredging and disposal activities, the Corps will request authorization to use one of the designated Section 102 sites for disposal of dredged materials. This will include a request for concurrence that the Corps' proposed Annual Use Plan is in compliance with the Site Monitoring and Management Plan. The proposed transportation of dredged material for placement or disposal in ocean waters will be further evaluated to determine that the proposed disposal will not unreasonably degrade or endanger human health, welfare, or amenities or the marine environment, ecological systems, or economic potentialities. In making this determination, the criteria established by the Administrator, EPA pursuant to section 102(a) of the Ocean Disposal Act will be applied. In addition, based upon an evaluation of the potential effect which the failure to utilize this ocean disposal site will have on navigation, economic and industrial development, and foreign and domestic commerce of the United States, an independent determination will be made regarding the need to dispose of the dredged material in ocean waters, other possible methods of disposal, and other appropriate locations.

5.3.3. **Clean Water Act**

Effects to water quality and effects from discharges and disposal into navigable waters, including 404 wetlands and waters including mitigation have been described in the pertinent sections of this EA. This Act also requires 401 Water Quality Certification from state or interstate water control agencies which certify that a proposed water resources project is in compliance with established federal and state effluent limitations and water quality standards. The proposed action is expected to be in compliance with the Act. A Section 404(b) (1) Evaluation has been prepared for the proposed action. The Section 404(b) (1) Evaluation and any additional necessary information will be submitted to the ODEQ and the WDOE. These agencies will be responsible for project review and issuance of the 401 Water Quality Certificates which will likely include terms and conditions to ameliorate impacts from the proposed action, including BMPs and turbidity monitoring requirements. The Corp will obtain these State 401 Water Quality Certifications prior to any inwater work or wetland fill. In addition, a National Pollutant Discharge Elimination System permit will be required from the USEPA and obtained prior to disturbance and work performed on federal lands in Washington, and the Corps intends to use the construction general permit after development of an appropriate Stormwater Protection Plan. The Corps has a general 1200-CA permit (#14926) through the ODEQ that, though expired, has been administratively extended indefinitely by ODEQ and remains in effect. The Corps intends to maintain compliance with its terms and conditions, including development of an Erosion and Sediment Control Plan prior to disturbance and work performed on federal, state, and local lands in the Oregon State.

5.3.4. **Coastal Zone Management Act**

This Act requires federal agencies to comply with the federal consistency requirement of the Coastal Zone Management Act. This activity will be coordinated with the Oregon Department of Land Conservation and Development and the WDOE. A consistency determination will be prepared and concurrence received from both States prior to construction.

5.3.5. **Endangered Species Act**

In accordance with Section 7(a) (2) of this Act, federally funded, constructed, permitted, or licensed projects must take into consideration impacts to federally listed or proposed threatened or endangered species. Information on federally listed species and designated critical habitat is presented in this EA. Biological Assessments (BAs) were prepared for the proposed action to address federally listed species under the jurisdiction of the NMFS and USFWS. The BAs were provided to the respective agencies for review and consultation.

On March 18, 2011, The Corps received a Biological Opinion from NMFS indicating that the Corps' proposed actions were not likely to adversely affect any listed species, with the exception of eulachon, humpback whales, and Stellar sea lions (2010/06104). For these species, NMFS determined that Corps' actions were not likely to jeopardize the existence of the species. NMFS also concluded that Corps actions were not likely to adversely modify any of the current or proposed critical habitats. There was a Conservation Recommendation to carry out actions to reverse threats to species survival identified in the Columbia River Estuary ESA Recovery Plan Module for Salmon and Steelhead. The Corps also provided a conference report for critical habitat that NMFS proposed for leatherback turtles, eulachon, and Lower Columbia River coho salmon. The Corps will request NMFS adopts its conference report when this habitat becomes designated. Prior to construction, the Corps will also request an Incidental Harassment Authorization of Stellar sea lions, humpback whales, California sea lions, and harbor seals.

On February 23, 2011 the Corps received a Letter of Concurrence from USFW regarding potential effects to species under their jurisdiction (13420-2011-I-0082). The Corps' determined its actions would have no effect on listed species, with the exception of bull trout, marbled murrelets, and snowy plover. The Corps concluded that its actions were not likely to adversely affect these species or their critical habitat. The USFW concurred with the Corps' determination. USFW also included four Conservation Recommendations to protect and improve snowy plover habitat and manage attractant waste derived from construction actions.

Mitigation components have been included in the proposed action by the Corps. These actions complement the Corps' affirmative commitment to fulfill responsibility to assist with conservation and recovery of ESA-listed salmonids.

5.3.6. Fish and Wildlife Coordination Act

This Act states that federal agencies involved in water resource development are to consult with the USFWS concerning proposed actions or plans. The proposed action has been coordinated with the USFWS in accordance with the Act. The Corps has also been in regular coordination with ODFW and WDFW regarding plan selection and development of wetland and waters mitigation projects.

5.3.7. Magnuson-Stevens Fishery Conservation and Management Act

The Sustainable Fisheries Act of 1996 amended the Magnuson-Stevens Act establishing requirements for essential fish habitat (EFH) for commercially important fish. Pursuant to the Magnuson-Stevens Act, an EFH consultation is necessary for the proposed action at the MCR jetties. Essential fish habitat is defined by the Act as "those waters and substrate necessary to fish for spawning, breeding, feeding, or growth to maturity." The estuary and the Pacific Ocean off the MCR are designated as EFH for various groundfish and coastal pelagic and salmon species. The proposed action will directly affect EFH for Chinook salmon, coho salmon, English sole, sand sole, and starry flounder from the permanent loss of sandy bottom habitat from jetty construction. Short-term disturbances to EFH would result for lingcod, English sole, sand sole, starry flounder, black rockfish, brown rockfish, China rockfish, copper rockfish, and quillback rockfish. However, the addition of rock would increase EFH for lingcod, black rockfish, brown rockfish, China rockfish, copper rockfish, and quillback rockfish. An EFH assessment under the Magnuson-Stevens Act was provided as part of the Biological Assessment submitted to the NMFS for the proposed action. In the subsequent Biological Opinion, no additional Conservation Measures were proposed.

5.3.8. Marine Mammal Protection Act

This Act prohibits the take or harassment of marine mammals. It is possible that the proposed action could result in harassment of the federally listed Steller sea lion with construction at the existing above-water portion of the head of the South Jetty. They can be present at any time of the year. Impacts to this species were evaluated and are described in this EA. Impacts were further evaluated as part of the Biological Assessment submitted to the NMFS for the proposed action. The Biological Opinion from NMFS indicated Corps actions would NOT jeopardize the survival of the species.

Prior to construction activities, an incidental harassment authorization (IHA) for marine mammals at the South Jetty will be obtained from the NMFS. The Corps anticipates that the new IHA permit will entail requirements similar to those in the previous permit for repair of the South Jetty. The Corps also proposed Conservation Measures as previously described.

5.3.9. Migratory Bird Treaty Act and Migratory Bird Conservation Act

These acts require that migratory birds not be harmed or harassed. Under the Migratory Bird Treaty Act, "migratory birds" essentially include all birds native to the U.S. and the Act pertains to any time of the year, not just during migration. The Migratory Bird Conservation Act aims to protect game birds. Impacts of construction at the jetties and the hauling of rock to the jetties could displace birds by causing flushing, altering flight patterns, or causing other behavioral changes, but it is not expected that effects would rise to the level of harm or harassment.

5.3.10. National Historic Preservation Act

Section 106 of this Act requires that federally assisted or federally permitted projects account for the potential effects on sites, districts, buildings, structures, or objects that are included in or eligible for inclusion in the National Register of Historic Places. This project is being conducted in an area that is highly erosive and has previously been disturbed by jetty construction and prior dredging. There are no known historic properties recorded within the immediate project footprint other than the jetties and associated trestle remains. The proposed action has been coordinated with the Washington and Oregon State Historic Preservation Offices (SHPO) in order to obtain their comments on this Section 106 action in accordance with the Act. The Oregon and Washinton SHPOs have concurred that the undertaking will have no effect on historic properties as the action will not affect the criteria that make the structures eligible, essentially, importance in historic events and alignment. Original workmanship and materials have all changed over a century of repairs and the alignment and configuration remain essentially the same.

5.3.11. Native American Graves Protection and Repatriation Act

This Act provides for the protection of Native American (and Native Hawaiian) cultural items, established ownership and control of Native American cultural items, human remains, and associated funerary objects to Native Americans. It also establishes requirements for the treatment of Native American human remains and sacred or cultural objects found on federal land. This Act also provides for the protection, inventory, and repatriation of Native American cultural items, human remains, and associated funerary objects. There are no recorded historic properties within the immediate project area and the probability of locating human remains in this area is low. However, if human remains are discovered during construction, the Corps and/or the Contractor will be responsible for following all requirements of the Act.

5.3.12. Environmental Justice

Executive Order 12898 requires federal agencies to consider and minimize potential impacts on subsistence, low-income, or minority communities. The goal is to ensure that no person or group of people should shoulder a disproportionate share of the negative environmental impacts resulting from the execution of domestic and foreign policy programs. The proposed action is not expected to disproportionately affect low income and/or minority populations and is in compliance with Executive Order 12898.

5.3.13. Executive Order 11988, Floodplain Management

The proposed action would not further encourage development in, or negatively alter any floodplain areas. Executive Order 11988 regarding Floodplain Management was signed May, 24, 1977. The order requires that Federal agencies recognize the value of floodplains and consider the public benefits from their restoration and preservation. The objective is to avoid long and short-term adverse impacts to the base floodplain (100-year flood interval), and to avoid direct and indirect support of development in the base floodplain when there is a practicable alternative. Though the jetties are located in the floodplain on accreted land at the Clatsop Spit and Benson Beach, the floodplain in which they are located is relatively recently created and is at the mouth of the Columbia River. Therefore, these areas do not provide much floodplain storage or peak attenuation capacity. Furthermore, there are no other practicable alternative locations to conduct repairs or their associated construction activities, as the jetties are in a fixed location which is water and location dependent to maintain navigation. Additionally, the construction activities and fill will not be affecting floodplain areas that that have any private property, and there are few structures within the vicinity of the State Park lands and action area. The location of the State Park also precludes additional development in the vicinity of the jetties. Finally, the Corps does not expect any loss of beneficial values in the floodplain, and will be conducting some mitigation and restoration actions that will improve wetland function and dune stabilization. In order to inform the public of the proposed action, a draft EA was widely distributed and public comments were solicited. None of the commentators remarked on concerns for floodplain issues.

5.3.14. Executive Order 11990, Protection of Wetlands

Wetlands near the North and South Jetties and Jetty A will be filled for the proposed action. Plans for filling wetlands and the associated subsequent mitigation has been documented here and has been documented through the Section 404 (b) (1) evaluation that has also been prepared for the proposed action.

5.3.15. Prime and Unique Farmlands

No prime or unique farmlands will be affected by the proposed actions.

5.3.16. Comprehensive Environmental Response, Compensation, and Liability Act and Resource Conservation and Recovery Act

There is no indication that any hazardous, toxic, and radioactive wastes are in the vicinity of the MCR jetties. Any presence of these types of wastes would be responded to within the requirements of the law and Corps' regulations and guidelines.

5.3.17. National Environmental Policy Act

A Revised Final Environmental Assessment (EA) evaluates the environmental effects for major rehabilitation and repairs of the North and South Jetties and Jetty A, including all associated actions covered in the Major Maintenance Report and the South Jetty dune augmentation. For a complete chronology and explanation of all NEPA conducted for this project, please see Appendix D. The final EA and FONSI will be posted on the Corps' district website for public notice.

5.4. REPORTS AND STUDIES

The following studies were conducted to obtain environmental information and data to evaluate the effects of the proposed rehabilitation of the MCR jetty system.

Pacific Northwest National Laboratory. February 2006. Use of Acoustic Telemetry to Assess Habitat Use of Juvenile Chinook Salmon and Steelhead at the Mouth of the Columbia River. PNNL-15575. Prepared for U.S. Army Corps of Engineers, Portland District, Portland OR.

Tetra Tech, Inc. April 2007. Clatsop Spit Plant Communities Investigation and Mapping, South Jetty, Mouth of the Columbia River, Clatsop County, Oregon. Final Report. Prepared for U.S. Army Corps of Engineers, Portland District, Portland OR.

Tetra Tech, Inc. April 2007. Wetland and Waters of the U.S. Delineation, North Jetty, Mouth of the Columbia River, Pacific County, Washington. Revised Final Report. Prepared for U.S. Army Corps of Engineers, Portland District, Portland OR.

U.S. Army Corps of Engineers. August 2006. Section 106 Documentation of Current Conditions: Historic Jetty Trestle Remnants. Portland District, Portland OR.

U.S. Army Corps of Engineers. September 2009. Mouth of the Columbia River North Jetty, South Jetty and Jetty A, Barge Offloading Facilities, Level I Sediment Evaluation. Prepared by Wendy Briner and Tim Sherman. Portland District, Portland OR.

(this page was intentionally left blank)

6. CONSTRUCTION AND COST ESTIMATE

6.1. GENERAL PROJECT DESCRIPTION

This chapter provides an overview of the construction methods (both land-based and water-based) and estimated production rates and schedule for the recommended plan. The associated cost estimates are provided.

The government estimate covers repair and rehabilitation of the MCR North and South jetties and Jetty A. The project consists of scheduled repairs to the jetties by rebuilding selected sections of the jetties. The repairs will be made by placing jetty stone that ranges from 6 to 33 tons. Stone placement from ocean-based equipment, such as jack-up barges, was considered. Because of harsh weather and strong wave action, only minimal use of ocean-based placement is likely.

In a land-based operation, jetty stone would be transported to the site either by barge, truck or a combination of the two. This estimate assumed barging would be the main delivery method for stone. Once on-site, the stone would be hauled to a stockpiling area. Existing roads may be used or new haul roads may have to be built. A haul road would be constructed on the jetty crest so equipment and material can reach the repair sites and where required, the jetty would be restricted using relic stone. At the jetty repair site, stone would be delivered to the site using off-road trucks. Depending on the size of the stone, the depth and distance from the equipment, either a crane or excavator would be used.

6.2. EXPECTED CONSTRUCTION SEQUENCE FOR RECOMMENDED PLAN

Due to both the magnitude of the construction effort and the projected sequencing of the work based on vulnerability, rehabilitation of the MCR jetties is expected to start in 2015 and would extend until 2020. Work would be performed every year during this time frame. In addition, the scheduled repair alternative for the North and South jetties are predicted repair activities and scheduling will vary with actual jetty degradation over time. Jetty A is a schedule repair alternative that is scheduled to occur during the first year of construction. Due to the large quantity of rock required to complete the work, the rock supply and storage activities can be expected to be continuous throughout the time frame.

Quarrying of the rock may be limited to the months of April through October depending on the regulations pertinent to each quarry. Rock delivery, however, can be conducted throughout the entire year by truck and during the months of April through October by barge. Approximate transport quantities by method are 30 tons per truck and 6,500 tons per barge. The majority of the jetty rehabilitation work is expected to be conducted from the root of the jetty seaward using an excavator or a crane.

Work elements fall into three general categories: (1) site preparation, (2) rock quarrying and delivery, and (3) jetty rehabilitation work. Site preparation would consist of the preparation of the rock stockpile and staging areas, as well as the construction of any barge-offloading facilities that may be required. Barge offloading facilities would be constructed with the first construction contract and be removed with the last contract. Ocean-going barges require 20-22 feet of draft when fully loaded. Under-keel clearance shall be no less than 2 feet. The elevation at barge offloading sites shall be no higher than -25 feet MLLW and shall provide for a maneuvering footprint of 400 feet by

400 feet with access to navigable water. The depth along the barge unloading sites would be maintained during the active period when barges will be unloaded.

6.3. CONSTRUCTION CONSIDERATIONS

6.3.1. Rock Placement

Placement of armor stone and rock on the MCR jetties would be accomplished by land- or water-based equipment. For water-based delivery of rock, a tow boat and barge would deliver the rock to either side of the jetties where water depth, waves, and current conditions permit. During rock offloading, the barge may be secured to approximately 4 to 8 temporary dolphins/H-piles, sheet pile, dock or utilize anchor arrays for tie-up or positioning. The dolphins/H-piles/sheet pile would be composed of either untreated timber or steel piles driven to a depth of approximately 15 to 25 feet below grade by a vibratory pile driver. If dolphins/H-piles/sheet piles are used, they will be located at a single designated location for each jetty and be removed at the completion of jetty construction. Rock would be off-loaded from the barge by a crane, land or water based, or with an adjustable ramp for land based equipment. The rock is then placed either within the jetty work area or stock piled for subsequent placement.

For land-based delivery of rock, jetty access for rock hauling trucks would be via an existing paved road to the Benson Beach parking lot at Cape Disappointment State Park (North Jetty) and via an existing paved road to the parking lot at the South Jetty. Work areas for delivery of rock, maneuvering of equipment, and stockpiling of rock near the jetties are already in place to facilitate recent and future repair work on the jetties. For water-based rock placement, a crane or a large track-hoe excavator could be fixed to a moored or jack up barge. The moored barge would use a series of anchors or the barge would be lashed to 4 to 8 temporary dolphins/H-piles paralleling the jetty work area (same concept as marine-based rock delivery). The crane or excavator would pick rocks either directly from the rock barge or from rock stock-piled on the jetty crest. The crane or excavator would advance along the jetty as work is completed.

For land-based rock placement, a crane or a large track-hoe excavator could be situated on top of the jetty. The placement operation would require construction of a haul road along the jetty crest within the proposed work area limits. The crane or excavator would use the haul road to move along the top of the jetty. Rock would be supplied to the land-based placement operation by land and/or marine-based rock delivery. For marine-based rock, the land-based crane or excavator would pick up rock directly from the barge or from a site on the jetty where rock was previously offloaded and stockpiled, and then place the rock within the work area. For land-based rock, the crane or excavator would supply rock via a truck that transports rock from the stockpile area. The crane or excavator would advance along the top of the jetty via the haul road as the work is completed.

The availability of adequate sources of rock has been a problem in several of the previous repairs jobs. This problem is further compounded by the fact that once the contract is awarded, rock quality and quantity both drive the resulting end product. The geometry of the rock is another area of great concern. In order to achieve a tight, minimum void, well distributed mass, with maximum interlock, the geometry of stones must be prismatic. The longest dimension of the stone must not be greater than three times the shortest dimension. This requirement eliminates slab-like pieces of rock that will not perform well in a rubble mound structure. Selective placement can only occur if adequate time to acquire and sort materials is allowed.

6.3.2. **Production Rates**

Due to the armor material size and weight requirements, crane size, supplemental counterweights, special rigging, and effective radius considerations, slower production rates may limit production rates previously experienced. The length of time between placements for the boom swing increases with a greater horizontal boom angle. Crane placement rates for the jetty stone may be as low as 80 to 100 tons per hour for outlying stations away from the root area. Effectiveness on daily production rates has been shown to increase dramatically with supplemental placement equipment such as a large hydraulic excavator, although the limited reach capabilities restricts land-based placement to within 15 feet down slope from the jetty crest and within the core and cap areas. As a contrast between equipment placement rates, during interim repairs to MCR South Jetty in FY 2006, crane placement rates of up to 173 tons per hour were observed over sections where large pocket holes were prevalent within a jetty segment. Hydraulic excavator placement rates up to 220 tons per hour were observed within the same set areas. However, due to effective radius limitations the hydraulic excavator is limited to placing material within the upper side slope and crest area. These rates came near the end period of the contract after several months of placement operations well beyond the initial learning curve.

6.3.3. **Barge Offloading Facilities**

Multiple barge offloading facilities may be used, as described below (see Figure 5-2 through Figure 5-5). Jetty offloading facilities would be removed upon project completion.

- Commercial Site in Ilwaco. For the North Jetty, barges would pull up to a dock at Ilwaco where rock would be transferred by crane onto trucks that would proceed by public road to Cape Disappointment State Park (formerly Fort Canby State Park). Trucks would then pass through the park grounds to the staging area adjacent to the jetty. For Jetty A, trucks would proceed through the Coast Guard facility to the staging area near the root of the jetty.

- Commercial Site in Warrenton. Nygaard Logging has a deep-water offloading site at their facility that could be used to offload rock. For the North Jetty, rock would be transferred to trucks that would likely use Highway 101 into Astoria, cross the Astoria-Megler Bridge, and head west through Ilwaco to Cape Disappointment State Park. Trucks would then pass through the park grounds to the staging area adjacent to the jetty. For the South Jetty, rock would be transferred to trucks which would then proceed West through Hammond to Fort Stevens State Park and use the existing park road to the staging area adjacent to the jetty. This site needs no improvement to accommodate deep-draft vessels.

- Contract-provided Site near South Jetty. Barges would dock at a site near Parking Area D within Fort Stevens State Park. For the North Jetty, rock would be unloaded by crane and hauled on the state park road to Highway 101, into Astoria, cross the Astoria-Megler Bridge, and then head west through Ilwaco to Cape Disappointment State Park and the Coast Guard facility. Trucks would then pass through the park grounds to the staging area adjacent to the jetty. For the South Jetty, rock would be unloaded by crane and hauled to the jetty via off-road trucks to the staging area.

- Contract-provided Site on North Jetty. Barges would dock at a contractor constructed offloading site on the channel side of the jetty. For the South Jetty, rock would be unloaded by crane and hauled on the state park road to Highway 101, cross the Astoria-Megler Bridge, into Astoria, and then head west through Fort Stevens State Park to the designated storage areas on Fort Clatsop Spit. For the North Jetty, rock would be unloaded by crane and hauled to the jetty via off-road trucks to the staging area.

- Contract-provided Site near Jetty A. Barges would dock at a contractor constructed offloading site on the tip of the jetty. Rock would be unloaded by crane or excavator and hauled along a causeway via off-road trucks to the staging area at the root of the jetty.

6.3.4. Dredging for Barge Offloading Facilities

Transport of rock would most likely be done by ocean-going barges requiring deeper draft (20-22 feet) when fully loaded than river-going barges. The elevation of barge maneuvering footprints at each barge-offloading facility would require no less than -25 feet MLLW with access to navigable waters. A barge offloading facility will be required in close proximity to each jetty. Dredging will be required to develop barge offloading facilities adjacent to the North Jetty and Jetty A, and for the South Jetty adjacent to Parking Area D at the east end of Clatsop Spit in Fort Stevens State Park. Appropriate depth to -25 feet MLLW is required for each facility. A clamshell dredge will be used for all dredging. The material to be dredged is medium to fine-grained sand, typical of MCR marine sands. Disposal of material will occur in-water and/or upland. The volume of material to be dredged is shown in
Table 6-1; these estimates are based on current bed morphology and may change. Also, maintenance dredging to a depth of -25 feet MLLW will be needed before offloading during each year of construction. Dredging is likely to occur on a nearly annual basis for the duration of the project construction period (approximately 6 years), but this will be intermittent per jetty depending upon which jetty is scheduled for construction in a particular year. The in-water work window for the Columbia River typically restricts dredging from November 1 to February 28, depending on the location.

Table 6-1. Dredging Volumes for Barge Offloading Facilities

Location*	Dredging Volume (cy)	
	Initial	Est. Maintenance**
North Jetty	30,000	30,000
Jetty A	60,000	N/A
South Jetty	20,000	20,000
South Jetty - Parking Area D	20,000	20,000

* Some of the locations will not be used on an annual basis; it depends on the construction schedule for each jetty.
**All dredging will be based on surveys that indicate depths shallower than -25 feet MLLW.

6.3.5. In-water Fill for Barge Offloading Facilities

Development of causeways from barge offloading facilities would be required to the North Jetty/Jetty A and near the South Jetty adjacent to Parking Area D at the east end of Clatsop Spit in Fort Stevens State Park (but not along the South Jetty). These structures would be removed upon project completion.

6.3.6. **Site Access**

Access to the construction areas will be via public roads, local access roads, and jetty haul roads as well as from the water for certain stages of work. Stone would be hauled from the quarries to the nearest port and loaded onto a barge. The stone would then be barged to offloading sites at the jetties. Once the stone is off-loaded at the site, the stone would be transported to a stockpile using off-road trucks. Local park roads will need to be repaired to pre-construction condition at the completion of the construction.

6.3.7. **Haul Road Considerations**

Equipment requires a flat road surface for travel as placement continues and for retreat during equipment exchanges and inclement weather. A number of contractor constructed equipment turnouts of adequate size will be needed for equipment passage along the haul road to the point of final placement. A minimum crest width of 30 feet is required for the anticipated crane size. Road width will accommodate a small gravel berm on each side of the haul road to act as a safety barrier for wheel traffic, and to support top of slope delineators for vehicle operators during haul and placement operations.

6.3.8. **Offloading Site Installation**

Offloading sites will be constructed during the first construction season and removed at the completion of each individual jetty. Offloading sites will be constructed either with mooring dolphins, with using existing spur groins with topping rock, or with a sheet pile retaining wall with backfill. Installation of about 4-8 temporary dolphins or piles will be needed for each barge offloading facility. Because sediments in the area are soft (sand), a vibratory or hydraulic pile driver will be used and is preferred over using an impact driver when fish are present. The presence of relic stone may require locating the piling further from the jetties so that use of this method is not precluded by the existing stone. It is possible that a bubble curtain or some other sound attenuation method may be employed along with a fish exclusion plan. Offloading sites would remain in place for the duration of construction at each jetty.

6.3.9. **Placing Jetty Stone**

The typical construction window on the Oregon Coast extends from approximately June through September, based on coastal wind and wave conditions. There are no in-water work restrictions for placing stones. Work activities on Jetty A may extend somewhat later in the season since this area is slightly more protected from sea conditions. The on-site placement operations will be dormant over the winter months. Early award of the contract must allow sufficient rock production and storage for placement operations during the optimal on-site placement timeframe. Continuous quarrying will allow for consistent rock production and stockpiling during the winter season as weather permits. The quarrying production process will be a critical element for optimal material selection/availability and when jetty rehabs are undertaken concurrently. Equipment capable of placing the stone individually in such a manner as to not displace the underlying material is required. The capabilities to move, turn, adjust, or relocate the stone after placement will be necessary. The selected equipment must be capable of placing the stone near its final position before release, and be capable of moving the stone, if necessary, to achieve maximum interlock with adjacent stones. Dropping armor stone from a height greater than 2 feet will be prohibited.

6.4. CONSTRUCTION SCHEDULE

The construction schedule for the MCR jetty system is based on the most recent TRACES MII version 4.1 estimate and constructability review. The estimate assumes the work will be accomplished with multi-year contracts. The schedule for the recommended plan is shown at the end of this chapter.

Rock procurement activities will be initiated for the North Jetty in 2014 concurrent with Plans and specification development. Quarries utilized are expected to be located in Oregon or Washington, although some rock may be obtained from Canadian quarries. The North jetty repair work will begin in 2015 repairing cross section damage between stations 20+00 and 45+00. The North Jetty will require installing a barge offloading facility on the channel side of the jetty at approximately station 45 in order to facilitate efficient rock delivery to the site. Dredging of 30,000 cy is anticipated to provide the minimum 25 feet of working clearance. Repair of Jetty A will occur concurrently with the first year of repair for North Jetty. Jetty A work will begin with constructing the off loading facility which requires approximately 60,000 cy of dredging to accommodate the rock delivery by barge, and constructing the jetty crest haul road from stations 40+00 to 84+00. Total new stone in 2015 will consist of approximately 170,000 tons of imported rock, equivalent to 5700 trucks or 26 barges.

In 2016, construction will continue on the North Jetty from stations 45+00 to 76+00. The haul road will need to be constructed with approximately 21,000 tons of rock fill material. Total new stone for 2016 will consist of approximately 86,000 tons of imported rock, equivalent to 2900 trucks or 13 barges. Site preparation work and stockpiling stone at the South Jetty will occur to prepare the staging and stockpile areas for 2017 construction.

In 2017, work continues on the North Jetty with placement of 29,000 tons of small and large armor near between stations 77+00 to 85+00. This ending stations corresponds with the beginning of the repair identified in the Major Maintenance report released prior to this rehabilitation report. Work at these seaward stations requires refurbishing the haul road and building vehicle turnouts. At the North Jetty the 29,000 tons of imported small and large armor stone is equivalent to 970 trucks or 5 barges.

In 2017, construction on the South Jetty is projected to begin, starting with repairing damaged cross-sections between stations 167+00 and 195+00. South Jetty construction will require either a haul road be constructed on top of the jetty or constructed from a marine plant. Total work effort on the South Jetty in 2017 is projected to consist of approximately 90,000 tons of small and medium armor stone; equivalent to 3000 trucks or 14 barges.

In 2018, construction on the South Jetty continues by extending the repairs from station 197+00 to station 222+00. It is anticipated that the haul road will have to be repaired and extended to accommodate the placement of the small, medium and large armor stone. Total work effort in 2018 is projected to consist of approximately 89,000 tons of small and medium armor stone; equivalent to 2970 trucks or 14 barges.

In 2019, construction on the South Jetty continues by extending the repairs from station 223+00 to station 246+00. The haul road will again have to be repaired and extended to accommodate the placement of the armor stone which is evenly divided between medium and large armor stone for these stations. Total work effort in 2019 is projected to consist of approximately 79,000 tons of small and medium armor stone; equivalent to 2640 trucks or 12 barges.

In 2020, the initial repairs for the three jetties are completed with the conclusion of South Jetty repairs on stations 258+00 to 290+00. The haul road will again have to be repaired and extended to accommodate the placement of the armor stone which large and very large armor stone. The transportation and placement of the stone may be accomplished by marine plant and land based crane depending upon the capabilities of the selected contractor. Total work effort in 2020 is projected to consist of approximately 87,000 tons of imported large and very large armor stone; equivalent to 2980 trucks or 13 barges. The size of the very large armor stone, (16-33 tons) may dictate how they are transported and will require additional time and effort for placement.

7. CONCLUSIONS AND RECOMMENDATIONS

7.1. CONCLUSIONS

- The MCR Jetty System Major Rehabilitation Evaluation Report and Environmental Assessment present the findings of studies conducted for the proposed rehabilitation to the authorized Mouth of the Columbia River three jetty system in Oregon and Washington.
- The purpose of this report is to assess the most efficient means of maintaining deep-draft navigation in a least-cost manner.
- This report also includes supporting documentation for the selected plan cost estimate and construction plan.
- Planning constraints recognized that alternatives were limited to the authorized footprint for the MCR jetties and that the entrance channel to the Columbia River would not be closed to navigation.
- A range of alternatives was considered. Besides the no action alternative, they included scheduled repair, immediate rehab and scheduled rehab. These were further divided into alternatives that held the head and those that did not.
- Three public meetings were held and multiple meetings to place with state and federal resource agencies to determine effects of the alternatives. It was concluded that no significant biological impact would result from the selected plan.
- The Environmental Assessment was released to the public for review in February 2006 and January 2010; in addition a public information meeting was held in February 2011.
- This report incorporates lessons learned from Hurricanes Katrina and Rita and provides an adaptive approach to planning, design, construction and monitoring.
- This report followed the Corps of Engineers' Environmental Principles in the formulation of alternatives, and the environmental documentation provided.
- Evaluation of the alternatives revealed that the most cost-effective method of maintaining navigation through the mouth of the Columbia River is improved monitoring and maintenance of the existing system.
- The different alternatives were evaluated with a MATLAB Stochastic Risk-Based Model that estimated damage on the jetties based upon historical wave data. The development of the model and the subsequent report was subject to multiple reviews compliant with EC 1165-2-209, which included two Agency Technical Reviews, two model certifications from the DDN-PCX and two reviews at the HQUSACE level.
- These documents have undergone numerous reviews: District Quality Control, Agency Technical Review, Independent External Peer Review and NWD Review.
- The project's combined BCR of 1.1 for the system (all three jetties) doesn't capture all the benefits related to protecting the entrance the Columbia River navigation channel (105 miles, 43 feet deep; $182M channel deepening project completed in 2010) and the Columbia Snake River system. For example, $20B of cargo annually travels through the entrance protected by MCR Jetties. To date, over $900M in new infrastructure investment has been made in the Pacific Northwest since 2010.

7.2. RECOMMENDATIONS

I have given careful consideration to all significant aspects of this study in the overall public interest including engineering and economic feasibility as well as social and environmental effects. The selected plan described in this major rehab report and Environmental Assessment provides the most efficient way to maintain the mouth of the Columbia River jetty system.

I recommend that the authorized mouth of the Columbia River project be maintained as described in the selected plan.

The recommended selected plan for the MCR jetty system includes:

- **North Jetty** – Scheduled repair with head stabilization at or near STA 101, (less extensive than the previously proposed capping). These repairs will be conducted after the base condition maintenance repairs to stations 86-99 and lagoon fill to stop erosion of the jetty root. It does not include spur groin construction.

- **South Jetty** – Base condition (interim repairs) allowing head recession. It does not include spur groin construction. Dune augmentation near the jetty root will be implemented in FY 13 as a separate action and not included in the cost estimate. Although the base condition is the NED plan, the interim repair, hold head alternative is very close in AAC, differing by 0.9 percent. When conditions are appropriate (i.e., repairs of the South Jetty allow for a haul road to be established to the end of the jetty approximately FY 2019), head stabilization could be re-evaluated—using parameters such as least cost, environmental acceptability and engineering feasibility.

- **Jetty A** – scheduled repair and head stabilization at approximately STA 89. It does not include spur groin construction. The modeling performed to assess the project alternatives assumes that Jetty A is in place and fully functioning. This is because Jetty A, as originally constructed, protects the North Jetty and helps to train the Columbia River main stem. In addition, Jetty A is believed to play an important function for the Columbia River plume. The plume is an important food source for the 13 Columbia River salmonid evolutionarily significant units (ESUs) listed under the Endangered Species Act (ESA).

The project has a combined BCR of 1.1 for the system (all three jetties).

The initial construction schedule is projected to be from 2014 through 2020. Based on the 100% federally fully funded, feasibility level design in 2012 dollars, project first cost at an effective price level of 01 October 2012 is $238,547,000 and a total project cost fully funded of $257,201,000**.** Total project costs fully funded are estimated as follows per jetty: North Jetty at $79,797,000; South Jetty at $146,884,000; and Jetty A at $30,520,000.

The recommendations contained herein reflect the information available at the time concurrent with departmental policies governing formation and environmental compliance. The information shown neither reflects program and budgeting priorities inherent in the formulation of a National Civil Works construction program nor the perspective of higher review levels within the Executive Branch.

MCR Jetty System Major Rehabilitation Evaluation Report

Appendix A1

Coastal Engineering

Appendix A1 - Coastal Engineering

Table of Contents

LIST OF TABLES

LIST OF FIGURES

Appendix A1 - Coastal Engineering

1. Scope and Purpose

At the mouth of the Columbia River (MCR), three jetties with a total authorized length of 10.2 miles were constructed on massive tidal shoals during 1885-1939 to secure consistent navigation through the coastal inlet. The morphology of the inlet has been changing ever since. The rubblemound jetties have experienced significant deterioration since construction, mainly due to extreme wave attack and foundation instability associated with the erosion of tidal shoals on which the jetties were built. The purpose of the proposed action is to perform modifications to the North and South jetties and Jetty A at the MCR that would strengthen the jetty structures, extend their functional life, and maintain deep-draft navigation.

This appendix analyzes the jetties at the MCR, for the purpose of identifying the need for major rehabilitation along each jetty. Appendix A1 will introduce the MCR navigation project, summarize the sequence of events that have led to the present condition of the MCR jetties, and describe the present structural condition of the jetties. A reliability and life cycle analysis was used to examine the performance of the jetties (past and future) and develop structural alternatives to increase the reliability of the jetty system. Appendix A2 evaluates the present condition of each jetty in terms of realized life-cycle performance, defines the coastal processes affecting jetty reliability, and summarizes the event tree and life cycle analysis. Finally, a holistic approach is used to propose a phased strategy for jetty rehabilitation.

Structural degradation of the 100+ year old MCR jetties has accelerated in recent years because of increased storm activity and loss of sand shoal material upon which the jetties are constructed. In addition, beaches on the ocean sides of the North and South jetties, which formed as a result of jetty construction, have been receding gradually over the years, exposing previously protected sections of the jetties at the beach line to storm waves. Taking no action to extend the functional life of the jetties would result in further deterioration of the jetties and the sand shoals upon which they rest, increasing the likelihood of a jetty breach. Recent interim jetty repairs (2005 to 2007) have addressed immediate critical needs. Additional modifications of the jetties are necessary to address critical near- and long-term needs and reduce the potential for emergency repairs, emergency dredging, and impacts to navigation.

Despite intermittent repair and rehabilitation efforts over their lifetimes, all of the jetties are currently in a significantly deteriorated condition. Appendix A2 discusses the details of present jetty condition, in terms of sustained damage and deferred maintenance. The last partial rehabilitation on the North Jetty was conducted in 1964 and addressed 17% of its length. The last partial rehabilitation on the South Jetty was conducted in 1982 and addressed 25% of its length. The last partial rehabilitation on Jetty A was conducted in 1961 and addressed 56% of its length. The portions of the North and South jetties which have never been repaired since original construction are 55% and 36% of original lengths, respectively. The jetties continue to recede back from their original length. The South, North, and Jetty A head positions are currently shorter than authorized lengths by 6200 ft, 2200 ft, and 900 ft, respectively. Due to the interaction of wave patterns and currents with the jetty configuration, the shorter jetty lengths can expose more shoals to erosion, influence shoreline position adjacent to the jetties, and alter the forcing climate at the project.

Progressive damages to one of the primary jetties could result in a significant breach which can trigger an emergency repair to the jetty, rapid infill into the navigation channel, and emergency dredging activities. The major rehabilitation approach for the MCR jetty system focuses on defining the larger processes affecting the jetty system and describing the jetty system reliability over time. Consequences evaluated included frequency and consequences of future jetty repairs as well as potential impacts to dredging and navigation. Potential navigation impacts were evaluated qualitatively rather than quantitatively. Each alternative adds additional elements of either process stabilization or above or below water cross section stabilization as well as varying degrees of cross section reliability improvement.

2. Project Authorization - MCR Project Features

At the mouth of the Columbia River (MCR), three rubblemound jetties with a total authorized length of 10.2 miles were constructed by the U.S. Army Corps of Engineers (USACE) to secure consistent navigation through the coastal inlet. The Rivers and Harbor Act of 5 July 1884 authorized construction of the South Jetty (first 4.5 miles) to attain a 30-foot channel across the MCR bar. The Rivers and Harbor Act of 3 March 1905 authorized the extension of the South Jetty to 6.6 miles and construction of the North Jetty (2.5-miles long) to attain a 40-foot bar channel (0.5-mile wide). The Rivers and Harbor Act of 3 September 1954 authorized a bar channel at a depth of 48 feet below mean lower low water (MLLW) and Spur Jetty B on the north shore of the inlet; however, funds for Spur Jetty B were not appropriated. Public Law 98-63, 30 July 1983, authorized deepening the northern most 2,000 feet of the MCR channel to 55 feet below MLLW. Jetty A was authorized and constructed to 1.1 miles in length in connection with rehabilitation of the North Jetty for the purpose of channel stabilization. Its purpose was to assist in controlling the location and direction of the ebb tidal flow through the navigation entrance. Figure A1- 1 and Figure A1- 2 illustrate the authorized structures as well as the surrounding shoals and inlet features.

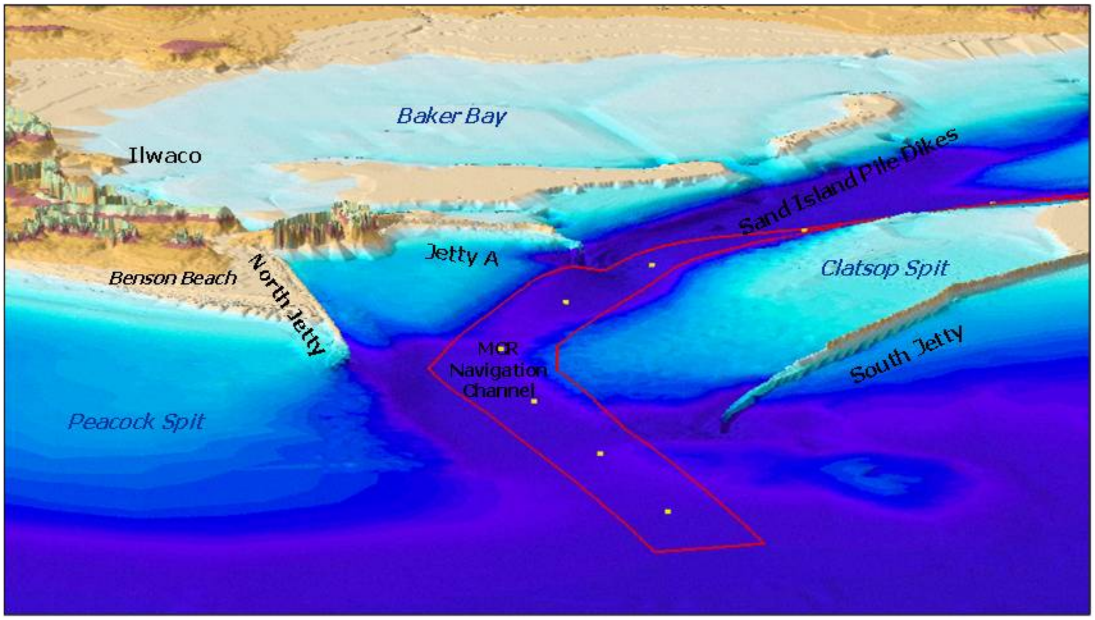

Figure A1- 1. Oblique View of MCR Project

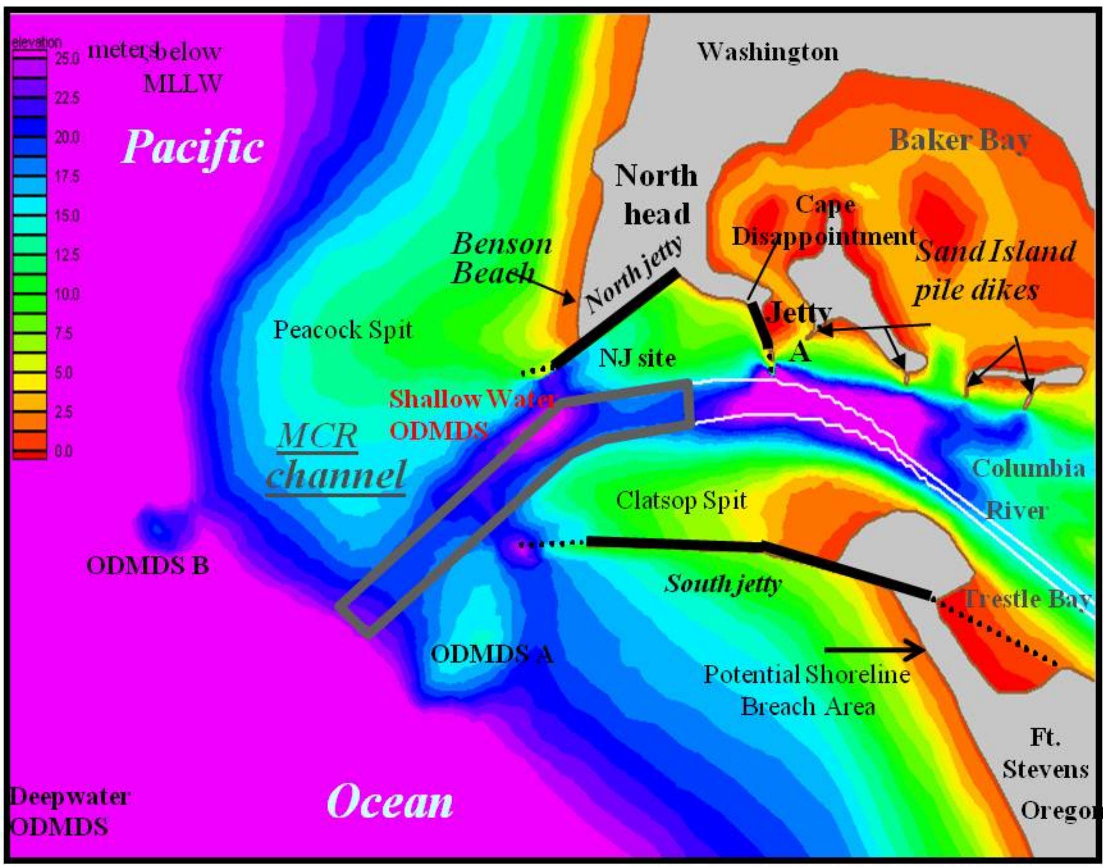

Figure A1- 2. Bathymetry & Navigation Features at the Mouth of the Columbia River, USA

The MCR is the ocean gateway for maritime navigation transiting to/from the 500-mile long Columbia – Snake River inland navigation system (Figure A1- 3). The present deep-draft navigation project at MCR consists of a dredged navigation channel 6-miles long (x 2,460 ft wide x 55 ft deep). The MCR channel passes through a jettied ocean entrance between the states of Oregon and Washington, along river mile (RM, defined from the river entrance) -3 to +3. The present condition of the MCR navigation channel is the result of continuous improvement and maintenance efforts. Figure A1- 4 illustrates the magnitude of the dredging effort at the Mouth of the Columbia River in contrast to the remainder of the Lower Columbia River system.

Figure A1- 3. Mouth of the Columbia River is an ocean gateway

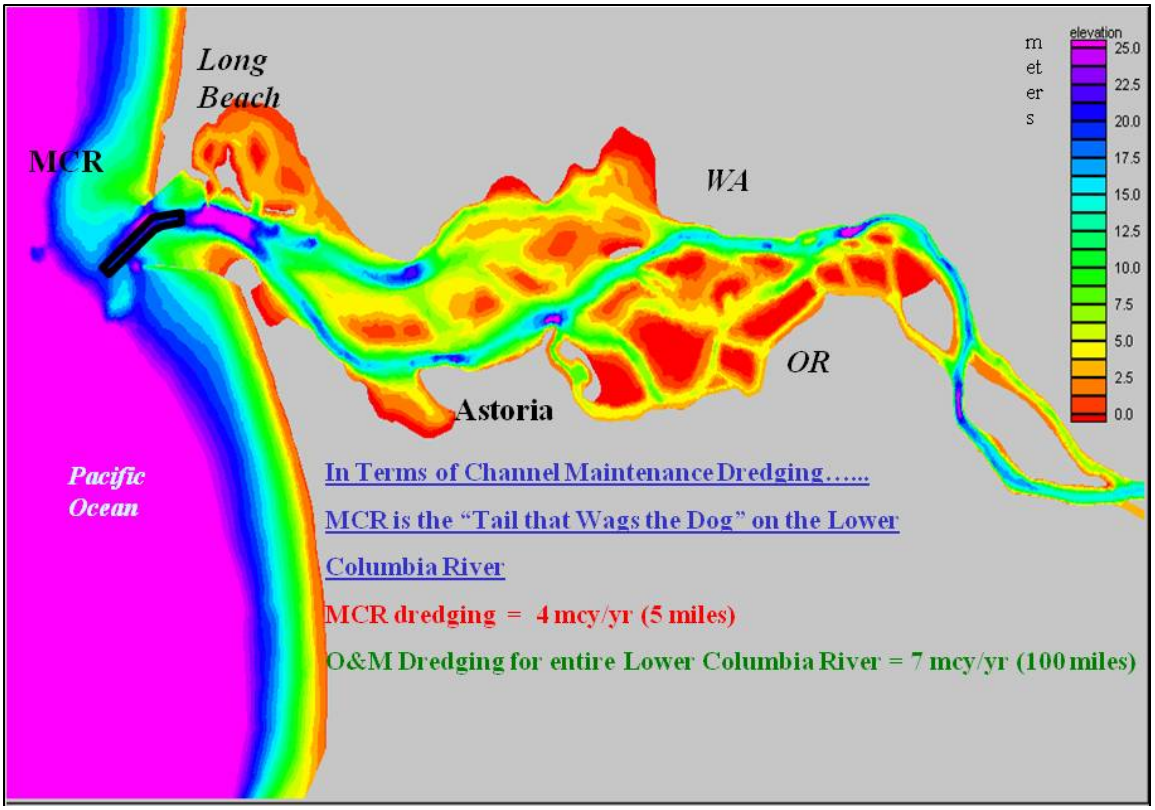

Figure A1- 4. MCR entrance vs Columbia River Dredging

Consistent navigation through the MCR is facilitated by five separate federal project features: 1) MCR navigation channel, 2) North Jetty (Figure A1- 5 and Figure A1- 6), South Jetty (Figure A1- 5 and Figure A1- 7), 4) Jetty A (Figure A1- 5 and Figure A1- 8), and 5) Sand Island pile dikes (Figure A1- 5 and Figure A1- 9). The Sand Island pile dikes are considered secondary structures and were not evaluated in this report. Each project feature was constructed to fulfill a specific hydraulic function, while minimizing the overall maintenance needed to provide safe navigation through the MCR. Figure A1- 2 shows project features, the present configuration of the subtidal shoals/morphology, and the location and orientation of the navigation channel. Figure A1- 10 illustrates the history of shipwrecks at the Mouth of the Columbia River which has had the reputation of being one of the most dangerous coastal entrances to navigate in the world.

Figure A1- 5. MCR entrance structures

Figure A1- 6. North Jetty

Figure A1- 7. South Jetty

Figure A1- 8. Jetty A

Figure A1- 9. Sand Island Pile Dikes

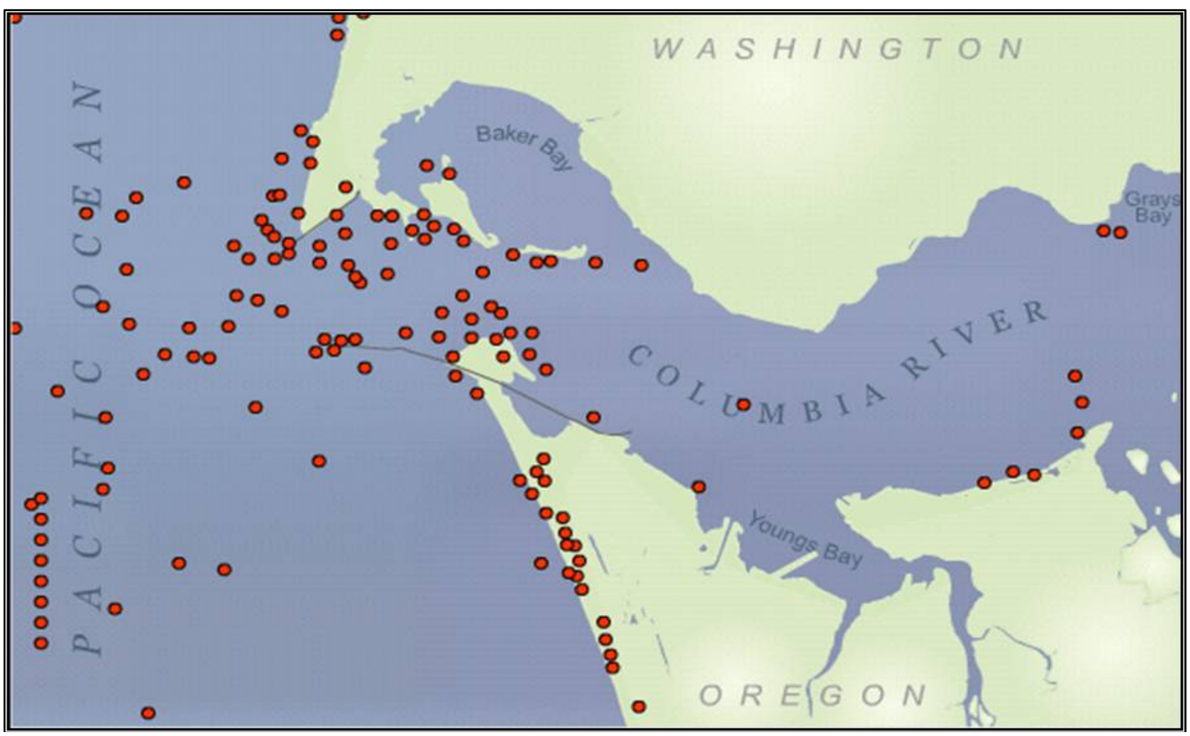

Figure A1- 10. Historical shipwreck locations at MCR (NOAA)

Through phased jetty construction (1885-1939) and the associated response of MCR morphology, all of the project features work together to maintain the function of the navigation entrance. Severe deterioration of any of these features can jeopardize the MCR navigation channel and adversely affect the other structures. Should the North Jetty experience substantial deterioration from its present condition, the MCR channel, South Jetty, Jetty A, and ultimately the Sand Island pile dikes would be negatively affected. A similar scenario would likely occur if the South Jetty experienced substantial deterioration from its present condition.

It is emphasized that the MCR jetties were constructed on tidal shoals, and that these tidal shoals have been changing since the time of jetty construction. The longevity of the jetties is tied to the stability of the shoals on which the jetties were built, and the stability of the shoals is now a function of the jetties. The jetties and shoals act as integrated units to confine tidally-driven circulation through the MCR and maintain the present channel configuration. As authorized by Congress, the basic function of the MCR jetties is to secure and stabilize the MCR deep draft navigation channel. The MCR navigation channel is inherently reliant on the presence and function of the jetties.

3. Location and Description

The 6-mile long deep-draft navigation channel at the mouth of the Columbia River (MCR) has become the ocean gateway for navigation access to and from the 500-mile long Columbia–Snake River system. The Columbia - Snake River navigation systems provides for efficient movement of commerce from the western slopes of the Rockies to the Pacific Ocean. Each year, ocean-going vessels on the Columbia River transport some $20 billion worth of U.S. products to world markets and 42 million tons of cargo passes through MCR annually. The lower Columbia River comprises the world's second largest grain export system, next to the Mississippi River. More than 40 % of the United States' wheat exports are shipped via ports on the Columbia and Willamette rivers. More than 3500 cargo vessels navigate through the MCR annually.

The present authorized deep-draft navigation project at MCR provides for a 2640-ft wide channel across the Columbia River bar. The northerly 2,000 ft of the channel is maintained at –55 ft MLLW (plus 5 ft for over dredging), and the southerly 640 ft of the channel is maintained at –48 ft MLLW (plus 5 ft for over dredging). Each year, the Portland District dredges 3 to 5 million cubic yards (MCY) of sand at MCR to maintain the 5-mile long deep-draft navigation channel. Due to the severe wave conditions of fall through spring, maintenance dredging at MCR can only be performed by hopper dredges operating during the relative calm of summer. Figure A1- 11 shows both a contract and a government dredge working at the MCR entrance. The dredged material is fine-medium sand (0.17-0.27 mm) and fine-grained material content is less than 4%. This material is disposed of in open water disposal sites (e.g. Shallow Water Site (SWS) and Deep Water Site (DWS)) as shown in Figure A1- 12.

Figure A1- 11. Contract and government dredges working at MCR

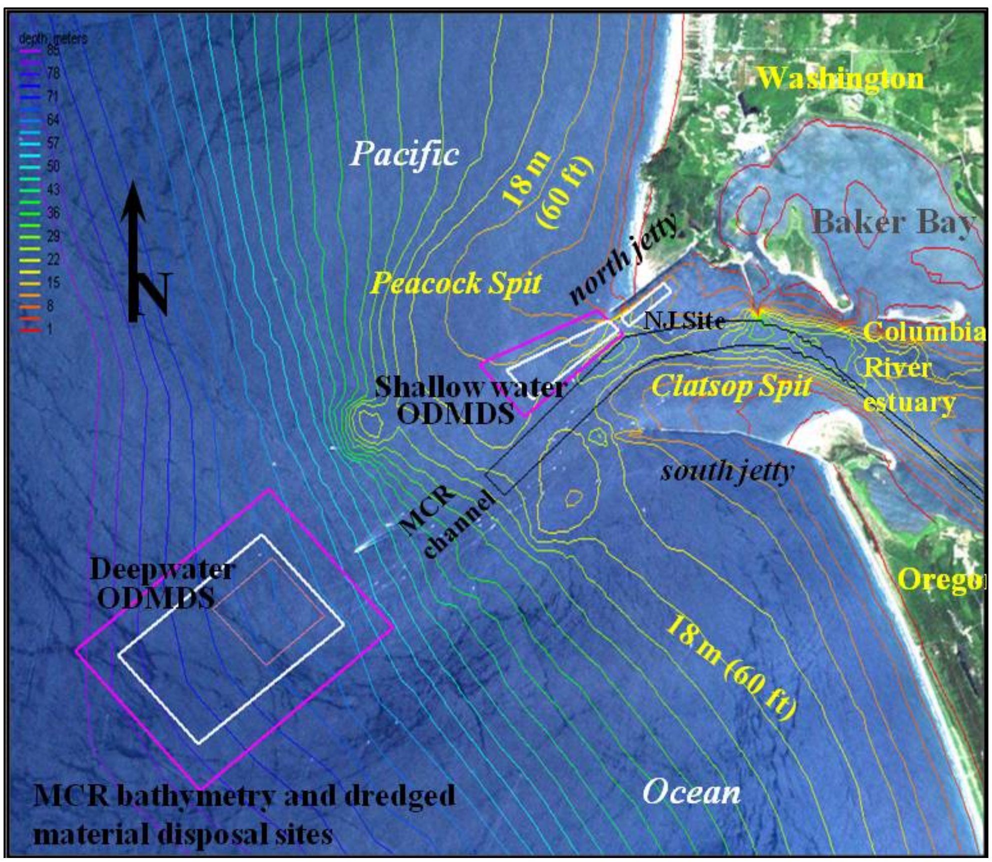

Figure A1- 12. Open water dredged material disposal sites at MCR

The central project feature at MCR is the navigation channel. The North and South jetties are the two most important features that act to maintain the stability of the navigation channel. The overall length of the rubblemound North and South jetties is 2.35 miles and 6.62 miles, respectively. Originally, each project feature was constructed as a separate entity to fulfill a specific hydraulic function, while minimizing the overall maintenance needed to provide safe navigation through the MCR. All the project features were justified based on the need to secure the MCR deep draft navigation channel.

a. MCR Upstream Physical Setting

Offshore of the MCR lays the vast expanse of the northeast Pacific Ocean. Inshore of MCR lies the Columbia River and its estuary, the coastal outlet for a 250,000 mi^2 drainage basin where the headwaters emanate from the western slope of the Rocky mountains. The course of the Columbia River is 1,210 mile long, dropping over 2,600 feet from its Canadian headwaters to the sea. The Columbia River accounts for 60% (winter) to 90% (summer) of the total freshwater discharging into the ocean from the Canadian border and San Francisco. The Columbia River estuary is the largest fluvially dominated estuary in the Pacific Northwest and its tidal prism is about 1,390 mi^2-ft [Jarrett 1976]. The upriver limit for the Columbia River estuary, defined in terms of salt water intrusion, varies between RM 28 and 38 and is a function of fluvial flow and sequencing of the tidal cycle. Current reversal due to tide can occur as far inland as RM 70. Tidal effects (fluctuation of water surface elevation) extend upriver to Bonneville dam (RM 145).

The annual discharge of the Columbia River is marked by seasonal variability, typically ranging from 100,000 to 400,000 cubic feet per second (cfs). Highest discharges occur during May through July due to snowmelt and rain runoff. Lowest flows occur during late summer and early fall [Neal 1972]. The average (regulated) river discharge is presently about 265,000 cfs. Peak river flow at the Dalles dam during the freshet of May 1997 was at about 600,000 cfs, which corresponded to a 3% chance of exceedence (35-year) regulated flow event. Physical characteristics of the Columbia River estuary differ from those of most North American estuaries - river discharge is much greater, salinities are much lower, tidal forcing is greater, and bottom sediment is less stable. Flushing time for the Columbia River's estuarine waters is 2-5 days, whereas the flushing time for many other estuaries may require weeks or months: The average flushing time for Chesapeake Bay is about 1 year.

Although the Columbia River is known for its low turbidity, swift river currents move a significant amount of bedload sediment within the lower reaches of the river and produce sand waves up to 10-ft high on the channel bottom. Within the Lower Columbia River (downstream of Bonneville Dam, RM 145), the amount of sediment contributed by the upper Columbia River is very small compared to the net water discharge and most of the sediment that is affected by bedload processes (sand-sized or larger) has originated from the Cascade arc. From 80% to 90% of the Lower Columbia River's sediment through-flow is composed of suspended sediment, yet relatively little suspended sediment is retained in the main stem of the estuary. The predominate sediment type in the main channels of the estuary (downstream of RM 30) is medium to coarse sand and small gravel which is transported as bedload, with finer silts and clays prevalent in peripheral bays and within limited areas of the main estuary

[Roy et al., 1982]. In terms of the overall estuary, average bottom sediments have been characterized as having 1% gravel, 84% sand, 13% silt, and 2% clay [Hubbell and Glenn 1973 and Roy 1982]. Fine sediment, which is normally transported in suspension, comprises only a small percentage of the sediment deposited in the main channels of the estuary. Approximately 67% of the suspended sediment (generally, silt-size and finer) discharged from the Columbia River is estimated to be transported to the continental shelf of Washington, 17% of which is estimated to be transported beyond the shelf break, down into submarine canyons [Sternberg 1986].

b. MCR Navigation Development

Prior to improvement in 1885, the tidal channels through the MCR shifted north and south between Point Adams (Fort Stevens) and Cape Disappointment, a distance of about 5.5 miles. Figure A1- 13 through Figure A1- 15 document the high degree of natural channel variability that had taken place from 1792-1885 at the MCR entrance. Note the southward migration of the natural channel from Baker Bay (1839) to the middle of the entrance and radical modification of the intervening tidal shoals (1885). The MCR was more than once divided into two or more channels, and the controlling depth of the dominant channel through the ebb tidal delta varied between 18-25 feet below MLLW. The ebb and flood tidal deltas at MCR entrance were distributed over a large area, immediately seaward and upstream of the river mouth. Ships often had trouble traversing the Columbia River bar, the area in which the flow of the estuary rushes headlong into towering ocean waves. On many occasions, outbound ships had to wait a month or more until bar conditions were favorable for crossing. To make the business of navigating through the MCR even worse, sailing ships had to approach either of the two natural channels (north channel or south channel) abeam to the wind and waves. The natural channels often shifted widely within the course of several tidal cycles. At best, crossing the bar was dangerous. At worst, it was not possible.

With the "opening of the west" that was occurring in America during 1860-1880, a consistent and reliable navigation channel was needed through the MCR to link inland areas of the Pacific Northwest with other parts of the country and world. It was assumed that a (South Jetty) stone dike would guide ebb tidal waters in the direction of the channel and away from Clatsop Spit, thereby deepening the channel. In order to improve the channel, Congress, by the River and Harbor Act of 2 August 1882, authorized a Board of Engineers to "examine in detail the mouth of the Columbia River, Oregon, and report such plan, with estimates, for its permanent improvement as they approve."

4. MCR Inlet – History and Present Condition

a. General

Navigation at many coastal inlets is typically secured using one or two rubblemound jetties. Figure A1- 16 illustrates the changes to the entrance after the first phase of the South Jetty construction. A rubblemound structure can be composed of several layers of random-shaped and random-placed stone (core), protected with a cover layer of selected armor units of either quarry stone or specifically shaped concrete units (armor layer). A jetty functions to confine tidal flow through an inlet (increase flow velocity) to promote scour and secure a navigation channel of specified depth. Figure A1- 17 and Figure A1- 18 illustrate that process in response to South Jetty and North Jetty construction at the MCR. Too little scour and shoaling degrades the navigation channel, too much scour and the inlet becomes unstable and the jetties can be undermined; regardless of how the jetty is constructed. A jetty can also stabilize an inlet by reducing the volume of open coast littoral circulation (and sand) that would otherwise enter an inlet, and lead to rapid shoaling of a navigation channel. A system of convergent jetties was used to establish and retain the deep draft navigation channel at MCR.

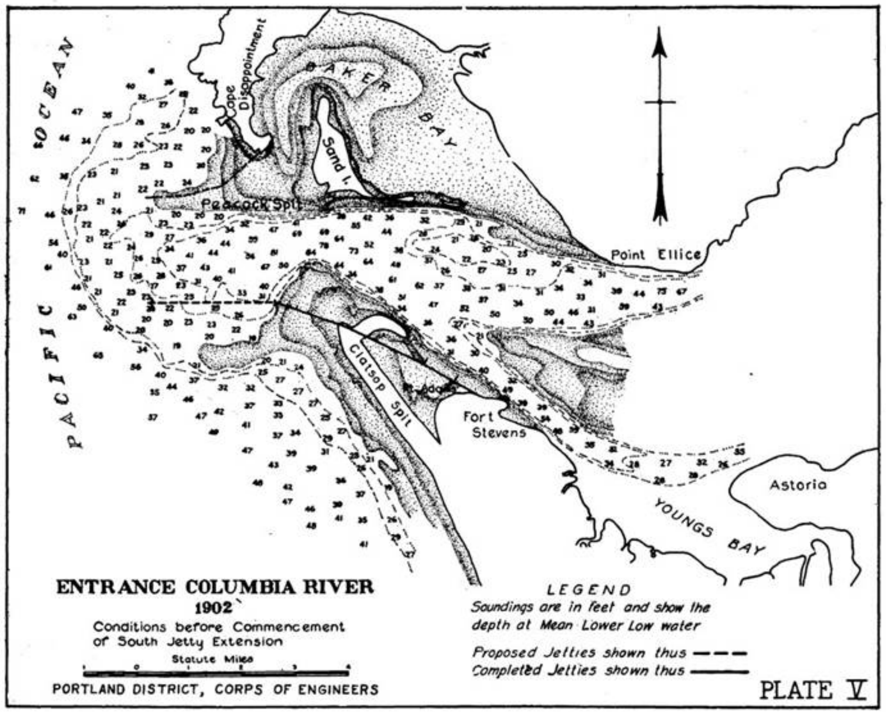

Figure A1- 16. 1902 Bathymetry at MCR

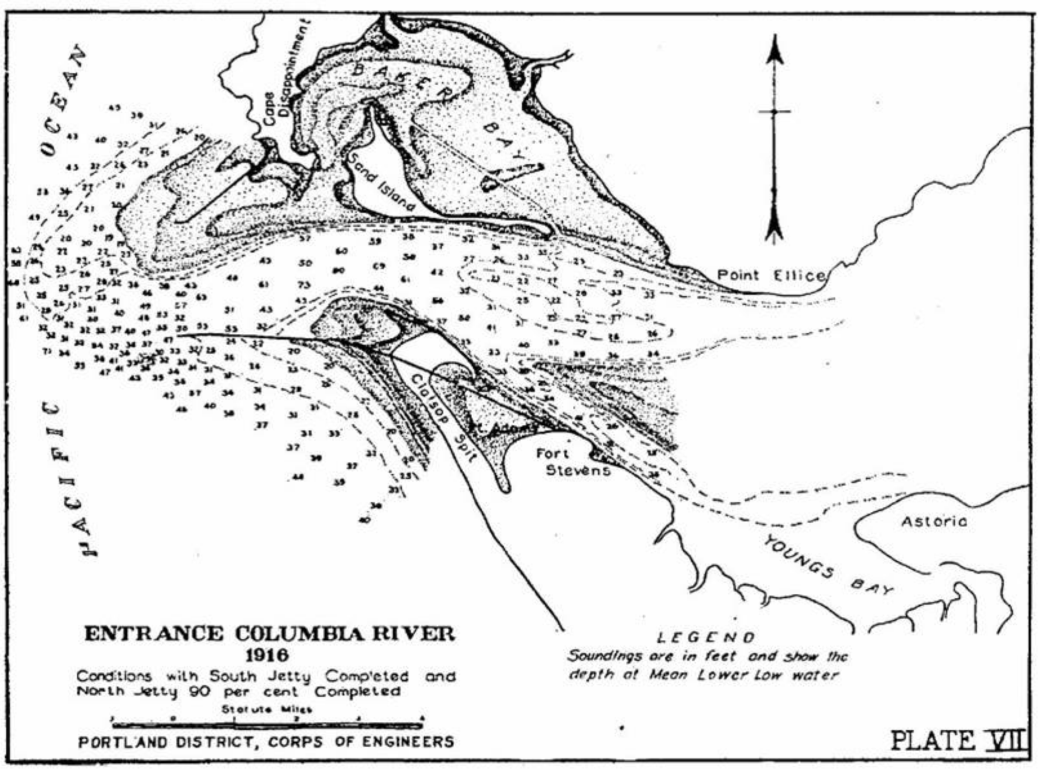

Figure A1- 17. 1916 Bathymetry at MCR

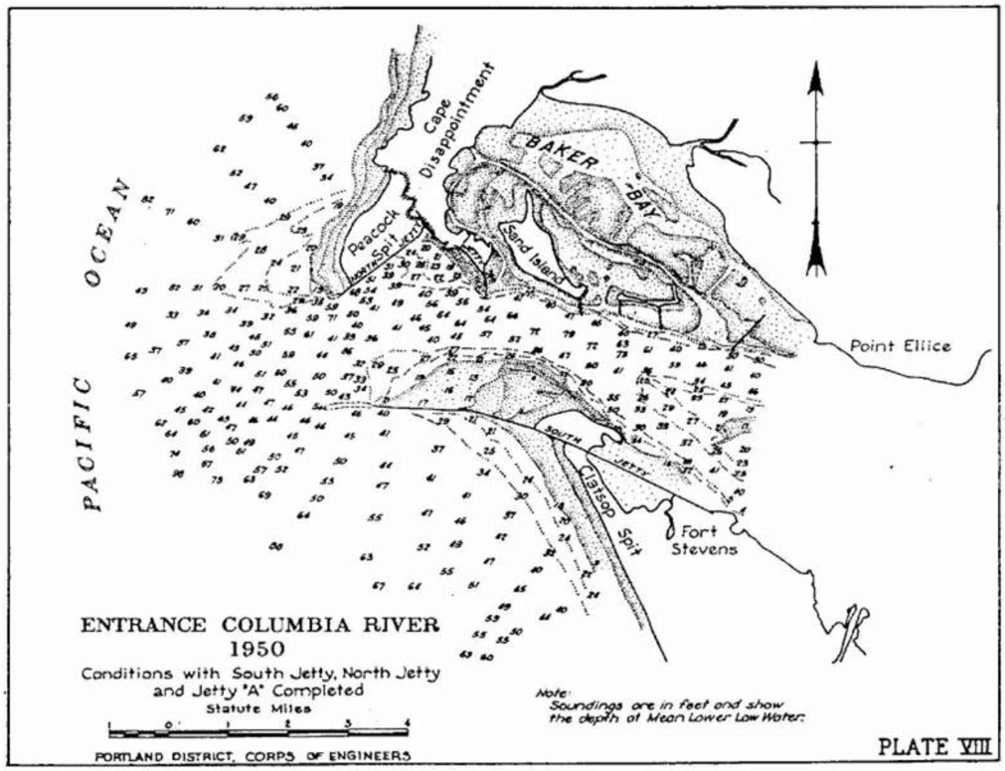

Figure A1- 18. 1950 Bathymetry at MCR

Construction of the MCR jetties reformed a broad and treacherously variable 5 mile-wide inlet into a stable 2 mile-wide inlet having a consistent thalweg suitable for navigation. Figure A1- 19 through Figure A1- 24 illustrates the reforming of the MCR inlet in response to the jetty construction. The central project feature at MCR is the navigation channel, which is secured by a system of large rubblemound jetties: 1) a 2.5 mile North Jetty constructed during 1914-1917, 2) a 6 mile South Jetty constructed during 1885-1913, and 3) a 0.5 mile Jetty A constructed in 1939. Approximately 11 million tons of quarried stone have been used to construct and maintain three MCR jetties. Figure A1- 25 through Figure A1- 31 illustrates the gradual changes both in location and depth in the navigation channel and the entrance channel bathymetry over time.

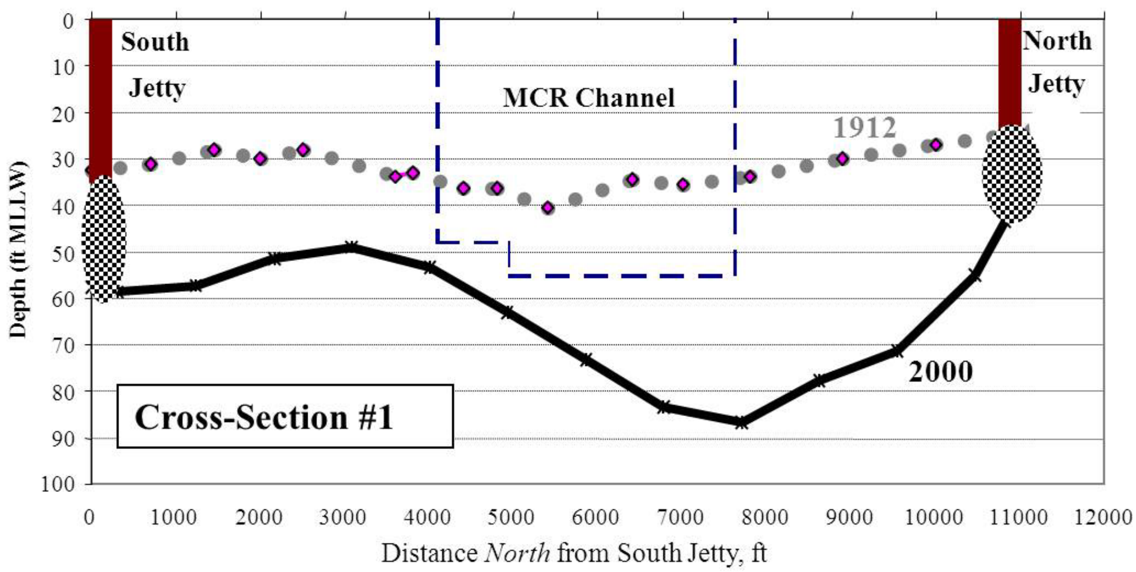

Figure A1- 30. MCR Channel X-Section #1

(View toward ocean, see figure A1-28 for X-S #1 location. Scour along toe of north and south jetties (highlighted by checkerboard shape) exceeds 12 ft and 20 ft, respectively. Since 1912, the MCR channel thalweg has migrated 3,000 ft northward toward the north jetty.)

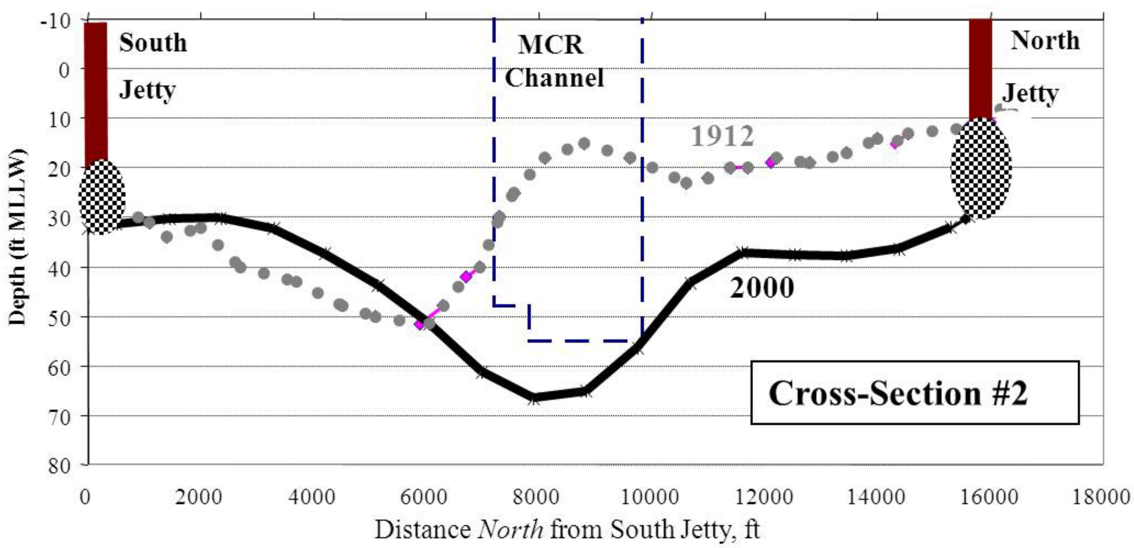

Figure A1-31. MCR Channel X-Section #2, view toward ocean, see figure A1-_28 for X-S #2 location. Scour along toe of north and south jetties (highlighted by checkerboard shape) exceeds 20 ft and 10 ft meters, respectively.

Figure A1- 31. MCR Channel X-Section #2

(View toward ocean, see figure A1-28 for X-S #2 location. Scour along toe of north and south jetties (highlighted by checkerboard shape) exceeds 20 ft and 10 ft meters, respectively.)

Over the last 120 years, the re-direction of currents through the jettied entrance of MCR resulted in the discharge of greater than 400 million cubic meters of sand from the estuary to the ocean and resulted in re-orientation of the tidal inlet. Much of the present-day Peacock Spit and Clatsop Spit were formed by sand discharged from MCR during/after jetty construction. However, these spits and tidal shoals have been eroding since the completion of jetty construction (1939). The water depth along each jetty varies from 0 at the root (landward tie-in) to >65 ft along the head (seaward terminus). The present forcing environment at the MCR inlet exposes the jetties to severe conditions particularly during the winter months (NOV- MAR), when intense maritime extra-tropical low pressure systems buffet the coast. During winter storms, the coastal water level can be perturbed by a potential 10 ft combined-transient storm surge allowing 33 ft high waves to attack the seaward end of the jetties. The wintertime sea state affecting MCR is characterized by large swell approaching from the northwest to southwest combined with locally generated wind waves from the south to southwest. The tides at MCR are mixed semi-diurnal. The 7.5-ft average diurnal tide range combined with an annual average Columbia River flow rate of 4,500 m^3/sec can produce peak estuarine flow through the MCR that exceeds 40,000 m^3/sec during ebb and flood tide. A tremendous amount of sediment transport can occur at the inlet and along the jetties when storm waves and storm-induced current interact with the inlet's estuarine circulation.

b. MCR Construction Timeline

1881. Proposed project to build a strong pile-dike, 3 feet above low tide, 8000 feet long, and 20 feet wide along a line previously established along the south side. The structure will start near the northeast corner of Fort Stevens, following the 12-foot curve; the dike will be directed a little westward of the outer part of the headland of Cape Hancock. It is stated that work should commence soon (during the summer and autumn) because channel maintenance is dependent upon building up Clatsop Spit.

1883. A jetty plan has been approved by the Board from the south cape of the entrance on the spit. A survey was conducted in October and November of the south cape, Point Adams, to extreme low water. The jetty will extend from Point Adams and make the distance between the outer end of the jetty and Cape Disappointment the same as the distance between Chinook Point and Point Adams. The Board stated that any structures placed in the river should not harm the river and should keep the channel open using the tide; therefore, the jetty should not obstruct the entry of the flood tide. It was recommended that jetty construction should begin as soon as possible. The jetty design calls for a crest elevation at low water level. The estimated depths of the various jetty sections from the landward end are: 5000 ft - less than +6 ft, 7500 ft – +6 ft to +11 ft, 4000 ft – +11 ft to +16 ft, and 7500 ft – +16 ft to +21 ft. The jetty crest elevation was designed to be at low water level because of the violence of the waves that could harm a higher jetty. The logic is that a higher jetty could be built, if needed later, by placing more stone upon the existing jetty. A jetty height to mid-tide level was suggested but not recommended because the lower jetty would be quite effective in directing the ebb tide and would interfere less with the flood tide. A higher jetty would result in higher maintenance costs due to the jetty being more exposed to wave action.

1884. The improvement plan for MCR was approved by the act of July 5, 1884 to maintain a channel 30-feet deep at mean low tide by constructing a low-tide jetty, about 4.5 miles long, from near Fort Stevens, on the South Cape, to a point about 3 miles south of Cape Disappointment.

1886-1896. Original construction of South Jetty from Fort Stevens (Station 25+80) across Trestle Bay and Clatsop Spit to Station 250+20. Rock is placed with a natural slope to an elevation of between 4 and 12 ft (MLLW), crest width is roughly 10 ft. "The jetty, of a brush-mattress and stone ballast, was built for 1,020 feet from ordinary highest tide-line, and minor constructions added." Material has filled along the south side of the jetty, moving the shoreline seaward. The highest tide-line is located at tramway Station 30+50. A 115 ft long spur was built landward of the jetty for shore protection. A 510 ft long sand-catch, consisting of heavy beach drift and loose brush, was built on the south side of the landward end of the jetty to continue filling the old outlet of a lagoon at the extreme end of Point Adams. The stone in the jetty was originally dumped in ridges, but the waves have flattened and compacted the rocks to a width of 50 ft. The report indicates that there is an urgency to extend the jetty in order to prevent further deterioration of the bar-channel.

1889. The jetty is now under construction for 1.5 miles. Clatsop Spit has more material visible at low water and the river channel has a tendency towards a straight course out to sea. Tillamook Chute is being closed. Sand is building up south of the jetty adjacent to and in front of the mattresses as they are constructed.

1890. Jetty construction is 3.25 miles underway. Jetty elevation is at MLLW for about 3 miles. 1.25 miles of tramway needs to be constructed. Clatsop Spit is building up; the outflowing waters are being concentrated over the channel bar. Station 25+80 is considered the beginning of the jetty. The jetty mattress has been advanced from Station 99+04 to Station 194+08. The jetty elevation is at MLLW to Station 170+00. From Station 170+00 to the end of the mattress work, there is about 9 feet of rock on top of the mattress. At Station 65+00, there were signs of sinking and a large amount of rock had to be dumped in place.

1903-1913. Extension of South Jetty. Crest elevation of jetty is raised to +10 ft MLLW from Station 210+35 to Station 250+20, and rock is placed from Station 250+20 to Station 375+52, elevation increasing in steps to 24 ft MLLW. Crest width is 25 ft and side slopes are natural slope of rock. A seaward bend in the jetty is added and called the "knuckle."

1913-1917. Original construction of North Jetty from Station 0+00 to Station 122+00. Side slopes are 1V:1.5H and crest width is 25ft. Crest elevation varies from 15ft to 32 ft MLLW.

1931-1932: Repair of South Jetty from Station 175+00 to Station 257+68.7 (shoreline to knuckle), side slopes are 1V:1.5H, crest elevation is 24 ft MLLW, and crest width is 24 ft. This is the first maintenance for the South Jetty. The jetty had been flattened to about low water level. 2.2 million tons of stone was placed in the super-structure. The work was completed in 1936. The end of the jetty would unravel 300 ft or more, so a solid concrete terminal was constructed above low water level. The terminal is located 3900 ft shoreward of the original jetty end that was completed in 1913.

1933-1934. Repair of South Jetty from Station 257+68.7 to Station 305+05 (knuckle to middle of outer segment). Two-level cross section with crest elevations of 17 and 26 MLLW. Crest width of each level is 24 ft. Side slopes are 1V:1.5H on channel side and vary from 1V:1H to 1V:1.75H to 1V:2H on ocean side.

1935-1936. Repair of South Jetty from Station 305+05 to Station 353+05 (middle of outer segment to existing end). Similar design to 1933 repair.

1936. Stone/asphalt cone-shaped terminal constructed on South Jetty from Station 340+30 to Station 344+30. Crest width of approximately 50 ft and elevation varied between 23 and 26 ft MLLW. Side slopes are 1V:2H.

1937-1939. Repair of North Jetty from Station 68+35 to 110+35. Crest elevation is 26ft MLLW and crest width is 30ft. Side slope is 1V:1.25H on ocean side and 1V:1.5H on channel side.

1939. Original construction of Jetty A from Station 40+94 to 96+83. Crest width is 10 ft from beginning to Station 53+00, 30 ft in width and elevation of 20 ft MLLW from this point on. Four pile dikes completed at Sand Island.

1940. Repair of South Jetty with replacement rock in locations as needed.

1940-1942. South Jetty repair from Station 332+00 to 343+30. Addition of concrete terminal and stone foundation. Crest elevation between 8 and 20 ft MLLW and crest width between 50 ft and 75 ft, 10 in. Side slopes determined by concrete terminal shape.

1945-1947. Repair Jetty A from Station 78+00 to Station 96+00. Crest elevation built to 20 ft MLLW with a crest width of 40 ft.

1948-1949. Repair 300 ft of Jetty A from Station 92+35 to 95+35 with a crest elevation of 20 ft MLLW, a crest width of 30 ft, and side slopes of 1V:1.25H.

1951. Repair of Jetty A from Station 91+50 to Station 93+00 with a crest elevation of 20 ft MLLW, a crest width of 30 ft, and side slopes of 1V:1.5H.

1952. Repair of Jetty A from Station 90+00 to 94+00 with a crest elevation of 20 ft MLLW, a crest width of 30 ft, and side slopes of 1V:1.5H.

1958. Repair of Jetty A from Station 41+00 to Station 79+00. Crest elevation raised to 20 ft MLLW and a crest width of 20 ft from Station 41+00 to 56+00. Crest width is 30 ft from Station 61+00 to Station 79+00.

1961-1962. Repair of Jetty A from Station 50+00 to 90+50, with no repairs from Station 68+00 to Station 76+50. Crest elevation was built with a 10% grade from 20 ft MLLW to 24 ft MLLW between Station 50+00 to Station 68+00. The crest elevation was raised to 24 ft MLLW between Stations 76+50 to 90+50.

1961. South Jetty repair from Station 194+00 to Station 249+00 (before knuckle, current stationing). Crest elevation varies from 24 ft MLLW to 28 ft MLLW, and crest width is 30 ft. Channel side slope is 1V:1.25H and ocean side slope is 1V:1.5H. Repairs occurred from Station 38+00 to 93+00 (old stationing). Elevation at 38+00 is +24 ft MLLW, and then is increased with a 0.5% grade up to +28 ft MLLW for the remainder of the repair section. The centerline of the repairs is located 13 ft north of the centerline of the original jetty design. The design crest width is 30 ft. The north slope is 1:1.25 and the south slope is 1:1.5.

1962-1965. Repair of South Jetty from Station 249+00 to Station 314+05 (beyond knuckle). Crest elevation begins at 28 ft MLLW and transitions to 25 ft MLLW for most of section. Side slopes vary from 1V:1.5H to 1V:2H and crest width is 40 ft (this appears to be the furthest seaward intact portion of current jetty). Repairs were from Station 93+00 to 157+50 (old stationing). The crest elevation is +28 ft MLLW at Station 93+00, then decreases to +25 ft MLLW at Station 95+00, then continues with this elevation to the end of the repairs. The crest width is 40 ft and has a slope of 1:1.5 from Station 93+00 to 152+00. The slope then transitions to 1:2 from Station 152+00 to 154+00. The centerline of the repair is 15 ft south of the trestle centerline.

1965. Repair of North Jetty from Station 89+47 to Station 109+67 with a crest elevation of 24 ft MLLW and crest width is 30 ft. Side slopes vary from 1V:1.5H to 1V:2H.

1982. Repair of South Jetty from Station 194+00 to Station 249+00 (segment before knuckle). Crest elevation varies from 22ft MLLW to 25ft MLLW. Crest width varies from 25 to 30 ft, and side slopes are 1V:1.5H. The crest elevation varies from +22 ft at Station 38+00 to +25 ft at Station 80+35 (old stationing). From Station 44+50 to 80+35, the crest width is 30 ft, and the slope is 1:1.5. The centerline of the repairs has a 10 ft maximum variance to the north for the South Jetty control line. Between Stations 80+35 and 93+00, the centerline of the repairs is the same as the South Jetty control. The crest elevation is +25 ft, the width varies between 25 and 30 ft, and the slope is 1:1.5.

2005. Interim repair of North Jetty from Station 55+00 to 86+00. Crest elevation used was +25 ft MLLW with a sideslope of 1V:1.5H.

2006. Interim repair of South Jetty from Station 223+00 to 245+00. Crest elevation used was +25 ft MLLW with a sideslope of 1V:2H.

2007. Interim repair of South Jetty from Station 255+00 to 285+00. Crest elevation used was +25 ft MLLW with a sideslope of 1V:2H.

c. Overall Jetty System Function

The function of the MCR jetties has evolved since initial construction. Improvement of the MCR navigation entrance was conducted incrementally with subsequent stages being initiated as a physical need was recognized. The South Jetty was constructed first as a mid-tide jetty to a moderate length (1885-1895). Instability of the South Jetty and continued migration of the navigation channel led to recommendations to extend the South Jetty and raise it to a high tide jetty. During improvement of the South Jetty (1905-1913), it became apparent that a North Jetty would be needed to maintain a stable navigation channel.

These sequential improvements were conducted during 1885 to 1917. During the early 1930s (after both North and South jetties had been in place and significant modification of the inlet's morphology had occurred), the North Jetty became threatened by high velocity ebb tide flow which threatened to undermine the structure's channel side foundation. Concurrently, the south side of Sand Island was being eroded by increased current action. Loss of either the North Jetty or Sand Island would have rendered the inlet unsuitable for navigation. The adverse circulation affecting the North Jetty and Sand Island was motivated by the northward migration of the estuary thalweg toward Cape Disappointment. In the late 1930s, the Sand Island Pile Dikes and Jetty A were constructed by USACE to stabilize the evolving inlet. The pile dikes stabilized Sand Island, preventing detrimental effects on Baker Bay and inlet navigation. Jetty A prevented the northward migration of the inlet's thalweg while deflecting ebb away from the North Jetty and flood current away from Sand Island. Collectively, all three jetties and the Sand Island pile dikes now function in concert to balance the large scale ocean processes affecting the entrance. Through the evolution of the inlet and its morphology, Jetty A now also serves as a breakwater to protect Sand Island and the Ilwaco entrance into Baker Bay from large ocean waves.

Since the original jetty construction, several large physical process changes have altered the current and projected future reliability of the system. These large process changes gradually impact the stability of the structures and the reliability of the system. It has been shown that as increased depths are secured in the improved navigation channel, larger waves are able to enter the channel and attack the jetties in addition to undermining the sandy foundation upon which they rest. These increased depths primarily affect the channelside of the jetties, and in particular, the North Jetty which is closer to the navigation channel. Along the landward half of the North Jetty, another de-stabilizing flow path has developed through the structure as tidal flow moves through the structure to the eroded lagoon behind the structure.

In addition another apparent large process change has been a gradual increase in the wave climate both in terms of storm wave height as well as number of large storms occurring in a given year. Concurrent with the increase in storm climate and the larger interior waves and currents, foundation erosion has accelerated both seaward and adjacent to the jetties. During 1993 to 2000, the 40 ft contour on the ebb tidal shoal receded landward at a rate 7 times faster than during 1930 to 1993, as shown in Figure A1- 32. As the ebb tidal shoal recedes, the wave and current regime at the entrance and jetties changes.

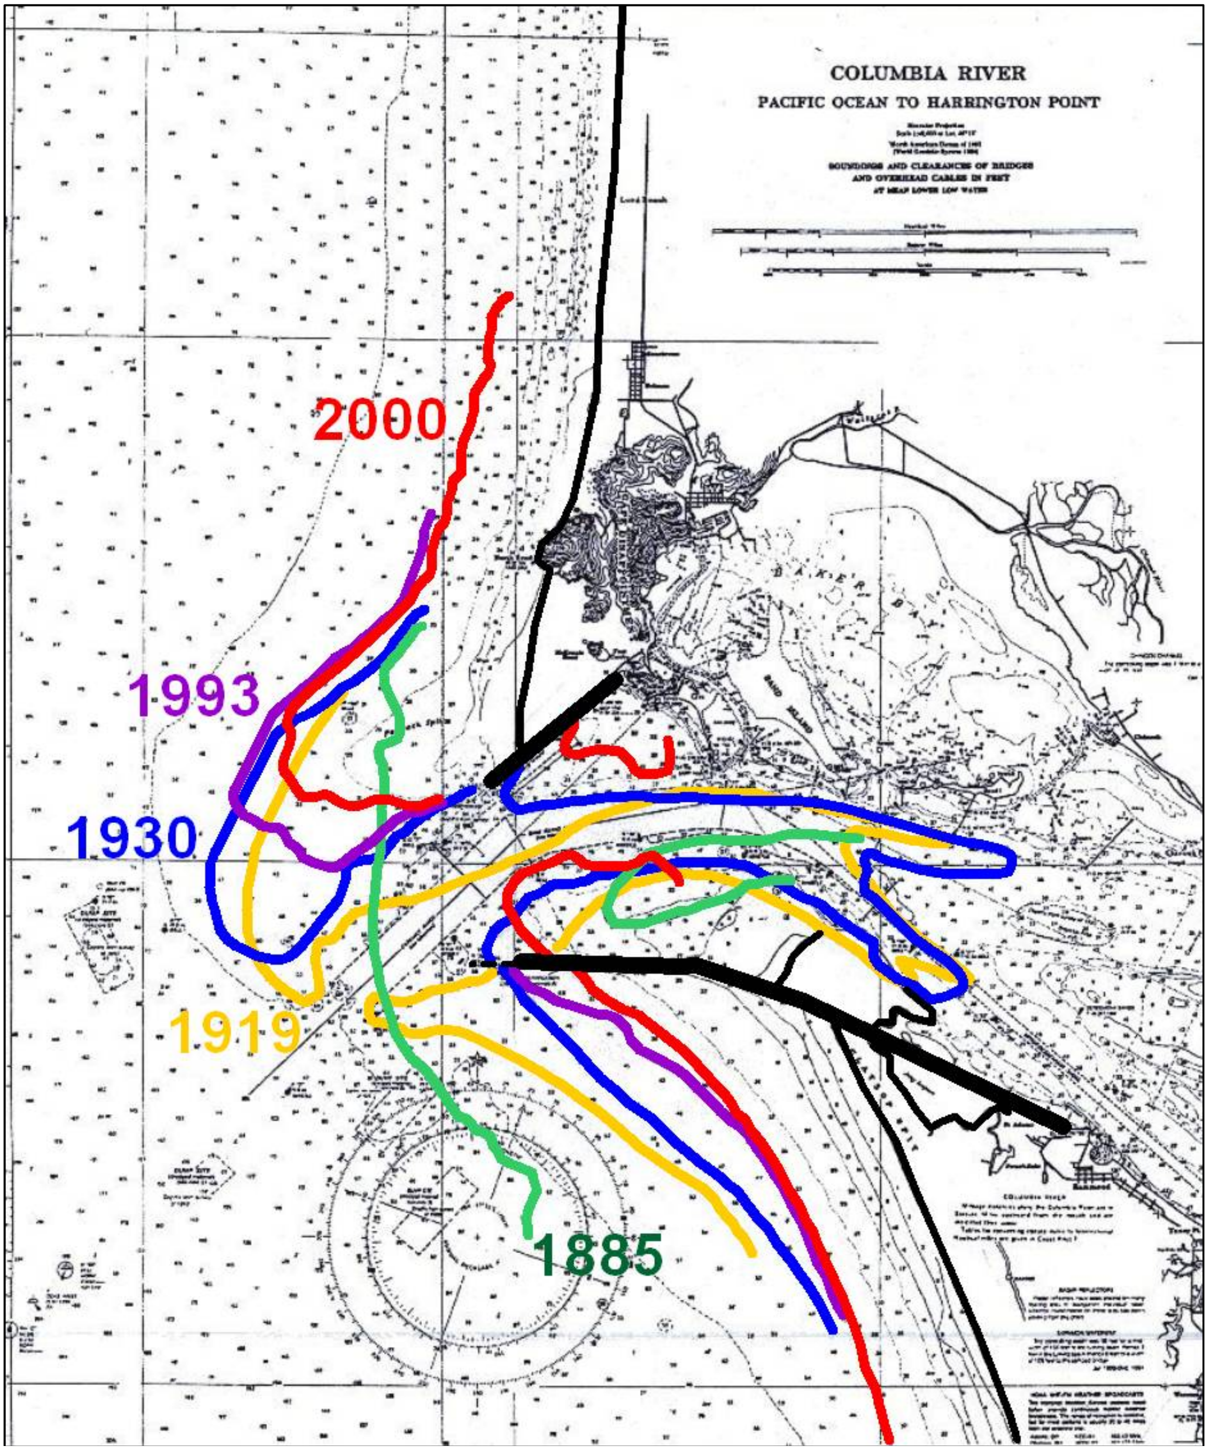

Figure A1- 32. Map of -40 ft contours around MCR Over Time – 1885 to 2000

The principal function of the MCR jetties is to secure a consistent navigation channel across the bar at MCR. If the reliability of the MCR channel is jeopardized due to jetty deterioration, then the jetty is considered to have "failed" and timely repair is merited. It is important to note that if a jetty deteriorates without significantly reducing the reliability of the MCR navigation channel, then the jetty is not considered to have "failed" and there is no need to expedite repair. However, cumulative and systemic jetty deterioration can result in a project failure.

d. MCR Dredging and Environmental Forcing

Successive Congressional authorizations have tasked the Corps of Engineers with deepening and maintaining the channel at the MCR; from a depth of -30 ft MLLW (1885) to -55 ft MLLW (1984). Since 1904, hopper dredges have dredged over 200 million cy at MCR. The dredged sand has been placed in ocean dredged material disposal sites (ODMDS, see Figure A1- 12). The present maintenance dredging requirement at the MCR is about 4 million cy/yr. While some of the dredged sand has been placed on or near the tidal shoals, a considerable volume of dredged sand is placed away from the tidal shoals. The disposal of dredged sand has historically been viewed as a wasting operation. Targeted use of the dredged sand to augment the tidal shoals has not been a focus of the MCR dredging program. The cost of dredging the MCR channel (and disposing of sand at the ODMDS) varies from $3.00 to $4.00 a cubic yard. The incremental cost of placing dredged sand on the MCR tidal shoals to prevent foundation erosion of the jetties is estimated to be $ 0.30/cy.

The orientation of the shoals/spits at MCR has changed due to waves and currents; the morphology and coastal processes at MCR are linked. Eddies that form within MCR arise due to the interaction of flow with the jetties and the morphology and greatly influence flow and shoaling within the channel. The littoral dynamics north and south of MCR are drastically different than at "open coast" areas away from the entrance. Depending on the regional wind field, the "coastal current" up-drift and down-drift from MCR can attain speeds of 3 ft/s. As the tidal shoals continue to recede (erode), the jetties will be exposed to larger waves and more vigorous currents. To make matters worse, the regional wave climate along the Northwest Pacific coast has become more severe in the last 10 years due to El Nińo, La Nińa, and decadal oscillation. The offshore design wave height (p-val = 0.01) has been revised from 40 ft to 47 ft [Moritz 2001]. Taken together, these changes will accelerate MCR jetty deterioration.

Approximately 60% of the sand annually dredged from the MCR entrance is placed in approved nearshore or other beneficial use disposal sites. The remaining 40% of sand dredged at MCR is placed offshore beyond the littoral zone. The preference for placing dredged material at nearshore areas (within the littoral zone) is motivated by the need to maintain the littoral budget north and south of the inlet; for the purpose of sustaining the inlet's morphology. The above approach is executed within a least cost consideration. Feeding the inlet's morphology is crucial for several reasons. First, it must be noted that the morphology at an inlet is the source of sediment for adjacent shorelines. Without stable morphology (shoals and sand bars) at a tidal inlet, the adjacent shorelines will erode.

The Shallow Water Site (SWS), located off the seaward end of the North Jetty, is an U.S. Environmental Protection Agency (USEPA) designated ocean disposal site that is highly erosive. Most of the dredged material placed at the SWS is transported northward onto Peacock Spit by waves and currents. Detailed evaluation has shown that the sediment transported from the SWS onto Peacock Spit continues to be further dispersed northward toward Long Beach Peninsula. Use of the SWS ameliorates, to some extent, the erosion of Peacock Spit that has been occurring, which is believed to be a result of gradual jetty head recession. The SWS has received large quantities of disposed dredged material in recent years, as much as 3.7 million cubic yards in one year. Currently, sand placed in the eastern part of the disposal site exhibits no long-term deposition and is readily dispersed to the north, while sand placed in the western part of the disposal site disperses to the west. Dispersion in the western part of the SWS occurs to a lesser degree than the eastern part. In the western half, sand has accumulated 1-3 ft on the seafloor since 1997. Since 1997, 80% of MCR dredged sand has been placed in the SWS or NJ Site. The NJ Site is a moderately dispersive disposal site located on the river side of the North Jetty and was established to aid in stabilization of the sand shoals upon which the jetty was constructed.

At the MCR inlet, the morphology (Peacock and Clatsop spits) serves as the foundation for the jetties, and protects the jetties from severe currents and wave action. The present morphological condition is characterized by deflation: each year, the morphology is losing more sediment than it is gaining. The rate at which sediment is eroding from the MCR spits far exceeds the volume of sediment dredged each year. There are initiatives currently underway to increase the amount of MCR dredged material beneficial use to 100%. The limiting factor for placing all MCR dredged material within the littoral zone is having approved sites available to place the sand. At present, there are approved disposal sites available only for the north side of the inlet. No site currently exists on the south side of the MCR entrance.

Even if all MCR dredged material could be placed in such manner as to optimally feed the present morphology, there is not enough dredged material to stop the morphological deflation at MCR. This condition should not render nearshore placement of MCR dredged material a pointless endeavor; it is imperative that the maximum amount possible be used to help sustain the inlet’s morphology. For without this effort, the inlet will degrade at a higher rate affecting infrastructure, shoreland, and other resources at a non-sustainable pace [Kaminsky et al 2010 and Moritz et al 2003]. With this perspective in mind, it must be acknowledged that dredged material cannot be used in-lieu of stone placement for maintaining the jetties at the MCR. The 100 year old jetties have sustained significant damage over time. Physical work on the structures themselves is needed to improve their resiliency and reduce the risk of navigation disruption due to a loss in jetty function.

e. Regional Littoral Budget at MCR - Future Jetty Implications

Figure A1- 32 illustrates the time varying nature (erosion) of the tidal shoals offshore of MCR, by showing the evolution of the 40 ft (12.2 m) depth contour. The landward recession of the 40-ft depth contour highlights the susceptibility of the MCR jetties to changes in the offshore extent of ebb tidal shoals. The pre-jetty (1885) configuration of the 40-ft contour displays a fairly symmetrical shape about the inlet indicating that littoral transport of sand on the ebb tidal shoals of the MCR was relatively balanced to the north and south. By 1919, the 40 ft contour had been displaced more than 2,000 m seaward in response to phased jetty construction and the morphology had been thrown out of equilibrium due to increased tidal flow velocity in and around the MCR. On the south side of the MCR, there was no seaward displacement of the 40 ft contour. Rather, the 40-ft contour south of the MCR had been receding landward since jetty construction in 1885. Note the northern vs. southern offset (asymmetry) in the 40 ft contour for 1919 and thereafter. By 1930, waves and currents were acting on the displaced morphology to bring the system to equilibrium. The displaced tidal shoals on the north side of the MCR were being eroded and the 40 ft contour was receding landward.

The offshore extent of the 40 ft contour on the south side of the MCR has been receding landward of its 1885 position, toward the South Jetty, since jetty construction. Within the inlet, along the northern extent of the MCR, the 40-ft depth contour has been moving landward and northward, toward the North Jetty. The jetties have been undermined, ever since initial construction (1885-1917). The process of tidal shoal erosion has continued to the present (the 2000 configuration of the 40 ft contour). Note that from 1993 to 2000, the landward recession of the 40 ft depth contour was at a rate 7 times faster than during 1930 to 1993. On the north side of the inlet, it has been estimated that 2-5 mcy per year of sand is presently being eroded from Peacock Spit [Gelfenbaum et al., 2002]. Shoal material eroded from the offshore extent of the Peacock Spit is believed to be transported by ebb tidal flow northward. Some of the shoal material eroded from the inshore part of Peacock Spit is believed to be transported by flood tidal flow southward to the MCR. Most of the shoal material eroded from the offshore remnants of Clasp Spit, south of the MCR, is believed to be transported toward the south by tidal- and wave-induced circulation.

The MCR rubblemound jetties were built on flood/ebb tidal shoals, which had protected the jetties from excessive waves and currents. To a large degree, the stability of the MCR channel is related to both the jetties and the morphology of Peacock Spit and Clatsop Spit. North, South, and Jetty A foundation changes (Figure A1- 33 through Figure A1- 35) show the MCR jetties have been gradually undermined along a portion of their length since construction. As the ebb tidal shoals offshore of the MCR change shape, the nearshore wave and current regime will change; adding to the shoreline re-adjustment (recession). If these shoals continue to recede landward at the present rate, the stability of the MCR jetties and the navigation channel will be jeopardized due to the likelihood of a jetty breach (failure). The water depth along the jetty gets deeper due to scour and the jetty fails due to increased wave action and foundation scour [USACE 1881-1948].

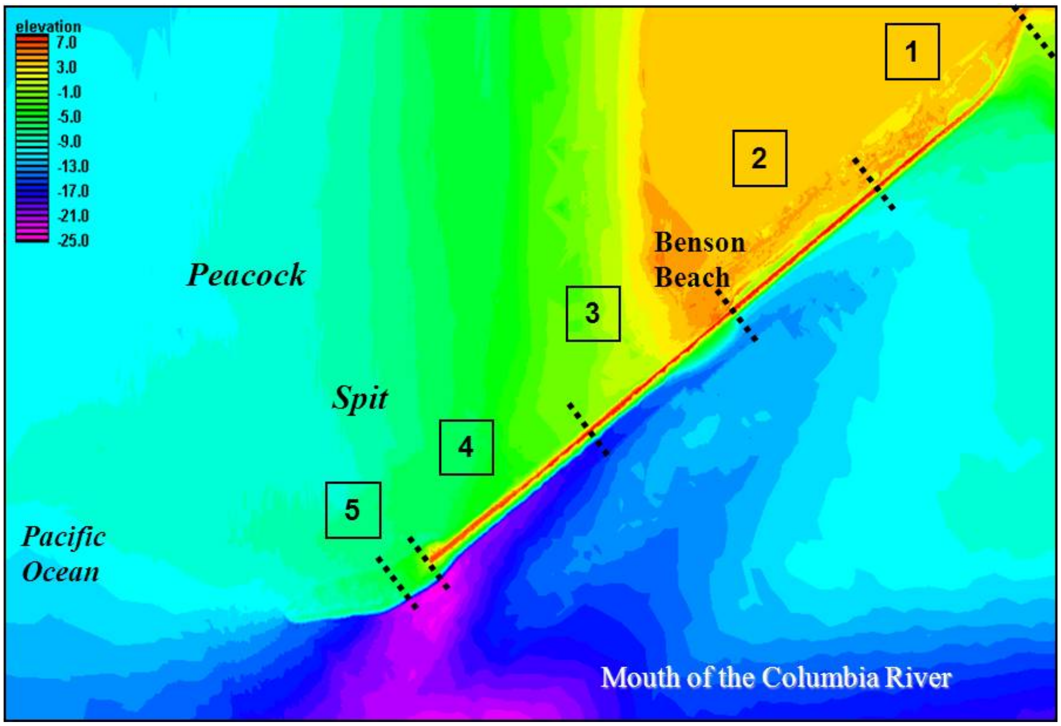

Figure A1- 33. North Jetty Bathymetry and Design Reaches

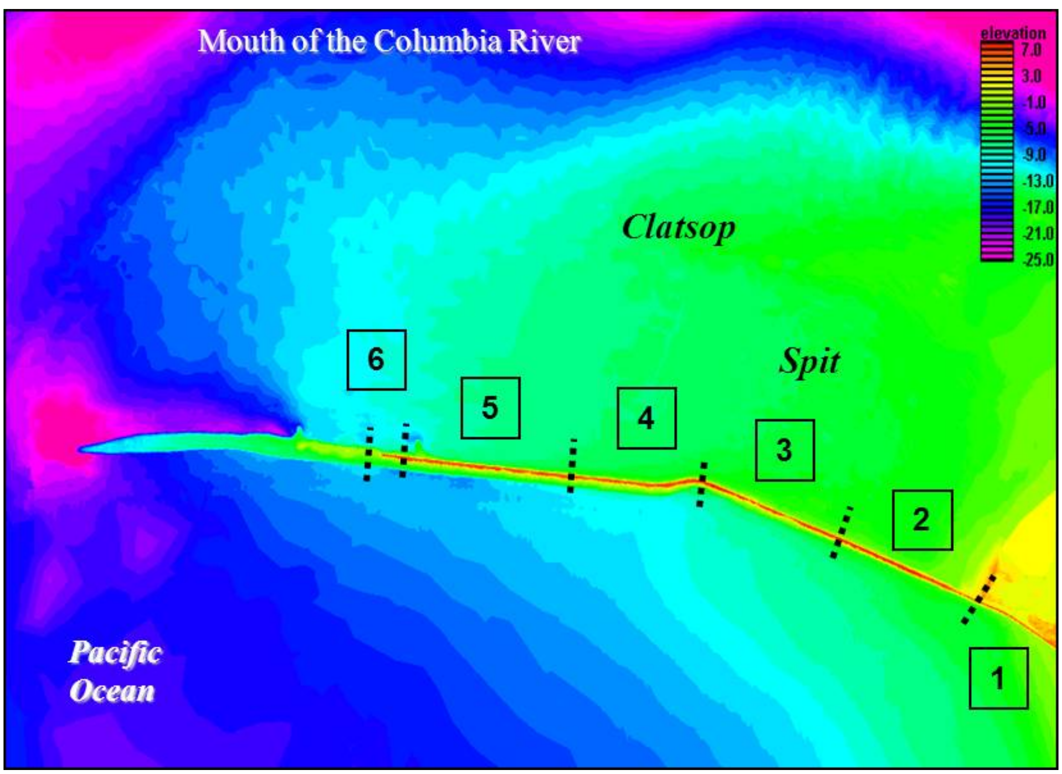

Figure A1- 34. South Jetty Bathymetry and Design Reaches

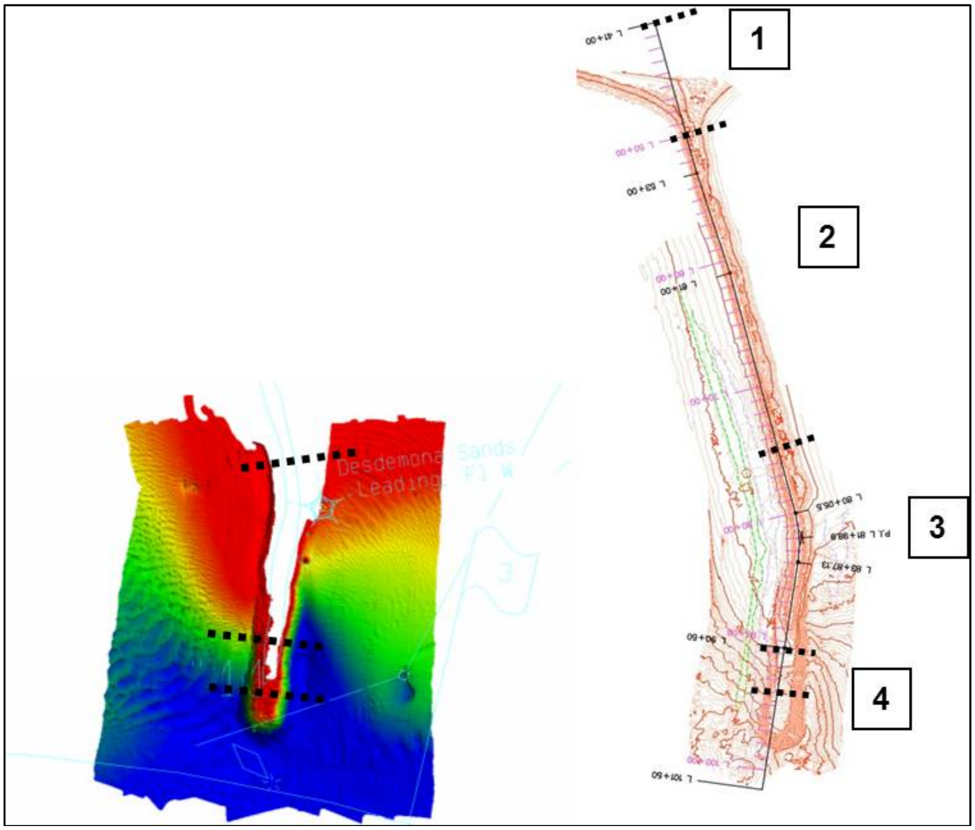

Figure A1- 35. Jetty A Bathymetry and Design Reaches

The large scale morphological changes which have occurred along the northwest Oregon and southwest Washington coast have been investigated by numerous researchers working individually and collaborating under several interagency studies. The results of these investigations lead to several conclusions. The morphological changes affecting shoreland areas are motivated primarily by the natural processes of the inlets adjacent to the shorelands experiencing change. The occurrence of a strong El Nino/La Nina event during 1997-2001 contributed to the regional changes in shoreland response observed during this period. The rapid accretion of Peacock Spit and Benson Beach soon after North Jetty construction was motivated by the processes at the MCR inlet being modified by jetty construction. To understand what the future holds for the MCR inlet and adjacent shorelands, it should be understood that the inlet has undergone a two-stage process since the time of jetty construction. Stage one was initiated at the time of jetty construction (1885), when a huge volume of sediment was discharged oceanward as the inlet width was reduced from 5 miles wide to 2 miles. Stage one was defined by a time of rapid morphological growth along the ocean margins of the inlet resulting in high rates of shoreland accretion. Figure A1- 36 through Figure A1- 40 illustrate sediment movement trends over time and the general project/inlet responses in the vicinity of the MCR inlet.

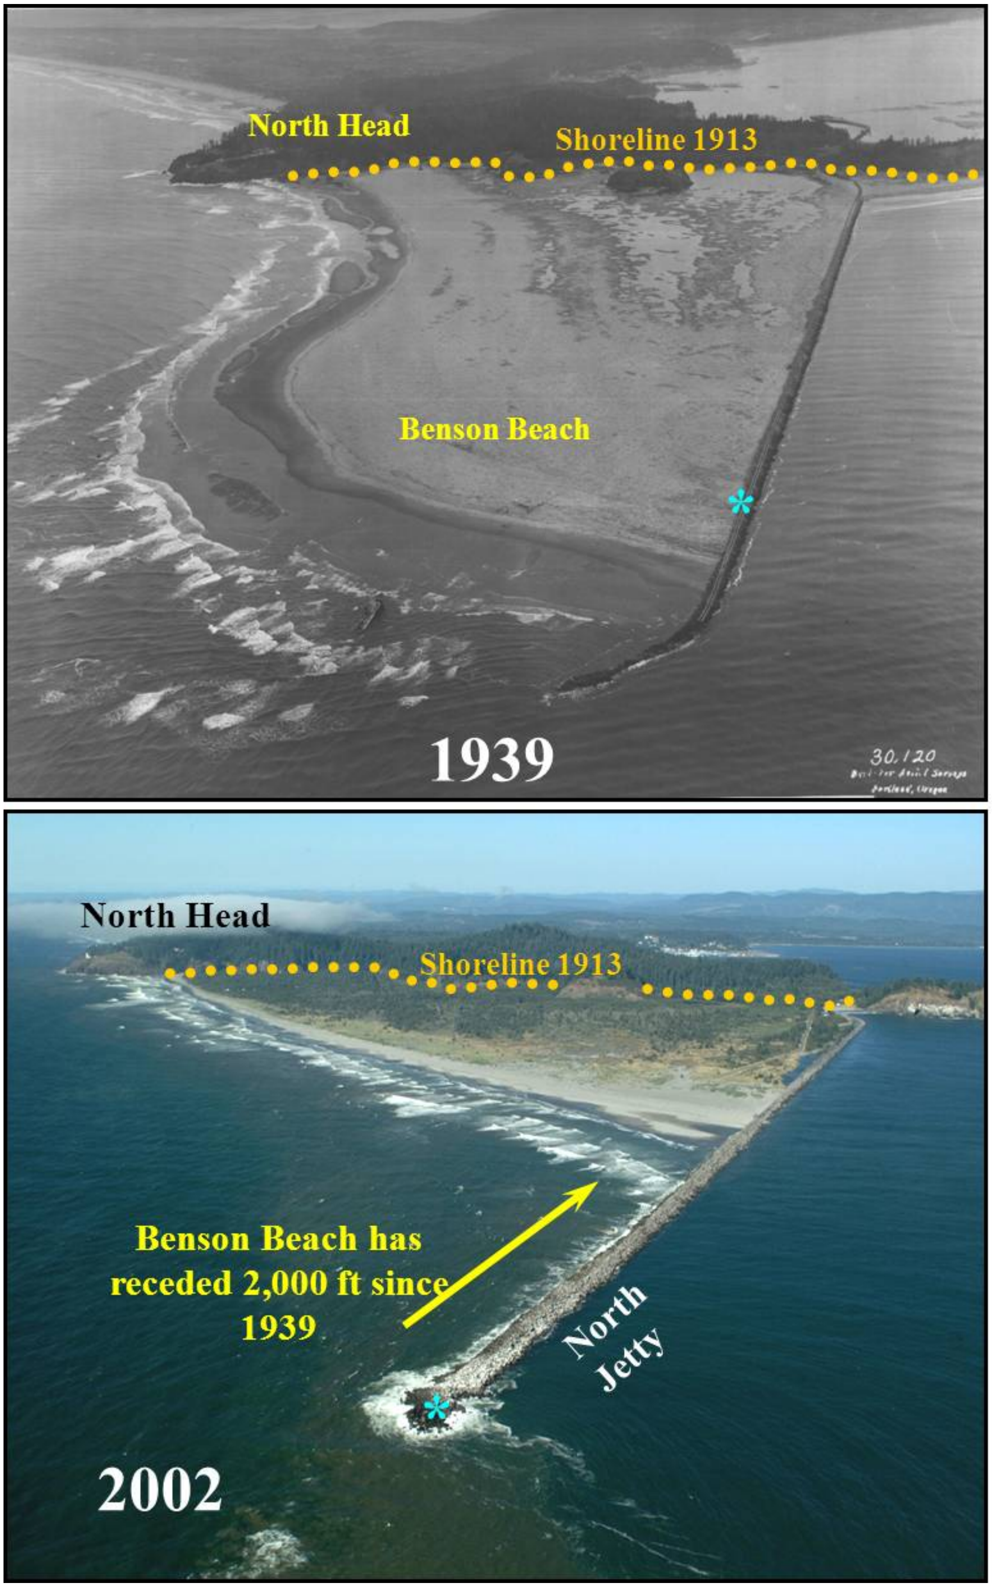

Figure A1- 38. Shoreline Response north of North Jetty

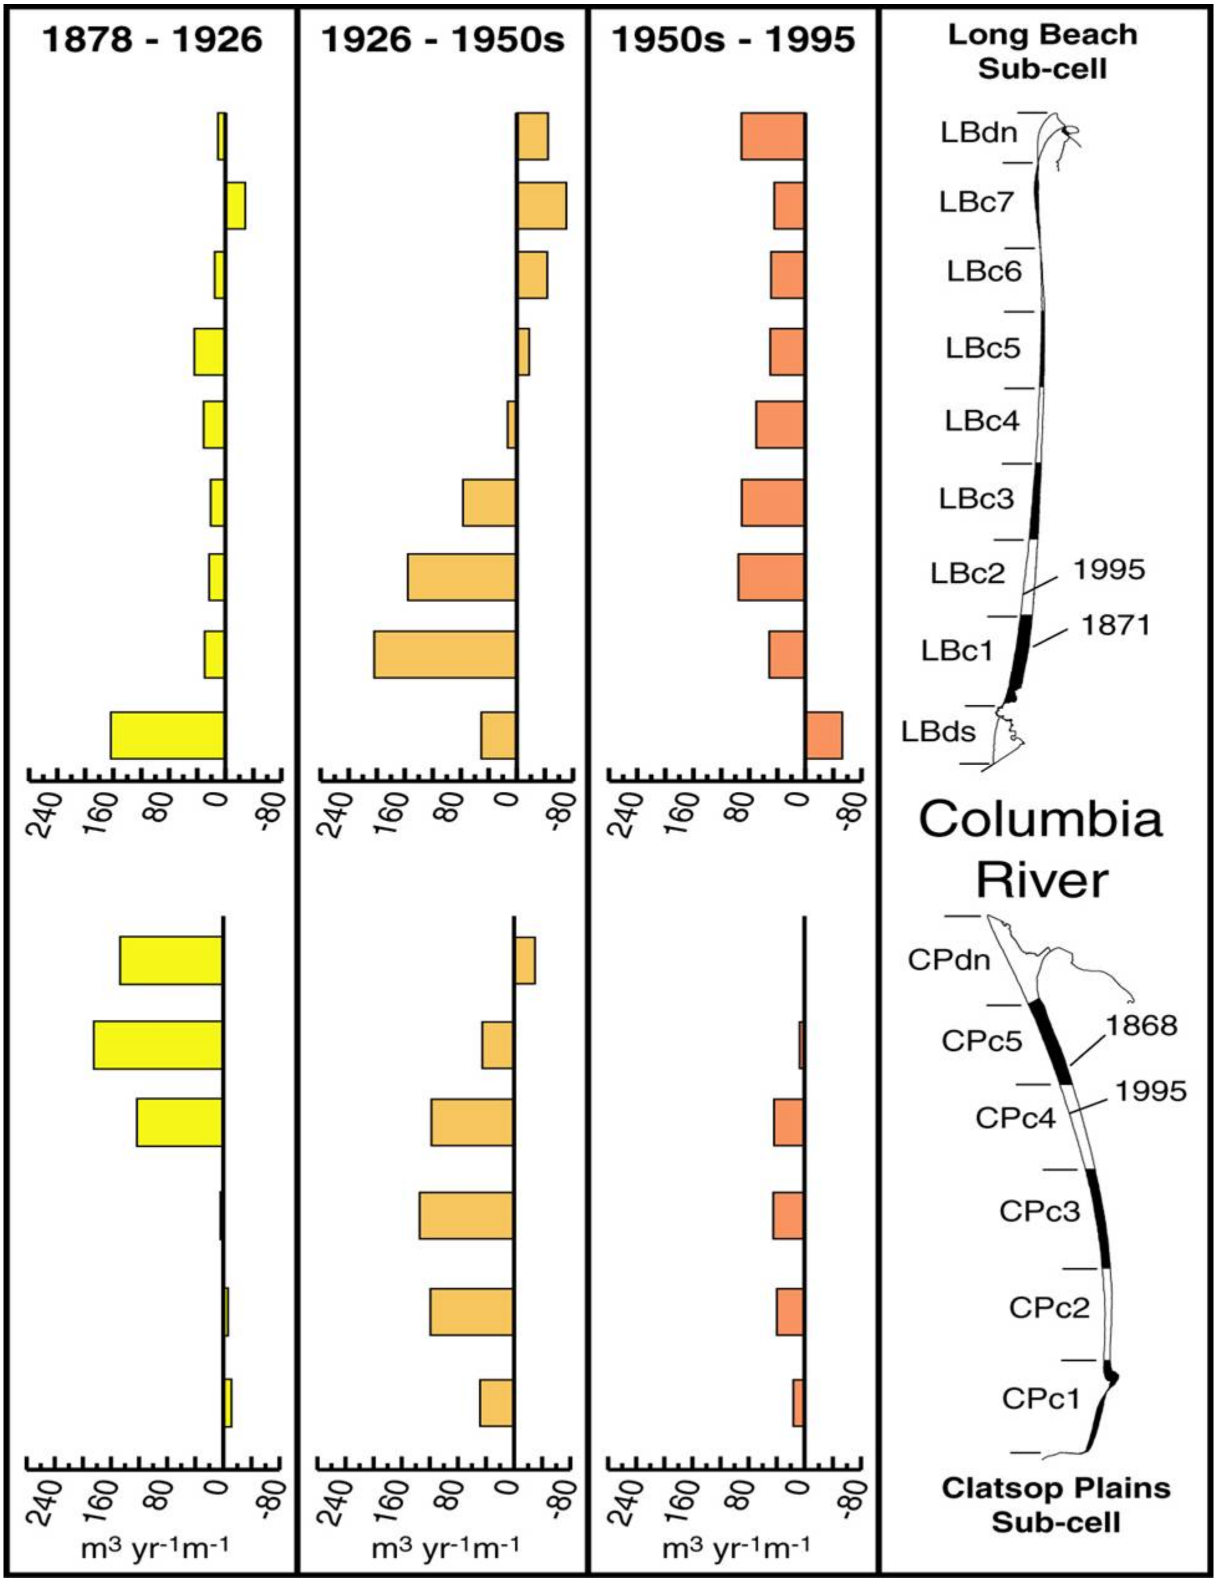

Figure A1- 39. Sediment Movement North and South of MCR – 1878 to 1995

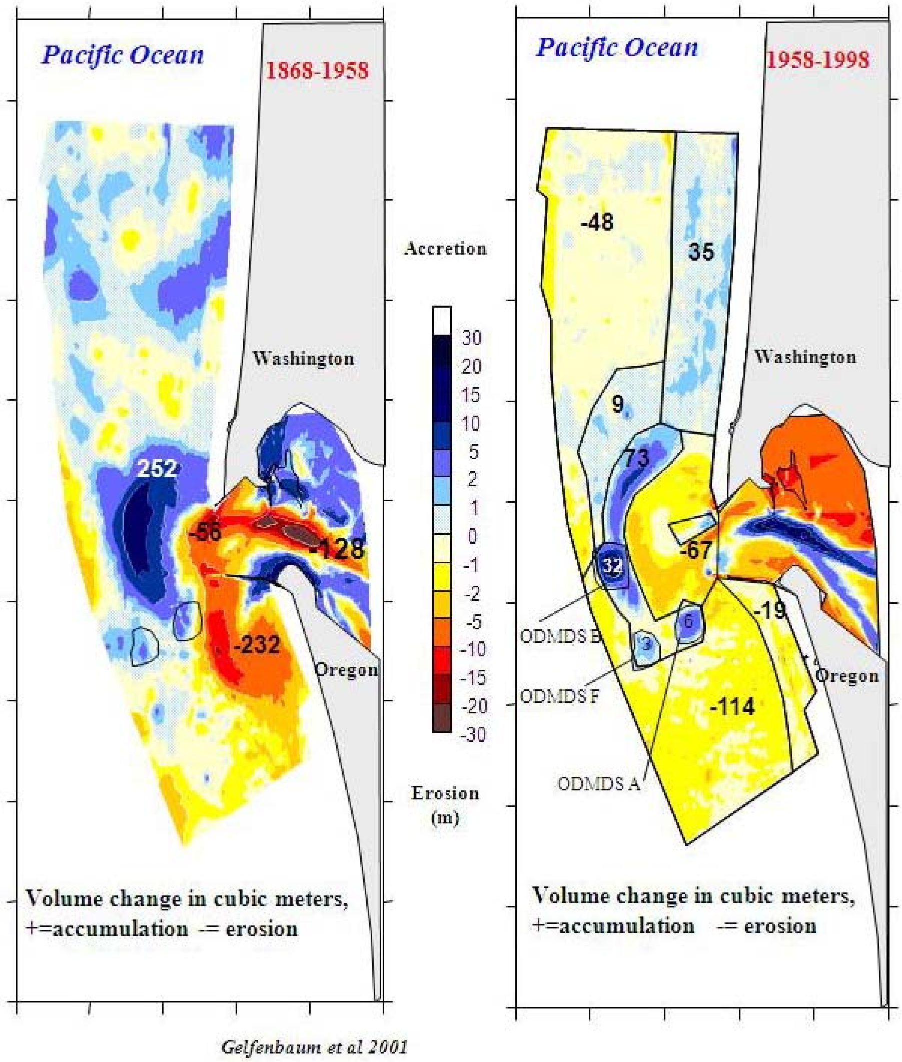

Figure A1- 40. Sediment budget deficits and surpluses around MCR over time

Stage two began shortly after the phased completion of the MCR jetties (1917) when the process of inlet en mass sediment discharge was completed (~1940). Stage two is defined as a time when the accretionary morphology, formed in Stage 1, no longer had the surplus sediment supply to continue the process of "rapid accretion." The morphology began to be re-aligned to accommodate equilibrium within the inlet's wave and current environment. In many cases, this morphological response is manifest in terms of recession; for shoals and shorelines. The Stage 2 processes continue to evolve and will persist into the future. Rehabilitation of the MCR jetties will have no calculable effect on near shore or shoreland areas beyond 1-2 miles north or south of the MCR inlet.

5. Construction and Repair History

a. South Jetty Construction

In 1884, Congress authorized the U.S. Army Corps of Engineers to construct a 4.5 mile (7.3 km) long South Jetty for the purpose of attaining a 30-ft (9-meter) deep channel across the MCR bar. The South Jetty was to extend northwesterly from Fort Stevens (on Port Adams) in a slightly convex manner along Clatsop Spit to a point about 3 miles south of Cape Disappointment. A jetty with crest elevation at mid-tide was originally considered due to the assumption that it would control currents as well as a high-tide jetty, but would cost less, and that it would contain sand better than a low-tide jetty. Table A1- 1 and Figure A1- 41 summarize construction and repair efforts for the South Jetty over the project life. Figure A1- 42 shows the original cross section design for the South Jetty. Figure A1- 43 through Figure A1- 55 illustrate historical construction and condition photos for both the North and South jetties.

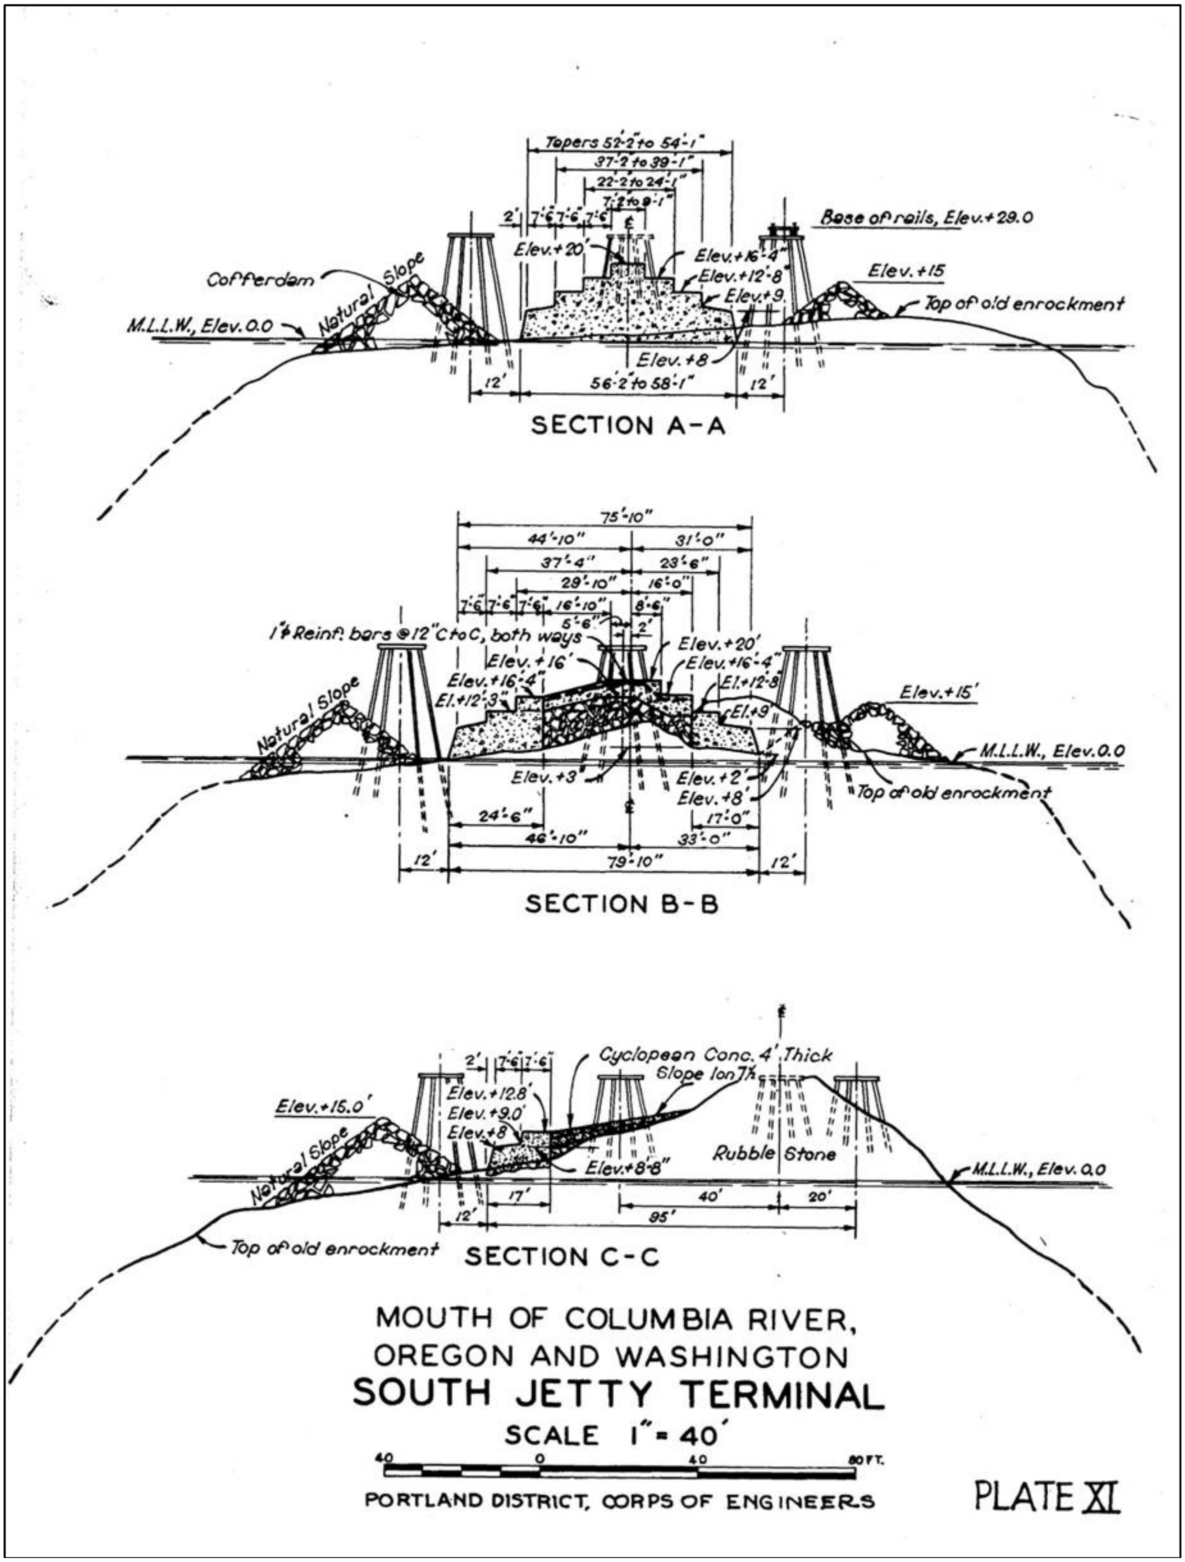

Figure A1- 55. South Jetty Terminal Sections

Originally, the crest elevation of the South Jetty was constructed to mid-tide elevation (3 to 5 ft above MLLW) and crest width was 10 ft. Figure A1- 42 shows the design cross-section and construction method used to construct the South Jetty. Emphasis was given to ensure a proper “bedding” layer underneath the jetty to establish a stable foundation. The maximum size of armor stone was 7 tons, based on professional judgment and limitation of the tramway equipment. The finished side slope of the jetty was approximately 1V:1H (natural slope). Improvements during jetty construction included the addition of four rock spur-groins (100-1000 ft long) on the north side of the South Jetty (at Station 52, 88,156, and 228) to prevent scour and undermining of the jetty and increasing the jetty crest elevation. From shore to Station 120, the jetty crest elevation was increased to 12 ft MLLW to reduce wave overtopping, prevent shoal migration, and protect the tramway. The crest elevation was sloped down from +12 ft MLLW (at Station 120) to +4 ft MLLW at Station 250+20. The 4.5-mile long South Jetty was begun in 1885 (at Station 25+80) and completed in 1895 (Station 250+20, known as the “knuckle”). A rock revetment was constructed east of the South Jetty root (along Station 0-25) to prevent erosion flanking of the jetty by waves and currents. Construction of the original South Jetty required 946,000 tons of stone, which was placed using a trestle-supported tramway with locomotives, side-casting cars, and crane. Stone was delivered to the tramway by barge. Before commencement of the South Jetty, there was no dominant channel though the MCR and the controlling depth was about -20 ft MLLW.

Upon completion of the original South Jetty, a well-defined channel had developed through the MCR with controlling depth of 30 ft. However, by 1902, all traces of a channel had disappeared and the governing depth over the bar reverted to 20-22 ft. In 1903, the Board of Engineers recommended that Congress authorize the Corps of Engineers to enact the following: A) the South Jetty be extended 2.5 miles in length toward the west and the jetty crest be raised to 10 ft MLLW or higher; B) a 2.5 mile long North Jetty be constructed on Peacock Spit (after completion of the South Jetty extension); and C) commencement of dredging at the bar, if needed. It was specified that the North and South jetties be 2 miles apart at their ends. The object of the recommended improvements was to obtain a channel 0.5 miles wide through the MCR with controlling depth of 40 ft below MLLW.

In 1905, Congress authorized the Corps to implement the Board of Engineers’ 1903 recommendations, for the purpose of attaining a 40-ft (12.2-meter) deep channel 0.5 miles (0.82 km) wide across the bar. Repairs were made to the original 4.5-mile long South Jetty (Station 175-250) using 410,000 tons of stone. Construction of the 2.1-mile long extension (Station 250 to Station 375) required 4.48 million tons of stone at a 1913 total cost of $7,618,764. Work on the 6.62-mile long South Jetty was completed in 1913. The alignment of the South Jetty extension was intended to extend the seaward location of the channel by following the shallow waters of Clatsop Spit as far as possible without making significant changes in the direction of the structure. It was thought that if the 2.1-mile long extension were constructed in continuation of the straight-line direction of the original jetty, the velocities of the ebb and flood tides would be significant enough to undermine the jetty foundation, unless groins were incorporated. South jetty extension was expected to prevent the ebb flow from losing energy and dissipating over Clatsop Spit, but instead to be guided toward the existing channel and help maintain its depth. It was expected that the extension would hold Clatsop Spit in position and allow it to build up by impeding the entrance of sand into the channel. The curvature of the jetty at the "knuckle" was intended to encourage deposition of sand along the channel side of the jetty, so that the installation of groins would not be necessary.

As completed in 1913, the South Jetty had an average crest width of 10 ft and an elevation of +10 ft MLLW along the inner 2.65 miles (Station 25-165) of the jetty. The outer 4 miles of the jetty (Station 165-375) had an average crest with of 25 ft and elevation of +24 ft MLLW. The finished side slope of the jetty was approximately 1V:1.5H (natural slope). An increased jetty crest elevation was needed to prevent wave overtopping damage to the lee side of the jetty, reduce sediment transport over the jetty, and protect the construction tramway from wave action. Stone size was the same as used for the original jetty (max size was 7 tons). Two (2) submerged rock groins (extending northward 200 ft from the jetty centerline) were constructed at the outer area of Station 309 & 333, to prevent scour along the north side of the jetty toe. It is noted that these two rock groins have been instrumental in stabilizing the outer end of the South Jetty toe since time of construction (see Figure A1- 56 and Figure A1- 57).

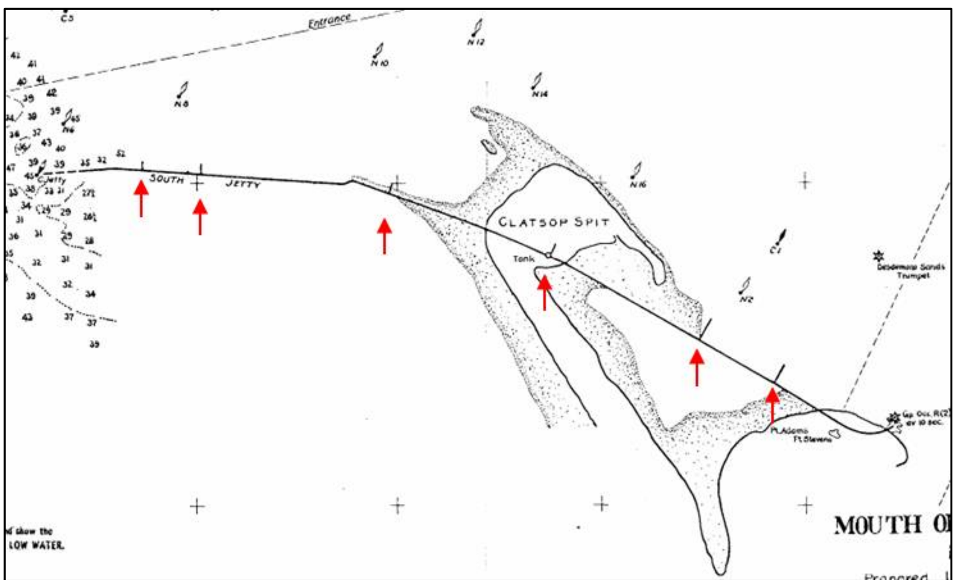

Figure A1- 56. Spur Groin Construction Along Channel Side of South Jetty

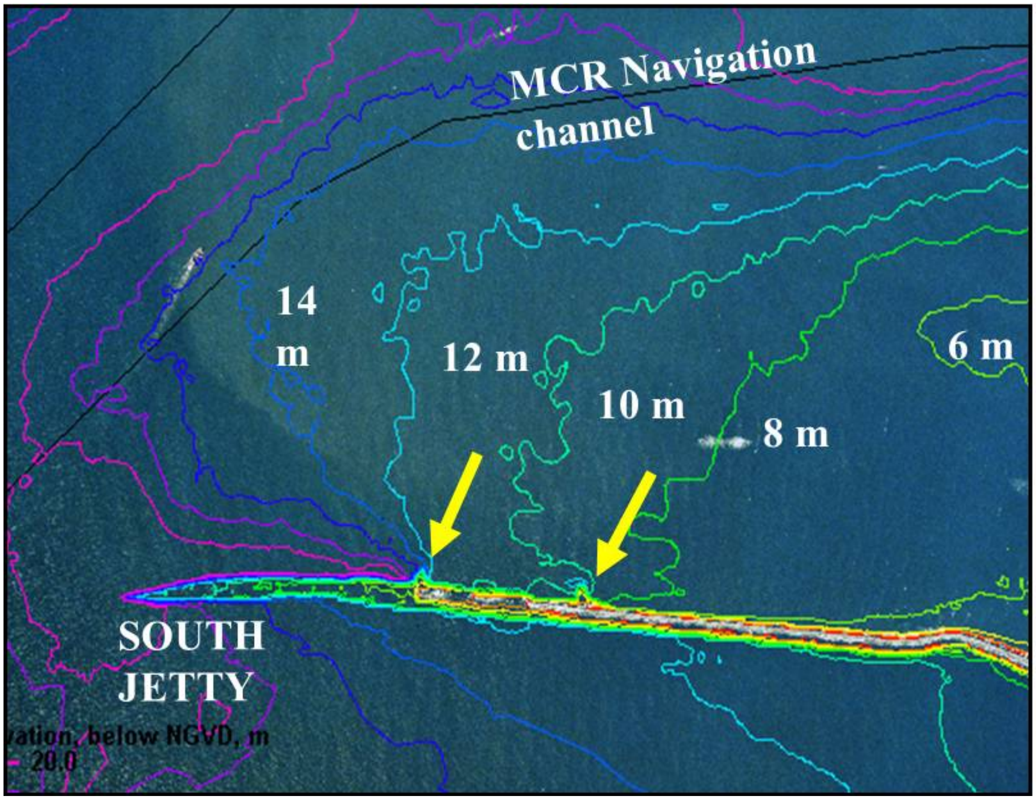

Figure A1- 57. Current Configuration of Outermost South Jetty Spur Groins

b. North Jetty Construction

As noted above, Congress authorized construction of the North Jetty through the Rivers and Harbors act of 1905. Construction of a North Jetty was needed to limit the northward migration of the navigation channel, in response to South Jetty construction during 1885-1913. The direction of the jetty was to follow approximately the shallow waters southwesterly across Peacock Spit without a sudden change in direction to a point roughly 2 miles north of the end of the South Jetty. Heavy scour along the jetty toe was expected and taken into account during the design phase, by incorporating additional bedding stone.

The Corps of Engineers began North Jetty construction in 1913, after completion of the South Jetty. The North Jetty was completed in 1917 (Figure A1- 58). The North Jetty extended southwest from Cape Disappointment (sta 0+00) along Peacock Spit for about 2 miles (Station 107), then turned westward for about 1,700 ft and terminated at Station 122. The 2.35 mile long North Jetty required 2.95 million tons of stone. The stone was placed using a trestle-supported tramway with locomotives, side-casting cars, and crane. Stone was delivered to the tramway by barge. The same cross-section shown in Figure A1- 42 was used for the original North Jetty construction, except that the crest elevation was at +28-32 ft MLLW. Crest elevation along the landward 3,000 ft of the North Jetty was +15 ft MLLW. Jetty crest width was 25 ft. Maximum armor stone size was 7 tons. The finished side slope of the jetty was approximately 1V:1.5H (natural slope).

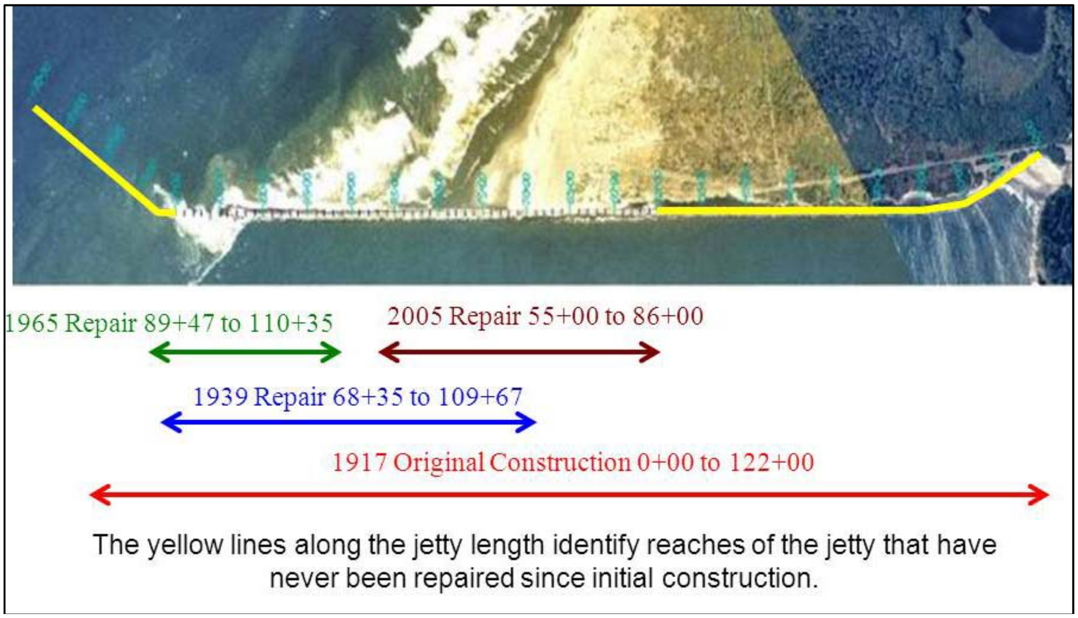

Figure A1- 58. MCR North Jetty Construction and Repair History

Upon completion of the North Jetty in 1917, the North and South jetties would function as a system to: A) constrict the MCR entrance to 2 miles wide at the terminal ends of the jetties, at which point the velocity of tidal flow would minimize the formation of shoals within the MCR entrance channel; and B) "hold" and prevent channel-ward encroachment of existing entrance shoals - Peacock Spit along the north side of the MCR entrance channel and Clatsop Spit along the south side of the channel. By 1917, the MCR navigation channel had attained a controlling depth of -40 ft MLLW and channel width was 1,000 ft. By 1937, the controlling depth was -46 ft MLLW and the distance between 40-ft depth contours along the channel centerline was 8,000 ft. The two-jetty system at MCR stabilized the inlet and enabled maintenance of an engineered entrance with a nominal amount of dredging. Table A1- 2 and Figure A1- 58 summarize North Jetty construction and repair history.

Table A1- 2. Construction and Maintenance activities for the MCR North Jetty

c. Jetty A Construction

During the early 1930s (after both North and South jetties had been in place and significant modification of the inlet's morphology had occurred), the North Jetty became threatened by high velocity ebb tide flow which threatened to undermine the structure's channel side foundation. Concurrently, the south side of Sand Island was being eroded by increased current action. In the late 1930s, the Sand Island Pile Dikes and Jetty A were constructed by USACE to stabilize the evolving inlet.

Original construction was conducted with Diorite rock from Station 40+94 to 97+36. From the beginning of the structure to Station 53+00, the jetty was just a small armament feature with a crest width of 10 ft. The jetty from 53+00 to 92+86 was 30 ft wide at an elevation of +20 ft MLLW. The centerline of the jetty was centered along the railroad trestle. At 92+86, the railroad trestle diverges into two trestles. The centerline of the jetty appears to be the center of the two trestles. Table A1- 3 and Figure A1- 59 summarize the construction and repair history for Jetty A.

Ending Station	96+83	96+00	95+35	93+00	94+00	79+00	90+50**

Multiple partial repairs were conducted during the 1940s to the 1960s. In 1958 they repaired approximately 3,800 ft of the inner end, from Station 41+00 to Station 79+00. The structure had degraded to an elevation of +15 to +20 ft MLLW and was rebuilt to +20 ft MLLW from 41+00 to 56+00 with the baseline on the centerline of the old trestle. Station 56+00 to Station 61+00 is a transition period where the centerline of the repair changes from 25' to the right of the baseline to 10' left. From 61+00 to 79+00 the crest width was 30'.

In 1960, they repaired approximately 3,150 ft of the outer end. The section was rebuilt to +24 ft elevation, from degraded elevations of +10 to 15 ft. A memorandum established a cap stone weight of 17.6 tons based on a wave height of 15.5 feet and a specific gravity of 2.4. The size considered for the 1960-1961 repairs was a 6-ton minimum and at least an average weight of 10 tons. Past designs allowed for the placing of Class B and C stones in the armor layer. The armor layer was designed to have Class A stone placed along the westerly/ocean slope and over the crest of the jetty. Class A and B stone would then be placed along the easterly/Baker Bay slope. Select Class A stone, weighing more than 15 tons, should be placed between Stations 90+00 and 90+50.

A 1960 design memorandum states that the history of repairs of the jetty "suggests major deficiencies in past construction." The design stated that since the jetty "is principally serving as directional current training and not as wave protection, the structure would adequately fulfill all requirements if the repairs were to end at Station 91+00 rather than 95+50. For the same reason, the height of jetty repair between Stations 78+00 and 91+00 should be held to elevation +20." Past designs allowed for the placing of class B and C stones in the armor layer. In the 1960 repair, only class A stone was allowed on the westerly slope and over the crest of the jetty. Rock in the armor layer was also individually placed with a crane, as opposed to being dumped onto the jetty from the trestle and tramway. Sta 41+00 to Sta 79+00, repaired in 1958, received considerable damage due to overtopping waves. Breaks in the jetty expose the jetty to further damage. The design report states that it was believed that the first damage to the jetty was due to subsidence caused by scouring of sand from around the jetty base resulting in armor stone displacement. Smaller rock was then exposed to waves, which resulted in further displacement.

A small armament was built from Station 49+93.89 until Station 53+00 according to plan drawings and the 1961 Design Memorandum. The jetty was then built to an elevation of 20 ft MLLW out to Station 92+86. From 92+86 to 97+36 a second trestle was built and the jetty crest width was built wider, with a crest width at the end of 90 ft. There have been six repairs since original construction. The centerline of the jetty has not remained the same throughout the repairs.

d. MCR Morphology Response to Jetty Construction

Figure A1- 19 through Figure A1- 22 illustrate how the MCR entrance evolved from a pre-jetty configuration in 1885 to a post-improved configuration in 1950, 33 years after jetty completion. In 1885, the unstable entrance was controlled by a relatively symmetrical yet dynamic ebb tidal shoal (Middle Sands), exposed flood tidal shoals, and a westerly-directed primary channel with controlling depth less than 25 ft. Note on Figure A1- 17 the tidal shoals on which the South and North jetties were constructed (Peacock Spit on the north and Clatsop Spit on the south).

The first phase of South Jetty construction was completed in 1895, with the jetty head terminating 4.5 miles offshore from Fort Stevens (Point Adams). By 1902, the South Jetty had facilitated significant landward re-distribution of Clatsop Spit on the south side of the entrance and offshore re-distribution of Middle Sands (and Peacock Spit) on the north side of MCR. Much of Clatsop Spit had been re-distributed along the South Jetty and points south for a distance 3 miles, creating a large above water (subareal) sand fillet. These shoal morphology changes were due to the modification of waves/currents/circulation within the MCR by South Jetty construction. The second phase of South Jetty construction was completed in 1913, producing a 6.6-mile long jetty. The full-length South Jetty promoted additional landward migration of Clatsop Spit, with water depths increasing along the outer end of the South Jetty.

The ebb-tidal shoal located on the northern side of the entrance (what was once Middle Sands) continued to be transported offshore, effectively decreasing the water depth offshore on the north side of MCR. In 1917, the 2.35-mile long North Jetty was completed, producing significant changes in morphology along the north side MCR. As the North Jetty was being constructed on top of a newly reformed Peacock Spit, shoal material was transported further offshore (west) of the inlet and was deposited along the northern side of the jetty while significant erosion/scour was occurring along the south side of the jetty.

By 1950, much of Peacock Spit (middle sands in 1885) had been dispersed offshore and to the north, and the inshore part of Clatsop Spit had shifted northward more than 3 km. The offshore part of Clatsop Spit, that was present in 1885, was displaced landward onto the south shore of MCR. Adjacent coastal shorelines north and south of MCR had experienced offshore accretion that exceeded 600 m since jetty construction (1885). The reformation of morphology had pushed the MCR channel north toward the North Jetty. Figure A1- 18 shows the scouring effect of channel migration upon the North Jetty. Jetty “A” (1939) and the Sand Island pile dikes (1928-32) were constructed to prevent additional northward migration of the MCR channel and disruption of the North Jetty. The redistribution of MCR tidal shoals, as noted above, has affected the foundation of the MCR jetties, necessitating 11 different jetty repair events.

e. Previous Rehabilitation Activities - North and South Jetties

The construction of jetties at the MCR produced significant morphological changes of the shoals on which the jetties were built, as noted above. Morphology change of the channel and tidal shoals changed the wave and currents patterns at MCR. In some cases, sand spits accreted along the landward flanks of the jetties resulting in the shore attachment of Peacock Spit along the north side of the North Jetty and Clatsop Spit along the South Jetty. Accretion of sand along the jetties acted as a barrier to waves and currents and protected the jetties. Offshore of the jetty root, significant erosion of tidal shoals occurred (along the jetties) following jetty construction. Severe scour of the jetty toe resulted, which destabilized areas of the north and south jetties due to undermining and jetty side slope re-adjustment. Jetty scour/undermining was problematic along the outer 2 miles of the South Jetty and along most of the south side of the North Jetty. Loss of the tidal shoals offshore and along the jetties allowed for increased wave action to directly impinge on the jetties. Wave action at the ends of the jetties (and other jetty locations) increased from pre-jetty conditions, due to increased water depth, destabilizing the armor stone due to increased wave action. The 7-ton armor stone used for jetty construction was no match for the winter storm waves of the northeast Pacific Ocean. The finished side slope for both jetties (1V:1.5H) was too steep for resisting wave action and undermining of the jetty toe due to scour. The heads of the jetties were particularly vulnerable due to focusing of wave action and scour. Results of jetty destabilization were first manifest on the South Jetty by 1920. Significant deterioration of the North Jetty became evident by 1930.

1931-1942 Rehabilitation. Due to the high cost of tramway construction and maintenance, jetty repair work was deferred during 1917-31. By 1920, the outer 2.5 miles of the South Jetty crest had been beaten down by wave action and scour to 4 ft MLLW. By 1931, the elevation of the South Jetty crest was at approximately MLLW from Clatsop Spit (Station 170) seaward to the jetty head (Station 375). The degradation of the South Jetty allowed significant re-distribution of Clatsop Spit along the north side of the South Jetty. Much of the sediment emanating from Clatsop Spit was transported northward and eventually deposited within the southern flank of the navigation channel. By 1931, the outer 1,500 ft of the North Jetty had been beaten down to about 3 ft MLLW and some settlement had occurred along its entire length. Except the outer end, the North Jetty had stood up rather well due to the accretion of sand along its northern side which by 1932 had extended to the jetty head (Figure A1- 38).

The first (and most significant) effort to rehabilitate the South Jetty was undertaken by three separate contract actions during 1931-1936. The total length of reconstructed jetty was 3.4 miles, beginning at Station 175 and ending at Station 353. As rehabilitated in 1936, the above waterline part of the South Jetty extended to within 3,300 ft of the end of the jetty as completed in 1913. During 1931-36, a total of 2.21 million tons of stone was placed. The stone was placed using tramway, dump cars, and a 25-ton crane. Stone was delivered to the tramway by barge. Average production of stone placement was 75,000 to 100,000 tons/month. To prevent future wave damage, the larger armor stone that was placed on the South Jetty during the 1931-1936 rehabilitation ranged between 6-25 tons. Average armor stone size was 9 tons. The armor stone size was chosen based on profession judgment and equipment limitations. Rehab crest width ranged between 24–70 ft and crest elevation was 26 ft MLLW. Even before repairs could be completed, it was realized that the outer 3,000 ft of the South Jetty could not be maintained due to continual stone loss from the jetty. In 1937, Station 350-353 (340-344) was rebuilt using 10,600 tons of armor stone impregnated with 12,800 ton of asphalt-sand mix. The asphalt bound jetty head performed poorly.

By 1941, the end of the rehabilitated South Jetty (Station 338-353) had been reduced to 0 ft MLLW elevation by wave action and toe scour/undermining. In an effort to form a stable jetty head, a massive concrete terminal was constructed during 1941-42. The terminal was 50-75 ft wide x 300 ft long with elevation +8 to +20 ft MLLW (requiring 14,000 cy of concrete and 76,000 tons of stone) and was constructed at Station 331 to form an armored cap. At present, most of the concrete terminal has been displaced by scour and wave action. Only the outer 100 ft of the concrete terminal remain today secured by relic stone (from previous repairs) and the rock groins along the north side of the jetty. The 1931-42 rehabilitation sequence was the last time that the tramway method of repairs was used on the South Jetty. A remnant of the concrete terminal presently forms the seaward-most extent (above water line) of the South Jetty, at Station 331 4,400 ft shoreward of the 1913 maximum offshore extent (Station 375).

The first effort to rehabilitate the North Jetty was undertaken during 1938-40. The total length of jetty reconstructed was 4,200 ft, from Station 68 to Station 110 using 243,833 tons of stone. Along most of this reach, the north side of the jetty had resisted wave action due to the accumulation of sand (Benson Beach, Figure A1- 38). However, the south side of the jetty was damaged due to undermining from current action and direct exposure to waves. All of the stone placed on the jetty trunk during the 1938-40 rehabilitation, was along the northern side to maximize the effectiveness of establishing a rebuilt cross-section. Each side of the jetty head received equal amounts of stone (Station 108-110). The stone was placed using tramway, dump cars, and a 25-ton crane. Stone was delivered to the tramway by barge. Armor stone size ranged between 6-25 tons. Average armor stone size was 9 tons. The armor stone size was chosen based on professional judgment and equipment limitations. Rehabilitated crest width was 30 ft and crest elevation was 26 ft MLLW. A concrete terminal (width of 70 ft and elevation 17 ft MLLW, using 3,280 cy of concrete) was constructed from Station 118-120 (approximately) to establish a secure jetty head. The seaward-most 1,400 ft of the North Jetty (Station 120-124) was not rehabilitated. By 1964, the North Jetty concrete terminal had been reduced to 0 ft MLLW or less. The 1938-39 rehabilitation sequence was the last time that the tramway method of repairs was used on the North Jetty. By 1964, north concrete terminal had broken into several pieces and settled to 6 ft MLLW. At present, the remnants of the concrete terminal have been beaten down to below –10 ft MLLW.

1960-1982 Rehabilitation. The South Jetty was repaired during 1961-1965 and in 1982. During 1961-65, approximately 521,000 tons of stone were used to repair the South Jetty between Stations 194-314. This was the first time that an empirical design approach (Hudson equation) was used to define armor stone size for the South Jetty in terms of incident wave height and jetty side slope. In 1961, jetty repairs were enacted along Station 194-249 and addressed the most severe damage, which had been sustained along Station 232-242, where the South Jetty crest had been reduced to 3-10 ft MLLW. Within this area, the jetty had been damaged by wave action to a degree such that the north side of the jetty had sustained damage by wave overtopping. Other areas along Station 194-249 had experienced a general damage trend due to wave action and scour/undermining along the south side of the jetty. Between Stations 194-249, the South Jetty was rebuilt with crest width and elevation of 24 ft and 24 ft MLLW, respectively. Jetty side-slope for the repair was 1.5H:1V on south side and 1:25H:1V on north side. An equal proportion of stone was placed on the north and south sides of the jetty. During 1961, a total of 213,461 tons of stone was placed. During 1962, Station 249-314 was repaired using a crest width of 40 ft and elevation of 25 ft MLLW using 308,000 tons of stone. Most of the stone was placed along the southern side of the jetty. Stone was placed using land-based crane and jetty haul road. The maximum (average) size of armor stone was 25 (10) tons.

The last time the South Jetty was repaired was in 1982 when 77,000 tons of stone was placed along Station 194-249 (same as the 1962 repair). Most of the stone was placed along the southern side of the jetty, to address wave damage. The amount of stone placed per unit length of jetty in 1982 (at 14 tons/ft) was less than 1/3 of any repair effort conducted on the MCR jetties, and represented an attempt to affect bonafide jetty repairs. Refer to Figure A1-60 for repair effort comparison. Armor stone size averaged 13 tons (max/min was 25/8 tons). The repair template had a crest elevation of 25 ft, crest width of 30 ft and side slope of 1.5H:1V. Stone placement was by land-based crane and jetty haul road. Stone was delivered to the job site by barge.

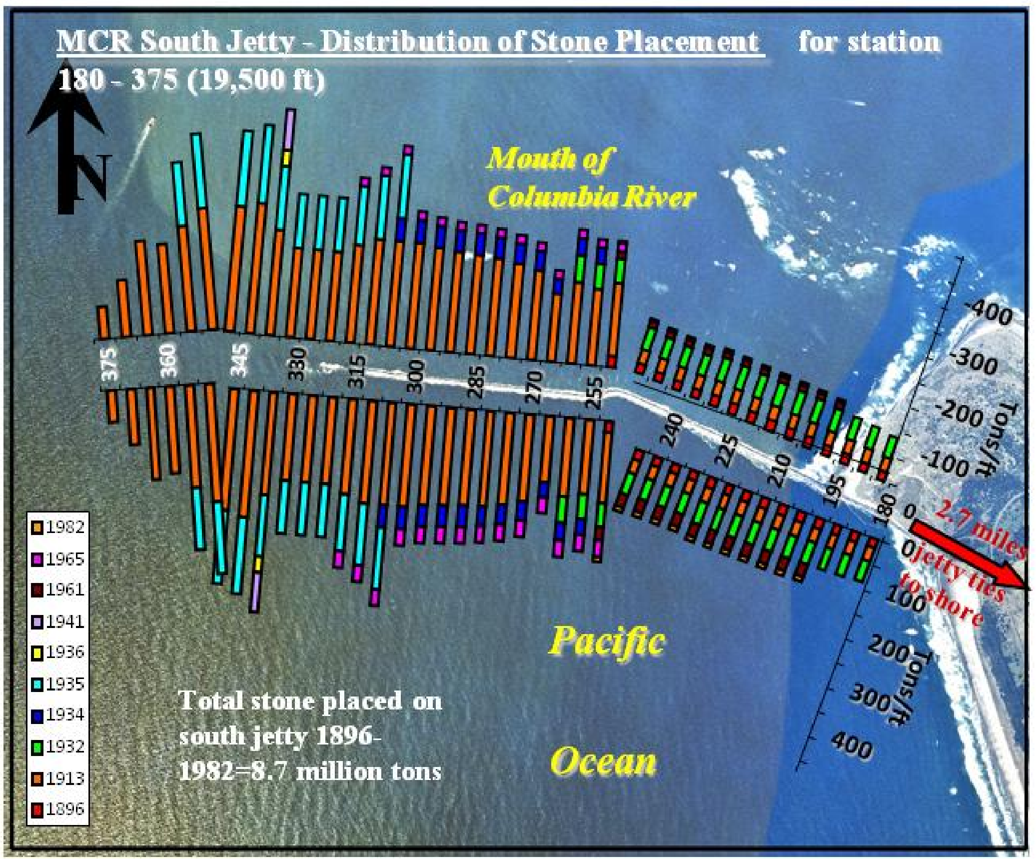

Figure A1- 60. South Jetty Distribution of Stone Placement

The last time the North Jetty was repaired was in 1965 when 132,000 tons of stone was placed along Station 89-110. Refer to Figure A1- 61 and for repair effort comparison. In 1964, the head of the North Jetty had been beaten back by wave action and undermining to sta 103. The original jetty head had terminated at Station 124. Along much of the southern side of the jetty, the outer armor stone had sloughed into the river exposing smaller core stone. In 1964, it was assumed that the southern side of the North Jetty was not exposed to wave significant attack. It was further assumed that the exposed core stone on the south side of the jetty was not subject to wave-induced damage. The armor layer along the north side of the jetty was missing between Station 98-103. The 1965 repair was needed to address damage along the southern side of the jetty caused by undermining of the jetty toe, and re-establish a stable jetty head. This was the first time that an empirical design approach (Hudson equation) was used to define armor stone size for the North Jetty in terms of incident wave height and jetty side slope. Model studies conducted by WES in 1963 indicated that rehabilitation of the North Jetty to its outer end would affect an improvement in flow patterns around the North Jetty such that less shoal material would deposit within the MCR navigation channel. Much of the repair effort was dedicated to re-establishing a secure jetty head.

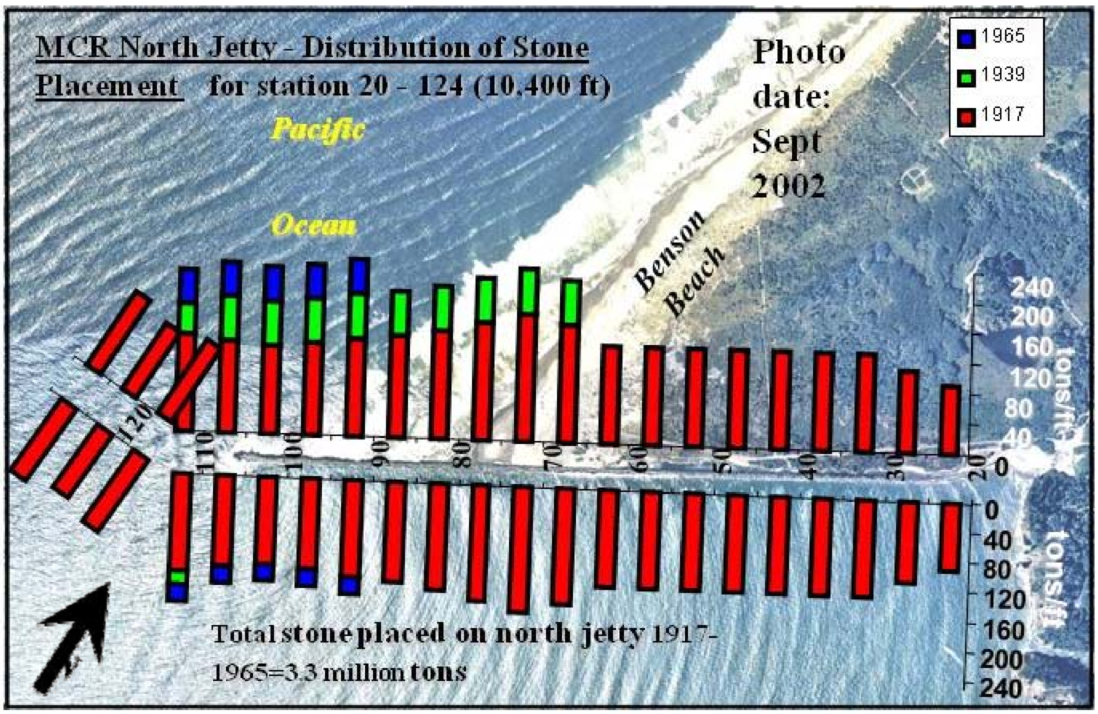

Figure A1- 61. North Jetty Distribution of Stone Placement

Most of the stone was placed along the North Jetty trunk was placed along the northern side, to efficiently re-establish a jetty cross-section. The exposed core stone along the south side was not believed to be vulnerable to wave attack, and significant water depth along the southern side of the jetty precluded an efficient cross-section renewal. Armor stone size ranged between 15-25 tons. The repair template had a crest elevation of 24 ft and crest width of 30 ft. Stone placement was by land-based crane and jetty haul road. Stone was delivered to Ilwaco by barge and transported 2 miles by truck to the job site.

Figure A1- 62 through Figure A1- 64 illustrate the actual year-by-year stone tonnage for construction rehabilitation and repairs for the North Jetty, South Jetty, and Jetty A, respectively.

f. Evolution of Structures and Morphology

Much of the present-day morphology at MCR (Peacock Spit and Clatsop Spit) and adjacent shorelands was formed by sand discharged oceanward during/after jetty construction. This dynamic produced an imbalanced condition with transient morphology features extending far offshore into the dissipative energies of waves and currents. In this regard, the reformed spits and tidal shoals have been eroding ever since jetty construction. The erosion trend of sand spits/shoals at MCR is problematic for the long-term stability of the jetties, the cost-effective reliability of the MCR project, and the supply of sediment to adjacent littoral areas north and south of the inlet. The resiliency of the MCR jetties is related to the stability of the morphology on which they are founded and vice versa. If the jetty foundation washes away, jetty reconstruction is problematic.

The stability and navigability of the inlet is tied to a stable morphology at the inlet, which in turn is secured by fully functioning jetties. If the jetties fail to function adequately, the inlet's morphology can destabilize; much of the sediment could be released back into the interior of inlet drastically suppressing the sediment budget of the adjacent shorelands and littoral areas. The goal of jetty rehabilitation will be to restore structural integrity of the jetties without affecting local or regional littoral sediment transport. The objective of jetty rehab would be to have no negative impact to Clatsop Spit, Peacock Spit or littoral cell sediment budget. Failure to implement jetty rehab at MCR could result in impacts to the regional sediment budget, particularly if jetty lengths are allowed to continue to recede. Should a jetty experience an enhanced loss in function (related to a breach), the regional sediment budget could be significantly affected.

The underwater shoals on which the MCR jetties were constructed are considered to be crucial project elements, as summarized in the following excerpt [USACE 1903]. *"The jetty is a long, thin, narrow backbone of solid material, resting upon a very doubtful foundation, against which the forces in action at the locality have accumulated large quantities of the shifting sands. These shoals in turn have been able to break the force of the waves and protect the jetty from destruction. The jetty's safety and the permanence of the present favorable condition of channel over the bar depend upon the amount of this sand that can be accumulated."* The stability of the MCR channel is related to both the jetties and the morphology of Peacock Spit and Clatsop Spit.

As the seabed along the jetty toe is eroded by scour, jetty stone along the toe "falls" into the scour hole. The scour hole propagates, and more jetty stone falls into the scour hole. The continual loss of stone from the jetty toe can lead to an unraveling effect that migrates upward along the jetty slope; initiating a creeping slope failure within the jetty cross-section. Near the water surface, armor stone is eventually displaced by the creeping slope failure exposing the jetty core to wave action. Wave action acting on small core stone and non-interlocking armor stone then dismantles the jetty.

The forcing environment affecting the jetties today is not the same now as it was 70 or 100 years ago. At the time of jetty construction and shortly thereafter, the jetties were protected by the broad shallow sand shoals on which they were built. Incident waves were severely depth limited along much of each jetty and currents were reduced, by the presence of shallow shoals. In some localized areas, jetty construction promoted shoaling along the jetty, further protecting it from wave and current action. In other areas, jetty construction motivated rapid dispersal of the sand shoals near the jetty, allowing larger waves and currents to affect the structure. The seaward terminus of each jetty experienced rapid deterioration immediately after initial construction, due to the jetty head extending off the inlet's shoals, exposing it to severe current and wave action.

During the initial phases of South Jetty construction, the meager cross-section employed along the most of the jetty's exposed length (mid-tide jetty crest elevation of +7 ft MLLW and crest width of 15 ft, with maximum size armor less than 10 ton) did not withstand the forces encountered and had to be rebuilt using an increasingly resilient cross-section. In some cases along the South Jetty, the repair cross section was based on a compound slope to increase jetty resiliency. The standard repair cross-section for MCR jetties had evolved to one based on crest elevation of +23 ft to +30 ft MLLW, crest width of 23 ft, and nominal armor size ranging between 9-20 tons. A larger repair cross section was based primarily on the need for the jetty to resist exposure to increasingly vigorous environmental loading and provide added resiliency after the structure becomes damaged.

The environmental loading along the MCR jetties has been increasing over time (since jetty construction) because of the evolving inlet and supporting morphology. As the inlet's post-jetty construction transient morphology has been eroded, large waves are able to get closer to shore; depth limited wave height along the jetties has increased. Along some reaches, the depth limited height affecting the jetties has increased by >30% since initial construction. At the same time, the foundation along various reaches of each jetty has been compromised due to erosion of the shoals on which the jetty is founded. Vertical scour along the toe of the MCR jetties has exceeded 35 ft in some reaches [Moritz et al., 2007]. The extent over which the jetties continue to experience increased forcing continues to change and constitutes a non-stationary loading condition. A significant proportion of the remaining above waterline elements of each jetty are in a deteriorated condition and the condition is worsening with time. "Just in time" repairs ($26 million) were recently completed in 2007 to address the most acute damage along limited reaches of the north and south MCR jetties, to prevent loss of jetty function (breach) and attendant interruption of navigation through the MCR. Based on the present damage trend and a lean maintenance strategy, the MCR jetties appear to be approaching a condition of continual repair.

The effective heads of all three jetties at MCR have been receding landward since the time of initial construction. The process of jetty head recession has facilitated the transport of littoral sediment into the inlet. The loss of this sediment from the coast has reduced the supply available to the littoral budget, deflated the morphology along the jetty root (exposing the jetty to more deterioration), and has added sediment to the MCR dredging requirement. The current head positions of the North, South, and Jetty A are 2200 ft, 6200 ft, and 900 ft shorter than authorized lengths.

The shoreface expression of Peacock Spit (Benson Beach) has receded approximately 40 ft/year for the past 4 years. This observation is based on active monitoring of the shoreface along Benson Beach using the ARGUS system at North Head light house (http://www.planetargus.com/north_head). Large scale bathymetry change of Peacock Spit during 1997-2007 has resulted in the seabed being lowered by 2-4 ft, with the exception of the areas within and 1 mile northward adjacent to the SWS. These areas have experienced no net erosion. In some cases areas, nearby areas affected by dredged material placement at the SWS have gained 2-4 ft of elevation. The bathymetry of Clatsop Spit (western flank, along South Jetty) has been lowered 4-10 ft during 1997-2007. The shoreface expression of Clatsop Spit (along the north side of South Jetty) has been receding at 2-20 ft per year, depending upon location. The shoreface immediately south of the South Jetty is receding landward at a variable rate of 0-20 ft per year.

6. Existing Condition of Structures and Morphology

a. General

To evaluate the existing jetty condition, a digital elevation model (DEM) was developed. The MCR DEM describes the present surface of each jetty and the bathymetry of MCR. The DEM was used to compare the existing condition of each jetty to the 'as-built' (or 'as-repaired') cross-section template. Assessments of North and South Jetty performance, present functionality, and reliability were made using the existing condition DEM.

b. MCR Digital Elevation Model

A substantial effort was undertaken by USACE Portland District to produce a detailed DEM for the MCR. The overall DEM was produced from data collected using three surveys with different methods during 2006:

1. Conventional single beam fathometry was used to survey bathymetry within and outside the main inlet of MCR. The conventional bathymetry survey was controlled using DGPS and NOAA tidal corrector.
2. Multi-beam fathometry was used to survey the submerged areas of the jetties. The multi-beam survey was controlled using RTK-DGPS.
3. Controlled aerial topographic mapping was used to survey the exposed (subareal) areas of the jetties. The aerial photography that was used for topographic mapping of the jetties was controlled using ground reference points with the aircraft camera being tracked using RTK-DGPS with an inertial measurement unit.

The nominal resolution of the DEM for bathymetry within and outside the inlet in water depths less than 230 ft is horizontal and vertical accuracy of ± 1.5 ft and ± 1.0 ft, respectively. The jetties were mapped at a resolution less than 3 ft (horizontal and vertical accuracy is ± 1.5 ft m and ± 1.5 ft). Positional reference for the MCR jetties is based on the original centerline alignment and jetty stationing. This means that the jetty stationing used in this report begins at the true landward most point for each jetty and no offsets are included within the centerline alignment. The MCR DEM was used to compare the present structural condition of the jetties to the as-built condition. The present condition of the jetties was evaluated by "cutting" cross-sections through the DEM every 10 ft, along the center line of each jetty. The reliability analysis of the MCR jetties (see Appendix A2) was made possible by the accurate definition of the present jetty condition. Numerical modeling for wave transformation and hydrodynamic circulation utilized the MCR DEM.

c. Maintenance History and Template Deficit

The existing condition and robustness of the MCR Jetties can be characterized by looking at the maintenance history as well as the current cross section deficit of each jetty compared to a standard or typical design template. The maintenance history of each jetty was outlined in Chapter 1 and Appendix A2. Figure A1- 65 through Figure A1- 67 summarize that information in approximately 50 year increments, a typical design life for a coastal structure. Also plotted on those figures is the estimated expected maintenance for the jetties over that same time period using a 0.7% x construction volume per year of structure life. Given the performance life of the North and the South jetties, 93 and 115 years, respectively, and the extreme exposure of the structures, more maintenance stone would have been expected over their life. In particular, the last 50 years has seen a reduction in maintenance activity at the jetties. Some of the repair activities for Jetty A utilized readily available but under-sized stone for maintenance activities which is reflected in the fairly large stone volume placed on the structure over its lifetime.

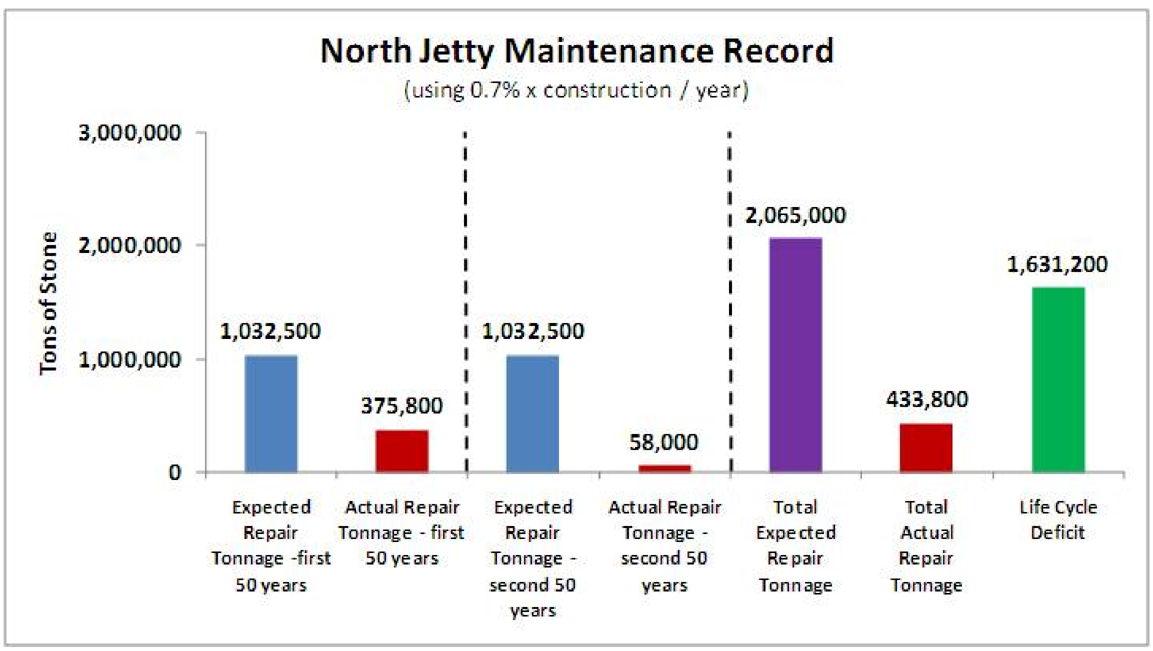

Figure A1- 65. North Jetty Maintenance Record Total Summary

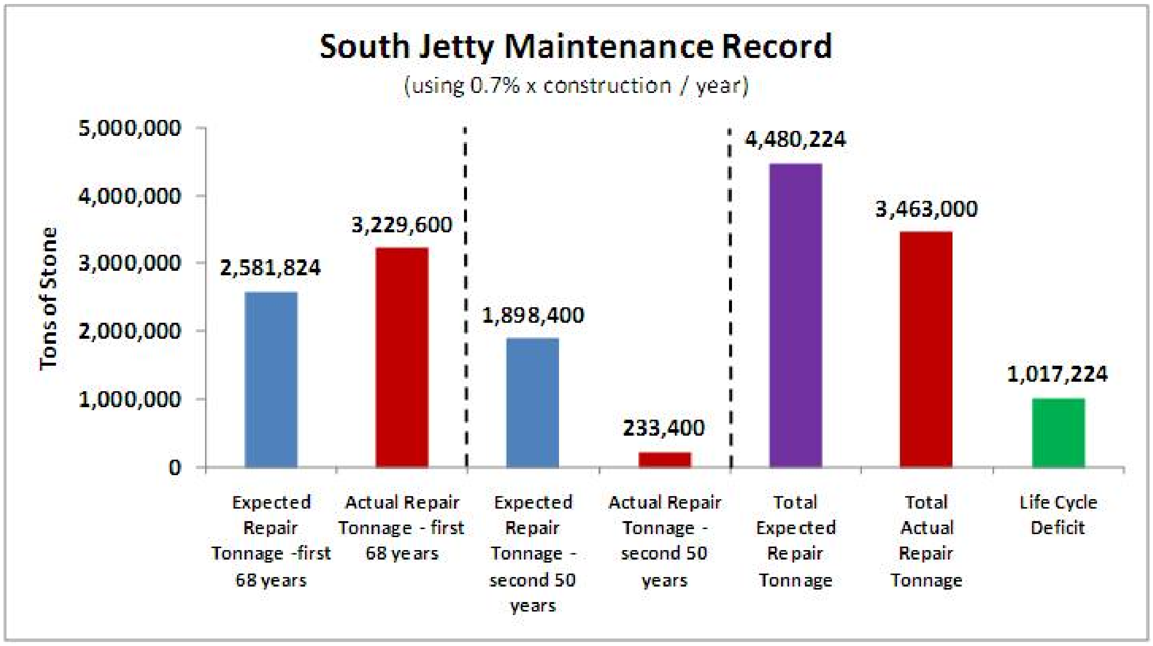

Figure A1- 66. South Jetty Maintenance Record Total Summary

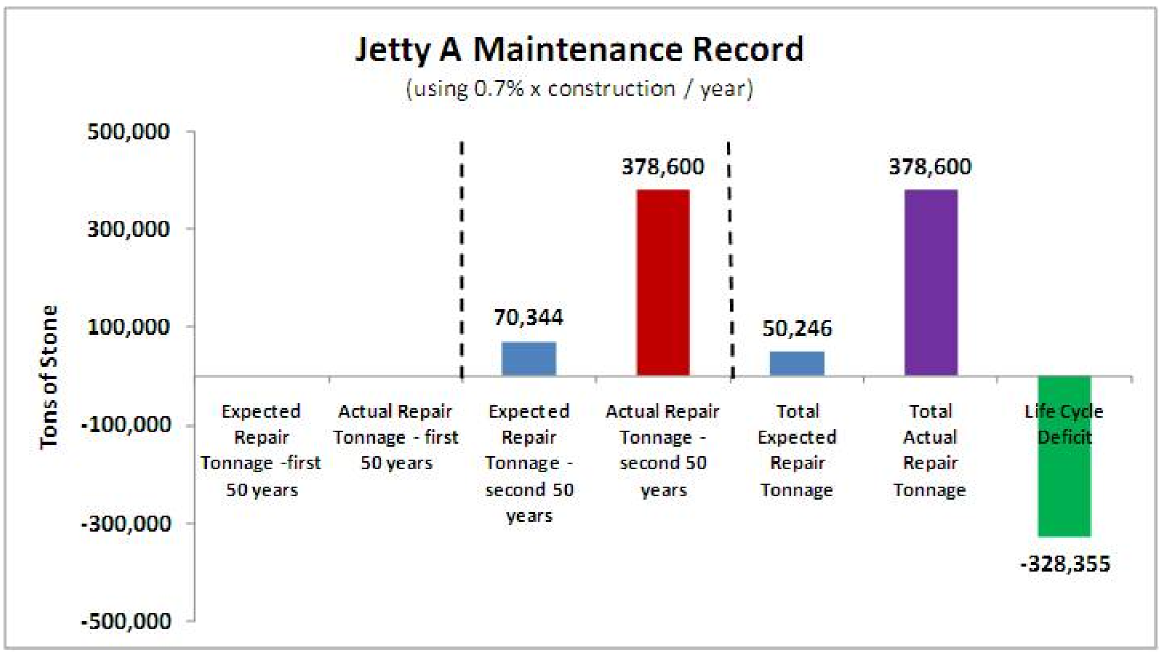

Figure A1- 67. Jetty A Maintenance Record Total Summary

Another measure of the existing rubblemound structure condition would be to simply calculate the deficit of stone volume between the existing structure surface and a standard or typical design template. Figure A1- 68 illustrates that comparison for the three jetties. Existing South Jetty deficits range from approximately 410,000 to 700,000 tons of stone to bring the existing structure up to a minimum or small template. For the North Jetty, approximately 240,000 to 570,000 tons of stone would be needed to bring the existing structure up to a minimum or moderate template. Jetty A would need approximately 87,000 tons to bring the existing structure up to a small template. A range of stone volumes is reported here to provide a framework for considering design or structure modifications necessary to respond to increased loading of the structure at some locations.

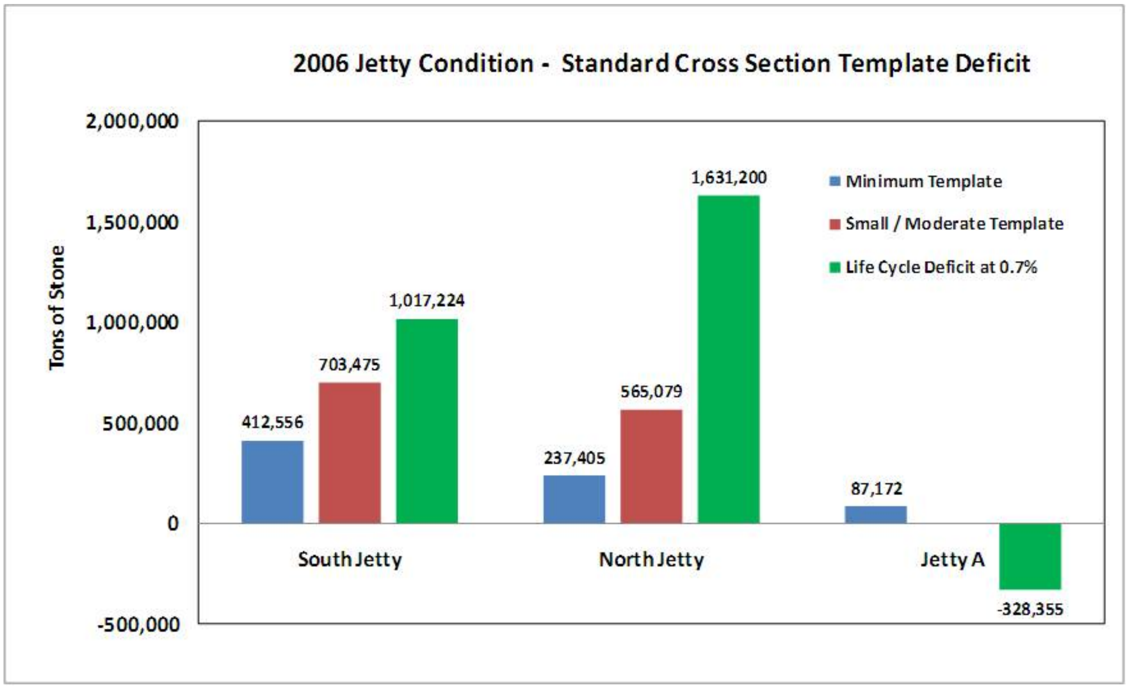

Figure A1- 68. North, South, and Jetty A Standard Cross Section Template Deficit

Crest elevation and jetty length changes are documented in Figure A1- 33 through Figure A1- 35 with respect to a complete project survey conducted in 2000. For the North Jetty, jetty length loss of approximately 2200 ft and significant channelside foundation erosion (up to 60 ft change in depth) impacting approximately the seaward half of the jetty are the most significant. In addition, as shown in Figure A1- 38, the north side of the North Jetty is being increasingly exposed to higher wave and water level conditions due to the erosion of Benson Beach. For the South Jetty, jetty length loss of approximately 6200 ft has worked interactively with ebb tidal shoal changes to increase loading particularly for the seaward half of the structure. The concrete monolith at approximately Station 330 and the channelside spur groins have slowed down the physical morphological changes at that location. Jetty A has lost approximately 900 ft and in addition, a large scour hole at the southern end of the Jetty A head, up to 120 ft depth, has impacted its stability.

Figure A1- 69 illustrates the critical shoals surrounding and supporting the MCR jetties. As previously stated, numerous modifications to these shoals over the project life and continuing today have the potential to impact the stability of the jetties. As the jetties recede, deteriorate, or become breached the adjacent morphology is affected; the inlet and jetties become increasingly exposed to wave and current action. Sediment mobilized from the morphology can increase the MCR O&M dredging requirement.

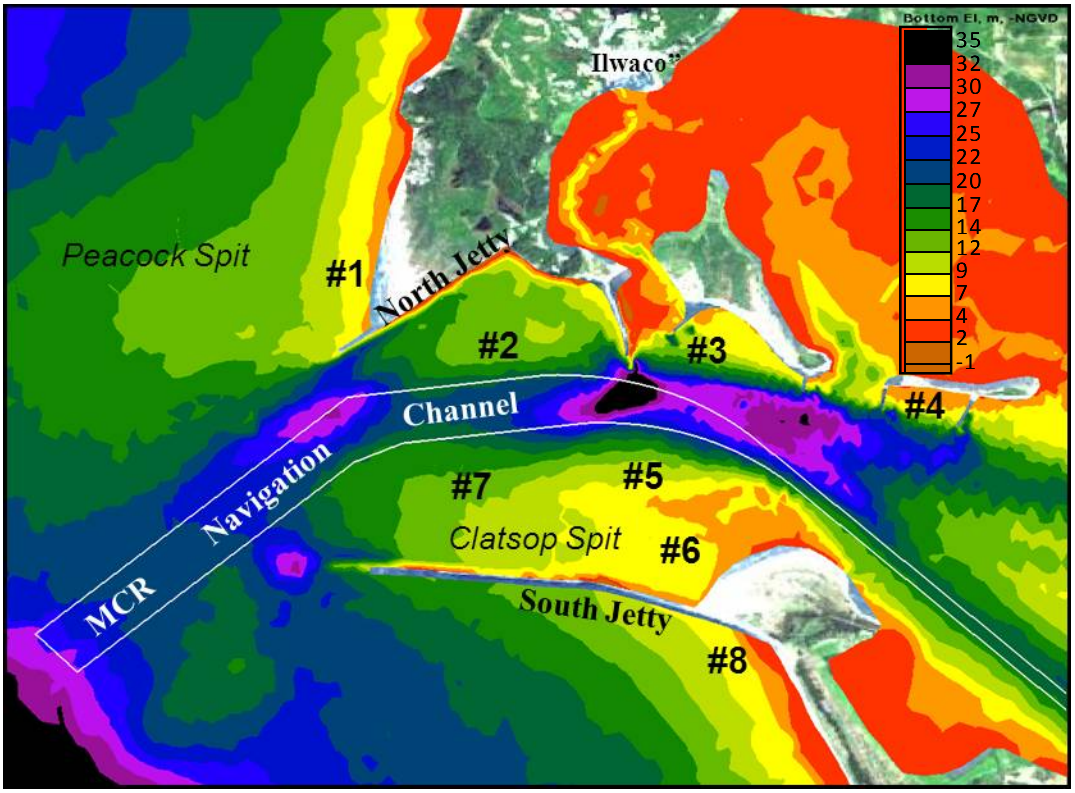

Figure A1- 69. Areas of MCR morphology affected by jetty deterioration

d. Performance of MCR Jetties and Key Structural Elements

The jetties have required periodic and extensive repairs every 20 years to maintain the functional integrity of each jetty. Since initial construction, the North and South jetties have required the placement of 3.62 million tons of stone to maintain the functional integrity of each jetty. Collectively, this represents 43% of the stone used to construct both jetties. The total resources expended to maintain the MCR North and South jetties since "new work" construction is significant because the environment in which the jetties were built is severe and the scale of the jetties is large.

Although considerable resources and effort have been invested to maintain the North and South jetties, the jetties have performed satisfactorily given the environmental setting. Damage sustained by the jetties is a process of both continual and episodic events, much like a linear trend with small steps. Jetty repair actions are not a continual process. They arise infrequently, when the cumulative damages are severe enough as to render the jetty susceptible to complete loss of function. A repair function would resemble an abrupt step-wise trend. Future jetty performance is contingent upon the level of rehabilitation that is now required to re-establish functional integrity.

7. Forcing Environment – General Considerations

a. General

Wave height is the environmental parameter that drives jetty armor layer design. The design of a jetty armor layer is a function of wave height[3] (incident at the jetty). Figure A1- 70 to view how wave height can influence armor unit size (weight). Basic coastal jetty design dictates that the *armor layer* withstands wave action commensurate with the jetty design life-cycle. If a jetty is to have a 50-year life-cycle, the cross section of the jetty (armor layer) should be designed to withstand a wave loading scenario associated with a 50-year event (incident at the jetty). A "50-year event" is an occurrence that is expected to be exceeded, on average, once every 50 years. The annualized probability of a 50-year event is 0.02 (or 1/50). For a coastal jetty, the design event is a combination of various forcing conditions (i.e., offshore wave height, tide level, storm surge, and nearshore bathymetry). A 50-year life-cycle also requires that the jetty foundation should withstand a 50-year cumulative scour potential (corresponding to destabilization of the jetty foundation).

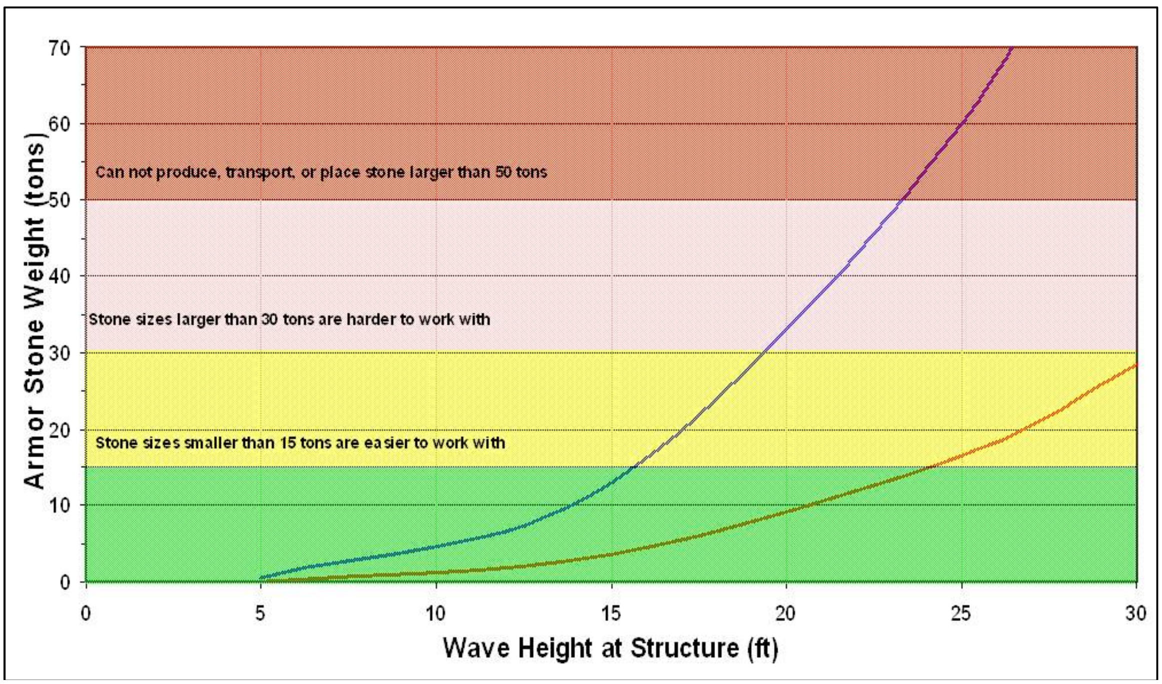

Figure A1- 70. Functional relationship between wave height (H) at jetty and required armor stone size (W), based on the Hudson Equation

(Results are shown for two different scenarios based on a variation in rock density (γ), stability number (Kd), and jetty side slope (θ). The two scenarios effectively define the envelope available for optimizing armor stone size, based on the above design parameters.)

The combination of elevated water levels and storm wave conditions creates an environment of enhanced shoaling and breaking waves that batter the jetties, displacing armor and core stone along areas of the jetties that have been weakened by foundation scour. Portrayal of the physical environment at MCR is essential for understanding the harsh context for which the MCR jetties must function and to develop a reliable description of the forcing environment (waves and tides) that is required to design jetty repairs. The following section describes the general physical environment at MCR and summarizes the forcing environment in terms of the parameters used for jetty (repair) design.

1. Waves Offshore MCR

In the northeast Pacific Ocean, winter-time weather fronts associated with maritime cyclonic storms can extend over the ocean for 1,000 miles and cover a latitude difference of 25 degrees. When these maritime low-pressure systems make land fall on the U.S. Pacific Northwest, the coast can be subjected to hurricane-like conditions: Sustained wind speeds can be greater than 40 knots for fetches greater than 125 miles. The resulting wind stress can produce ocean waves greater than 30 ft high having wave periods (Tp) greater than 16 seconds, and a "set-up" of the mean water level (storm surge of 1-5.5 ft for 1-6 hours duration), depending on storm evolution. Wave heights (Hmo) of up to a maximum of have been recorded at NDBC buoy 46029, located 18 miles offshore the MCR (Figure A1- 71).

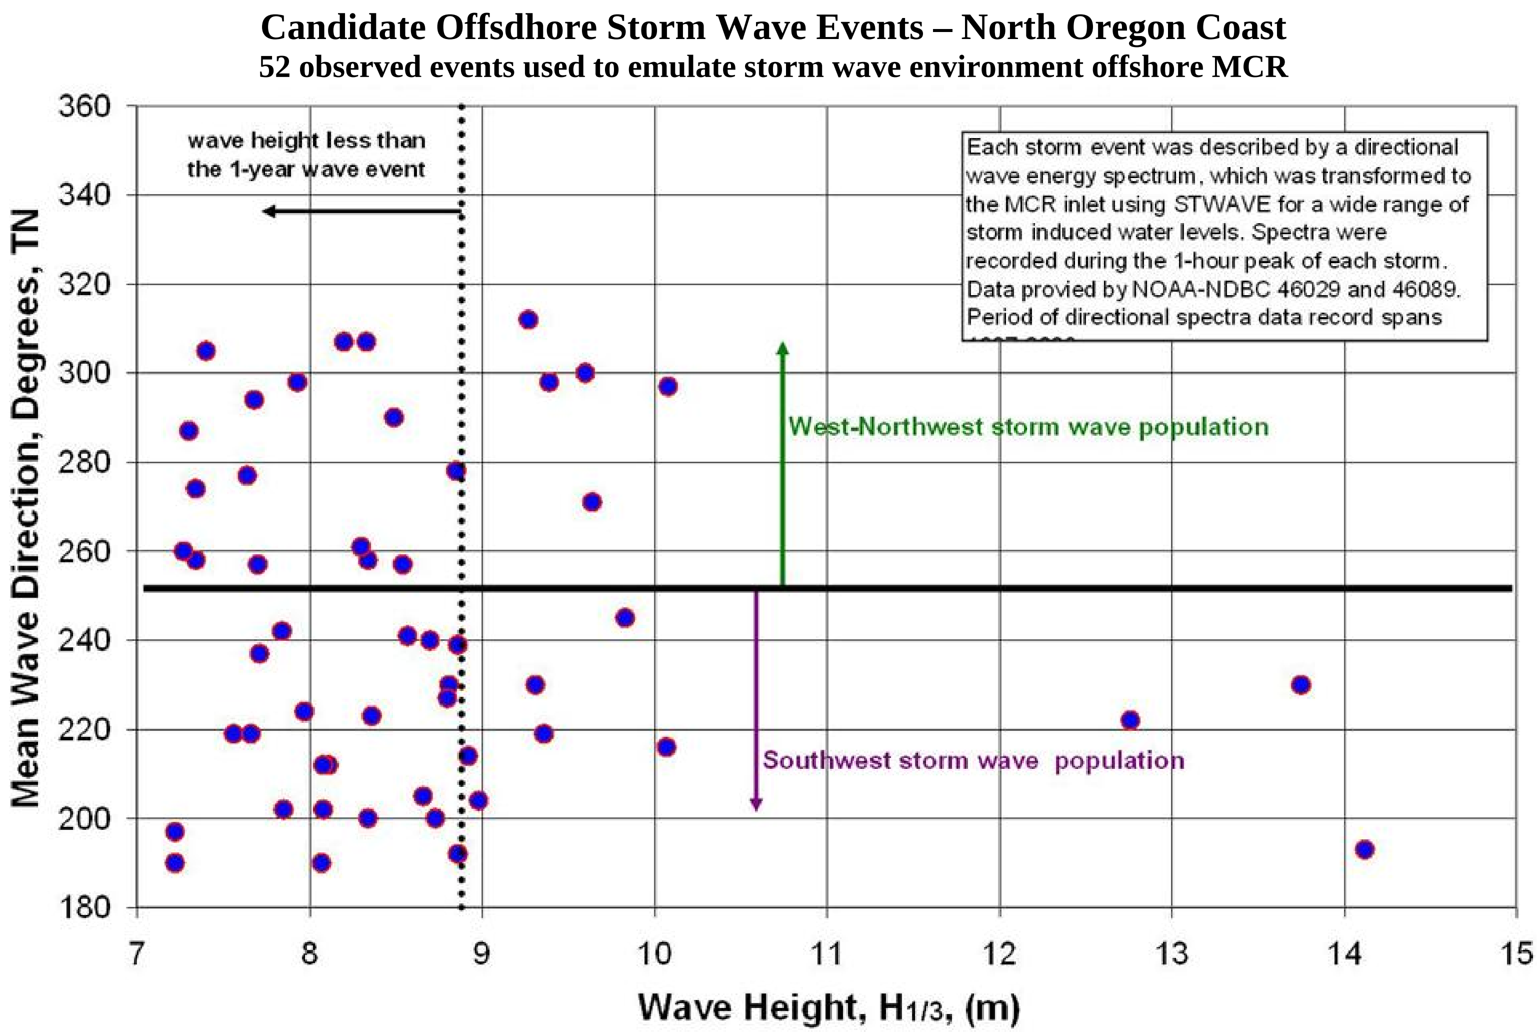

Figure A1- 71. Offshore wave events used to characterize incident wave environment at MCR jetties

The ocean entrance at MCR is characterized by large waves and strong currents and has been considered one of the world's most dangerous coastal inlets [Gonzalez 1984]. The transition from coastal regime to oceanic is abrupt at MCR. Excluding Astoria Canyon, which is about 11 miles (18 km) offshore, the continental shelf break (1,000 ft water depth) lies approximately 18 miles (30 km) offshore from the MCR. The sea state at MCR during storm conditions is characterized by high swell approaching from the northwest to southwest combined with locally generated wind waves from the south to southwest. During October-April, the seasonal average wave height and period is 9 ft (2.7 m) and 12 seconds, respectively. During intense winter storms, waves can exceed 30 ft (9 m). Individual waves having a height of 45-55 ft (trough to crest) were recorded 5 miles south of MCR in water depth of 135 ft [Moritz 2001]. During May-September, average wave height and period is 5 ft (1.5 m) and 9 seconds, respectively. Figure A1-68 illustrates that approximately 70% of all offshore storm waves approaching the MCR are from the west-northwest [Moritz 2007].

2. Waves at MCR Inlet

As waves propagate shoreward toward the MCR, the waves are modified (waves begin to shoal and refract) by the asymmetry of the MCR's underwater morphology. Nearshore currents and tidal currents are also modified by the jetties and the MCR's morphology. These modified currents interact with the shoaling waves to produce a complex and agitated wave environment within the MCR. The asymmetric configuration of the MCR and its morphology is characterized by the significant offshore extent of Peacock Spit on the north side of the North Jetty, southwesterly alignment of the North/South jetties and channel, and the absence of a large shoal on the south side of the MCR. The asymmetry of the MCR causes incoming waves to be focused onto areas which would not otherwise be exposed to direct wave action. An example of this wave-focusing effect is the area along the south side of the North Jetty. Upon initial inspection, it would appear that this area is most susceptible to wave action approaching the MCR from the southwest. However, this is not the case; the opposite is what occurs. The area located between the North Jetty, the navigation channel, and Jetty A is affected by wave action during conditions when the offshore wave direction is from the west-northwest, because of the refractive nature of Peacock Spit. Waves passing over Peacock Spit (approaching from the northwest) are focused to enter the MCR along the south side of the North Jetty. Conversely, large waves approaching the MCR from the southwest are refracted/diffracted (changed in direction) around the South Jetty and over Clatsop Spit, protecting the south side of the North Jetty from large, southerly waves.

3. Time-Varying Changes in Nearshore Wave Climate at MCR

The changes in regional and localized waves at the project site since original construction can be described in two separate categories. The first approach is to look at our understanding of any increasing trends of the regional wave environment associated with variable climate effects. The second approach is to look at the impacts of morphology evolution on the depth-limited characteristics of the waves at the project. Measurements of the deep water wave climate offshore of the MCR project area are available for 1984 to present (NDBC 46029). Analysis of this deep water wave data indicates that height of storm-related waves and frequency of storms may be experiencing an increasing trend. Due to the relatively short data record, it is not known whether this trend is a persistent increase or just a subset of a larger data base of wave heights that experiences a wide range. The data record describes deep water wave conditions. However, the wave heights actually impacting the MCR jetties are shallow water waves, being transformed to shoreward over the nearshore bathymetry. The actual impact (associated with climate variation) on shallow wave heights at the structure will be dampened by the depth-limited wave characteristics of the project site. Wave height is physically reduced as the water gets shallower, oftentimes eliminating any increased increment of wave height by the time it reaches the project. This fact introduces the second element of wave height change over the project life; morphology change at the inlet. If the nearshore bathymetry (submerged shoals) at the project area becomes deeper over time, waves (height) affecting the structure can increase. The opposite is true for morphology accretion.

When the water depth near a structure becomes shallower over time, the depth-limited wave height is reduced. This is why the morphology at the MCR inlet is crucial to the permanence of the jetties: The morphology created by jetty construction protects the jetties from large damaging waves. If the morphology along the jetties recedes excessively, large damaging waves can attack and destabilize the jetties. The wave environment at MCR has evolved in response to the morphology changes induced by jetty construction. Depending on the location at the inlet; the wave environment could be less severe now than at the time of jetty construction. In some cases, the wave environment along a given MCR jetty was reduced or eliminated soon after jetty construction due to rapid accretion of sand shoals. As the accretionary feature was dispersed over time, the wave environment gradually increased to the point of being larger now than at the time of jetty construction. A combined wave and water level modeling approach was applied to account for the evolving nature of the morphology at MCR. The wave modeling effort used numerical modeling (STWAVE) to transform offshore waves to the project site. Jetty life-cycle analysis and design utilized the above wave modeling to estimate waves in the past, present, and future. The depth-limited wave heights at the project increase as the depth along the jetties increase.

4. MCR Tidal Regime and Circulation

Astronomical tides at MCR are mixed semi-diurnal with a diurnal range of 8.5 (2.6m) feet. Twice each day, the MCR is the hydraulic battlefield between two distinct water masses, the freshwater outflow of the Columbia River and the marine inflow from ocean tides. The instantaneous flow rate of estuarine water leaving the MCR during ebb tide can exceed 2 million cfs (70,000 m^3/sec) and the flow rate of marine water entering MCR during flood tide can exceed 1 million cfs (35,000 m^3/sec). Currents within the navigation channel can attain 2.5 meter/sec (5 knots or 8 ft/sec) and are highly variable, in time and space, across the MCR. A large, clockwise-rotating eddy current has been observed to form between the North Jetty, the navigation channel, and Jetty A during ebb tide. A less pronounced counter-clockwise eddy forms in response to flood tide. The North Jetty eddy has varying strength and direction (based on location and timing of tide) ranging from 0.3 to 3.3 feet per second.

In coastal waters immediately adjacent to the MCR, the dynamics of the Columbia River estuary dominates circulation, tending to draw (denser) bottom marine waters into the estuary while discharging low salinity waters (the plume) at the surface. The asymmetry of tidal flow, coastal currents, and wave action in vicinity of MCR is caused by the orientation of bathymetric contours offshore of Peacock and Clatsop spits. The nearshore wave and tidal environment at MCR is greatly affected by Peacock Spit and Clatsop Spit, due to the spits' significant offshore extent (Figure A1- 1 and Figure A1- 2). The orientation of the shoals/spits at MCR has arisen due to interaction of jetties, waves, currents and sand. Figure A1- 72(B) shows a simulated "snap-shot" of the flow pattern at MCR during an ebb tide on 6 October 1997. During ebb tide, much of the primary flow passes through the deeper areas of MCR and impinges on controlling features that boarder the deeps. Figure A1- 72(A) shows the time-averaged flow through MCR during 2-10 October 1997 and highlights the residual circulation (eddies and gyres) that forms within the inlet. Eddies and gyres that form within MCR arise due to the interaction of estuarine and coastal flow with jetties and the morphology. These eddies greatly influence circulation and shoaling within the channel. Detailed simulation of circulation at the MCR was performed using Deflt-3D (Gelfenbaum et al., 2007) and CMS (Kraus et al., 2007). Results of these detailed simulations are described elsewhere in this appendix.

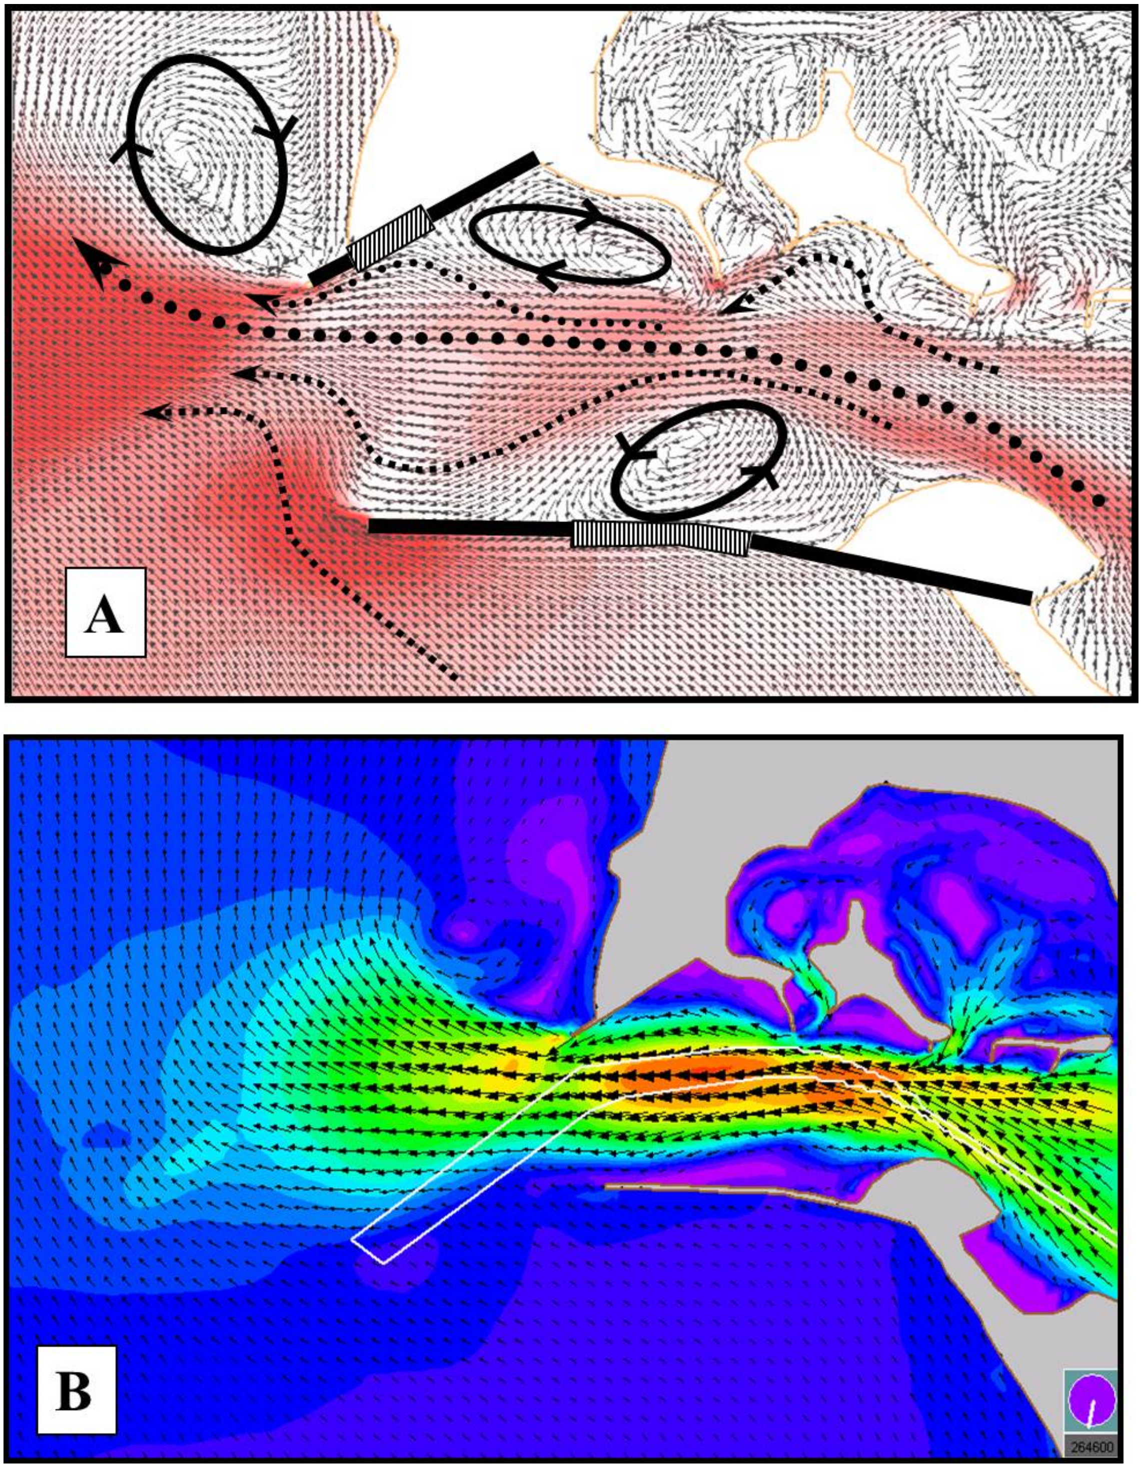

Figure A1- 72. Estimated Average Circulation at Columbia River Mouth & Simulation of Ebb-flow Currents

(A) Estimated average circulation at Columbia River mouth, based on ADCIRC 2-D hydrodynamic computer model, for 1-10 Oct 1997. Eddies and several flowlines shown for clarity. Shaded areas indicate higher current magnitude. (B) Simulation "snapshot" of ebb-flow currents (when tide level is almost at low stand) during 6 Oct 1997, (orange) peak flow is 2.5 m/s

5. Littoral Transport and Ephemeral Morphology at MCR

Historically, the Columbia River has been a major source of sediment to the northwest coast. On the ocean side of the MCR, the inlet is flanked by broad sandy beaches. To the immediate south lies Clatsop spit where the beach is backed by substantial dunes. To the north lie Peacock Spit and a rocky headland (Cape Disappointment), which anchors the shore. The sandy sediment on the southwest Washington and northwest Oregon coastal beaches originated from the Columbia River. Development of navigation at the MCR (jetty construction) has significantly altered the dynamics of the littoral zone and sediment budget near the inlet. The stability of the MCR channel is related to the jetties and the morphology of Peacock Spit and Clatsop Spit (Moritz et al., 2003). Through phased jetty construction from 1885 to 1939 and the associated response of the MCR morphology, the project features at the MCR and the resultant morphology are now mutually dependent, both in terms of structural integrity and project feature functional performance.

On the ocean side of the estuary, marine sand from the coast is transported to the MCR by the north and southbound littoral currents and flood-tidal currents. Previous studies indicate that some of the sand-sized sediments within the lower Columbia River estuary have been transported into the estuary from adjacent nearshore and shelf regions of the Washington and Oregon coasts [Lockett 1962 and Roy et al., 1983]. The Columbia River estuary is being filled not only by river transported sediment, but also by marine sediment entering the MCR by tidally-induced movements of bottom water entering the estuary from the ocean. The littoral dynamics immediately north and south of MCR (within 2-4 miles) are drastically different than at "open coast" areas away from the entrance. Depending on the regional wind field, which varies seasonally and during storms, the "coastal current" north and south from MCR can attain speeds of 1 m/s. The combination of large waves and strong tidal currents can transport large volumes of sediment at MCR. During the course of several tidal cycles (1-2 days), the seabed on MCR tidal shoals can vary by 1-3 ft. As presently authorized by Congress, the MCR navigation channel requires annual O&M dredging of 3-4 million cubic yards (mcy). The dredged material is sand (0.15-0.23 mm) and is placed in open water disposal sites.

b. Definition of Offshore Wave Climate and Water Levels

1. Design Wave Climate - Offshore

An analysis of the wave record at the NOAA-NDBC buoys (during 1984-2008) is the basis for defining the offshore wave environment at MCR [Moritz 2007]. The wave data used in this analysis was extrapolated from an existing, verified record of hourly wave data from the NOAA NDBC buoys #46029 (located 20 NM west of the mouth of the Columbia River (MCR) entrance) and the #46089 (located 60 NM WNW of Tillamook, OR). Data from these buoys was used to create as complete a data record as possible for the period of 1984-2008. Storms in this dataset were initially separated into individual 'blocks' based on a threshold of 4.0 meters. Each 'block' identifies a separate storm event and is defined as the consecutive number of data records for which the wave height exceeded 4.0 meters. In this manner, the individual storm events are kept separate and independent from other storm events. Storm wave events were grouped by *water* year, as opposed to calendar year. Water year is defined as the period from 1 OCT to 30 SEPT of any given year. 1 OCT 2000 to 30 SEPT 2001 is considered water year 2000. This step was taken for consistency with the SRB life-cycle modeling. A given 'year' is synonymous with water year.

A graphical summary of the analysis for all observed storms producing a peak significant offshore wave height >= 4 meters is shown in Figure A1- 73 and Figure A1- 174. Results are based on a partial-duration frequency analysis for a 17-yr period of record using data that was recorded at 1-hour intervals. Data gaps reduced the 24-year duration of observation to a 17-year period of record. Results were extrapolated to a 100-yr frequency of occurrence using a fitted Weibull distribution (k-0.75) and are presented here in terms of an annualized return interval (RI). The expected value for 10-year offshore wave height = 41 ± 6 ft. The offshore wave height expected to be exceeded approximately 5 times within a given year (RI = 0.2) is 22 ft.

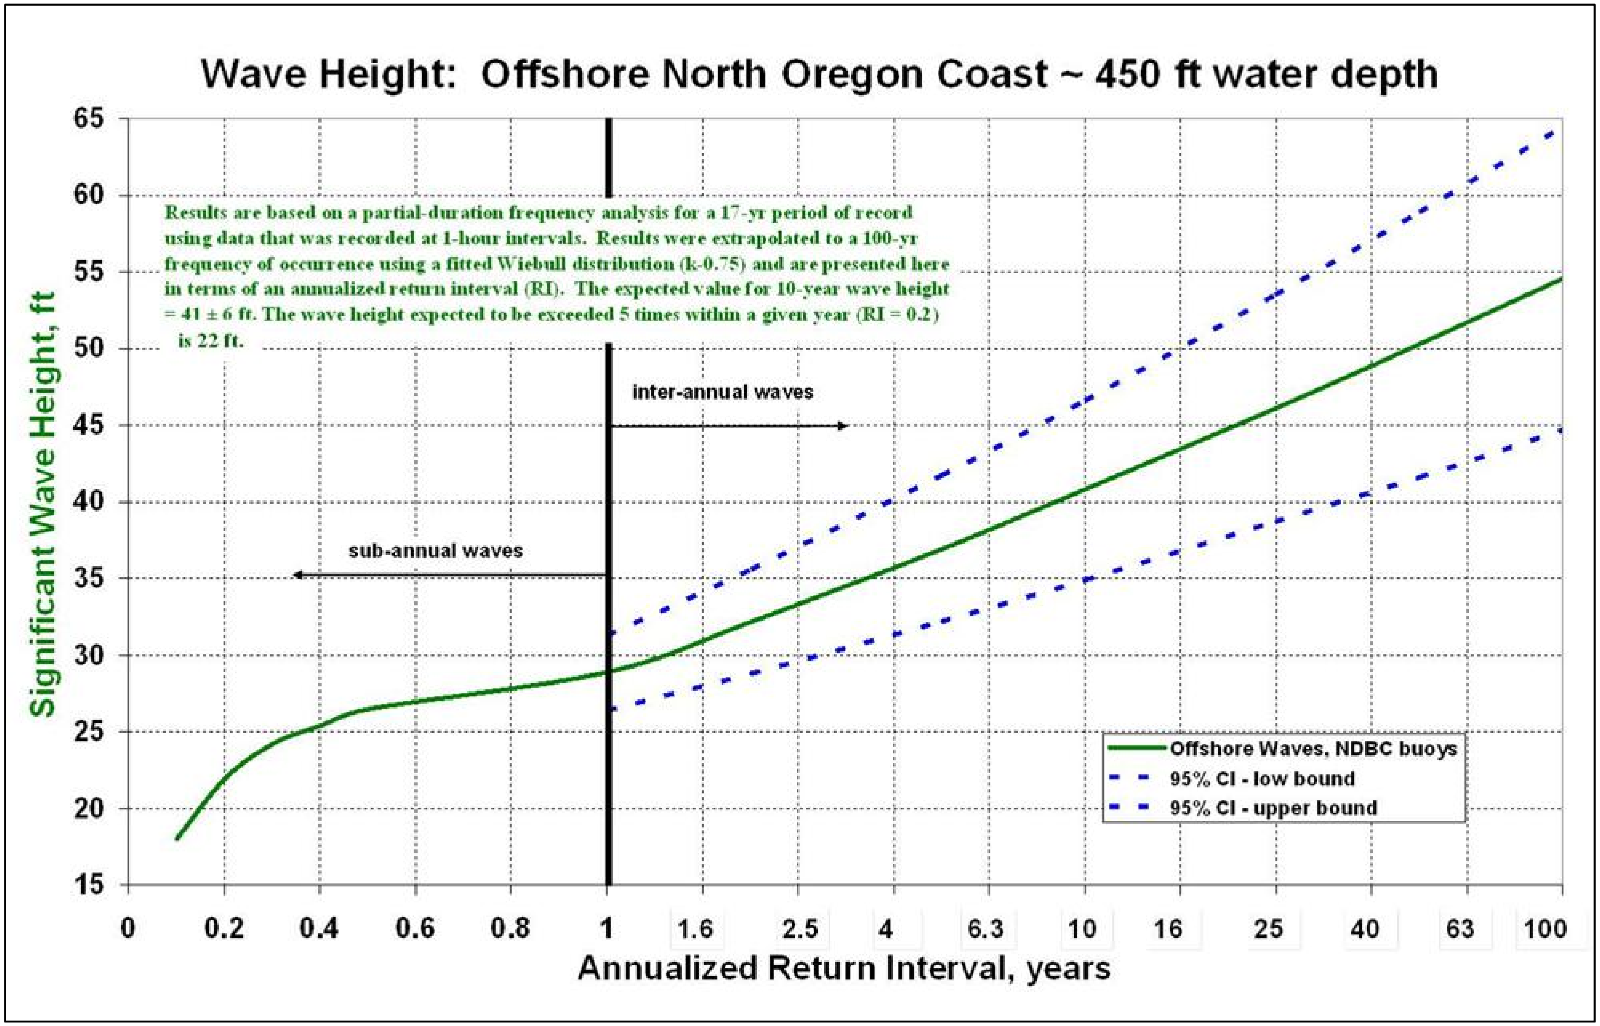

Figure A1- 73. MCR Offshore wave environment expressed in terms of annualized return interval

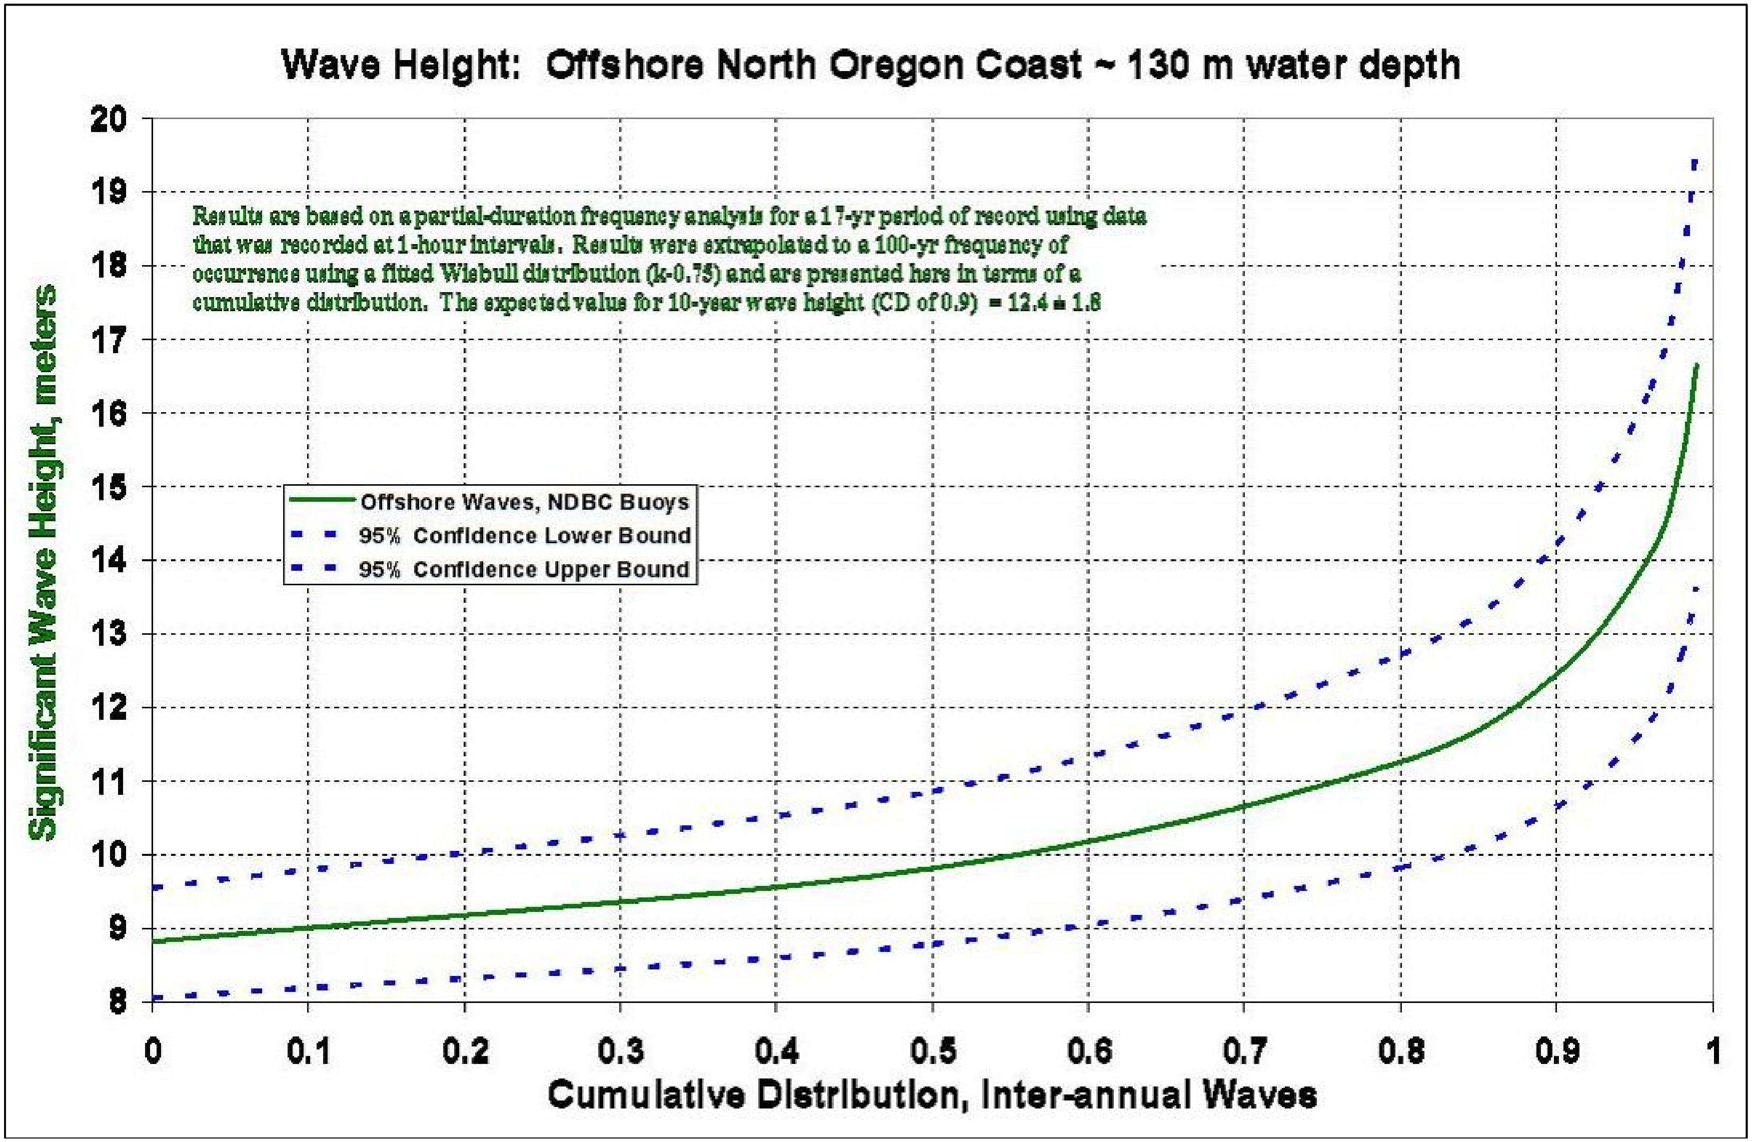

Figure A1- 74. Cumulative distribution for MCR Offshore wave environment

Recall that offshore waves are modified as they travel into shallow water and the water level can have an important effect on nearshore wave modification. This means that the 10-year wave height incident at the MCR jetties will *not* be the same as the offshore 10-year wave. The wave height *at* a jetty is predicated by the offshore (deepwater) wave climate, nearshore bathymetry, and water level. As offshore waves travel close to shore, wave height is limited by the water depth: A higher water level will allow bigger waves to travel closer to shore (or a jetty). This means that water levels (tide + “storm surge”) can have a significant effect on the design wave used for jetty design. Note that offshore gravity wave (swells and seas) conditions are *not* affected by water level variations; the water depth offshore is too deep to have an effect on offshore waves.

A procedure for offshore wave event and water level selection was combined with wave modeling to define the incident wave environment affecting each jetty at MCR. The results from this procedure were used to define the design attributes for jetty repair and rehabilitation, and to drive SRB life-cycle simulations (see Appendix A2).

2. Water Levels at the MCR Coastal Margin

A high water level along the coastal margin allows larger waves to attack a jetty, and topple armor stones if the armor layer is not designed and constructed accordingly. Water levels along the Oregon Coast are primarily a function of astronomical tide influences (Figure A1- 75). “Other factors” that can influence water levels are atmospheric pressure, wind set-up, and wave set-up (Figure A1- 76shows a wave rose for offshore of MCR). Wave set-up can be modulated by infragravity transients, which are low frequency variations of the water surface (1-4 minute period) induced by groups of storm waves (Figure A1- 77). Collectively, these “other factors” are called storm surge; when the observed water level exceeds the predicted tidal water level during storms. The total storm-induced water level (SWL, used for calculation of nearshore wave height) was estimated by adding “storm surge” to predicted tidal water level:

Total storm-induced water level = Water surface elevation due to tides + storm surge

*where S*torm surge = Static component of storm surge + infragravity transients

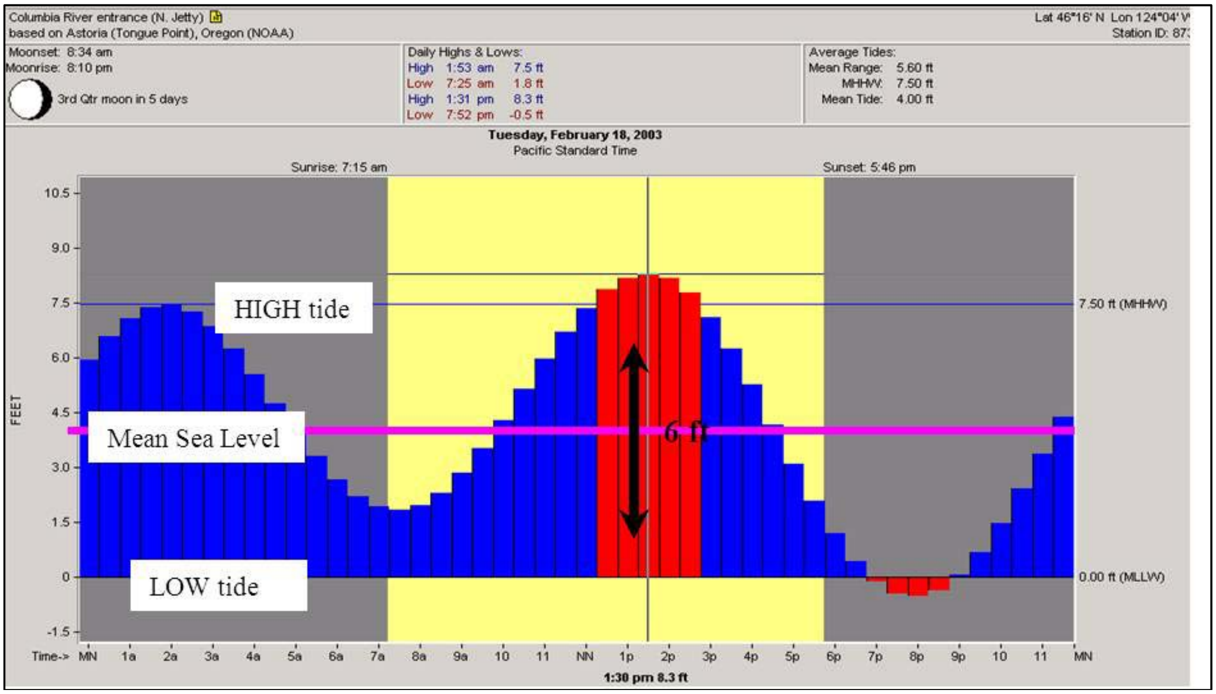

Figure A1- 75. TIDE on NW PAC Coast is Semi-Diurnal

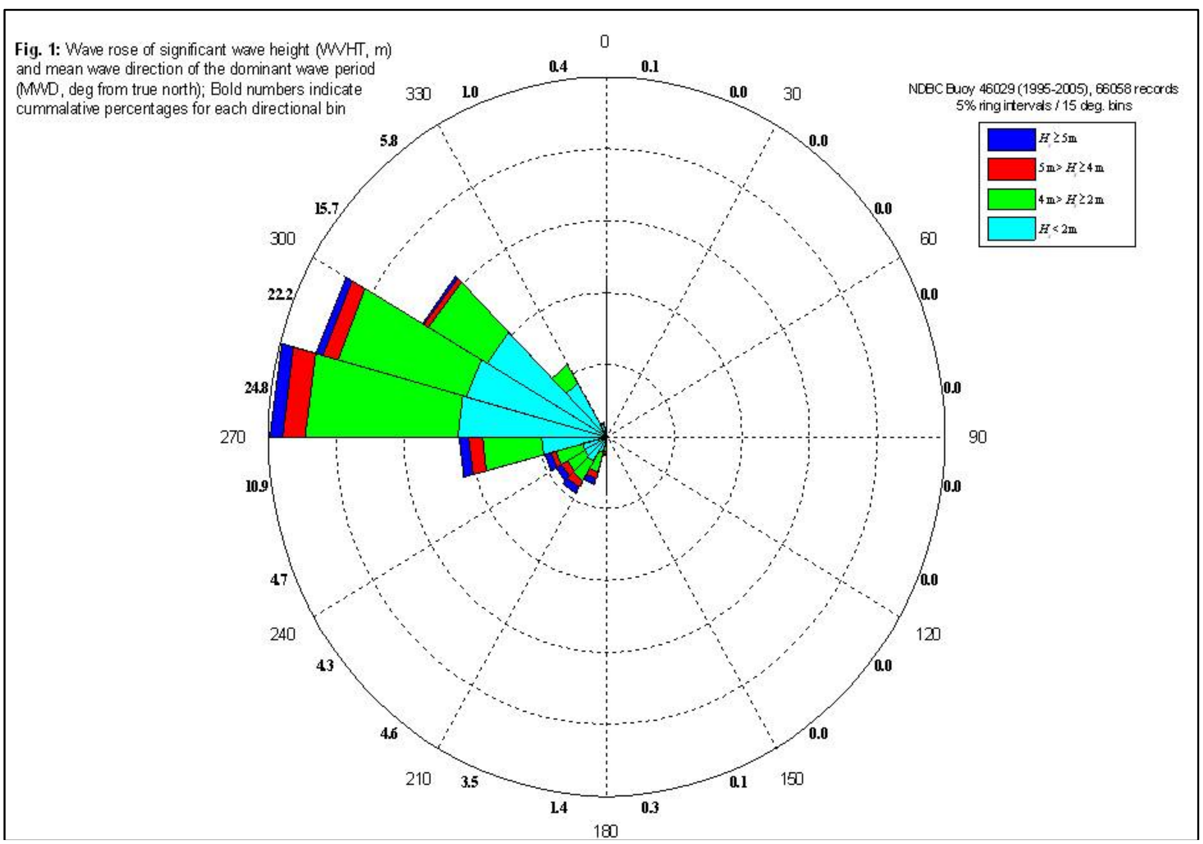

Figure A1- 76. Offshore Wave Rose at MCR

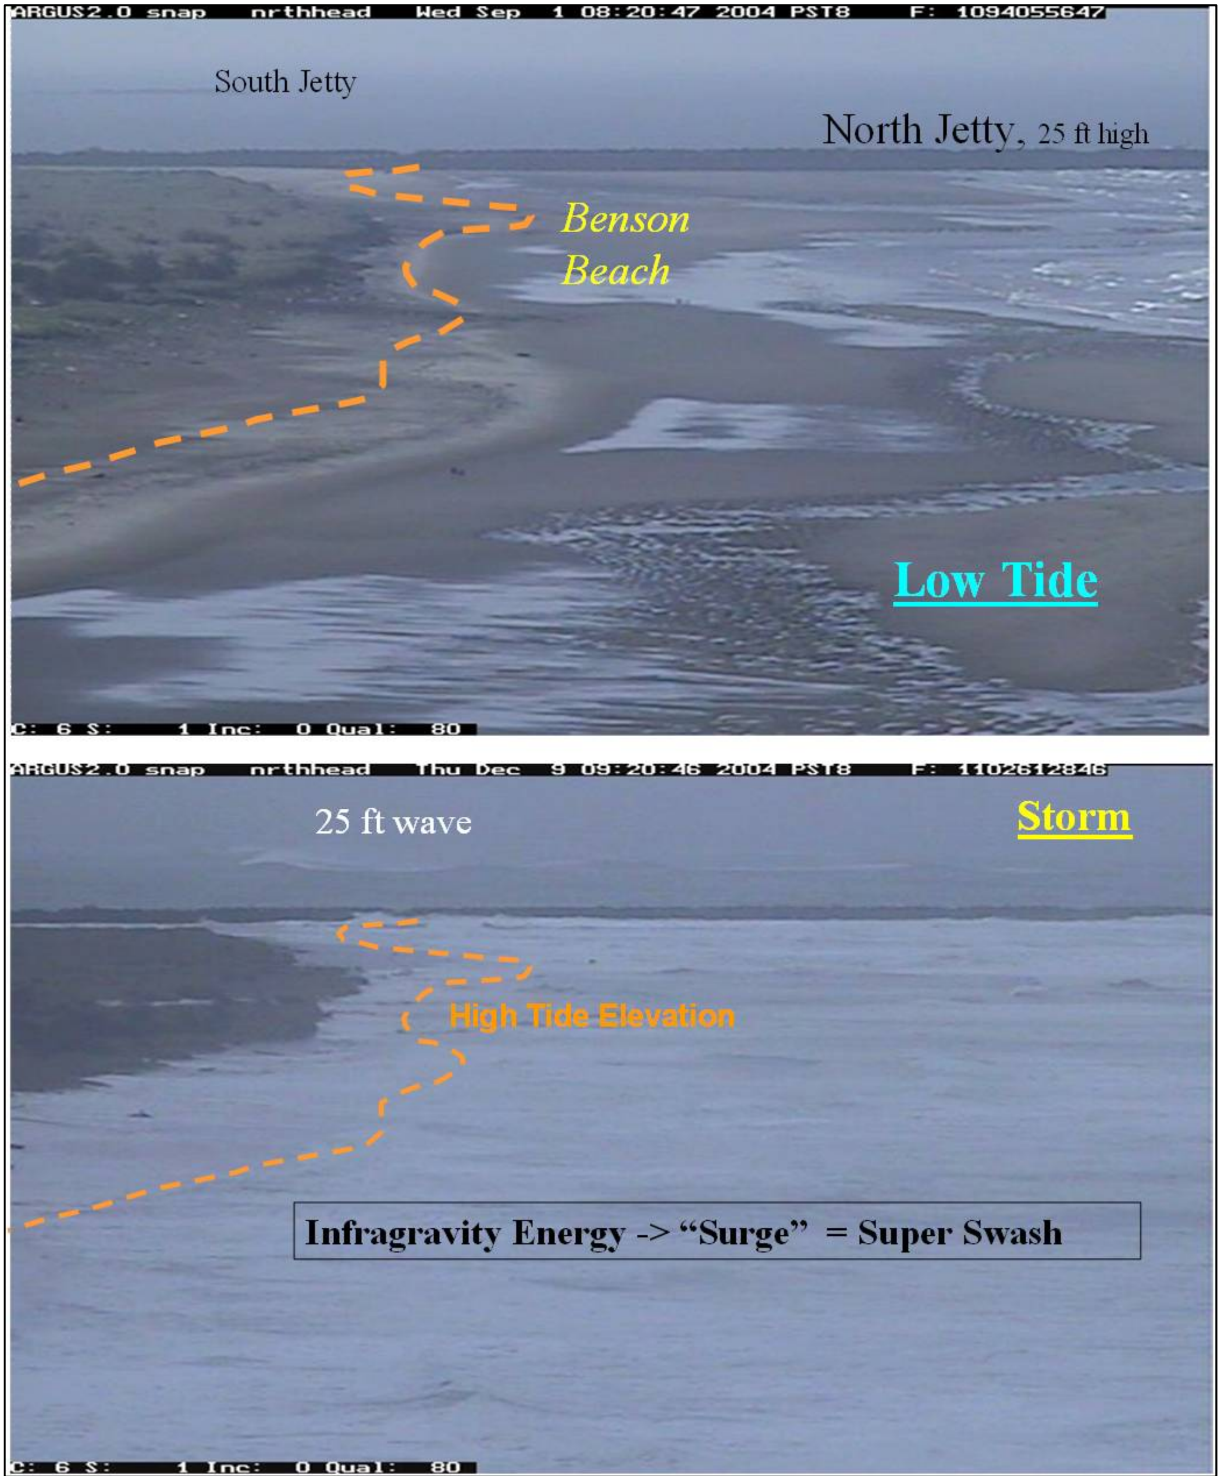

Figure A1- 77. Effects of Storm Water Level on Jetty Root Stability

Image of MCR North Jetty as viewed from the north facing south.. (A) LOW tide @ -5.5 ft NGVD during summer. (B) HIGH tide pus surge @ 14 ft NGVD during winter storm. During elevated water level, large waves attack vulnerable areas of the jetty root. Images from ABMS camera at North head light house.

Figure A1- 78 summarizes the water level components associated with storm events [Moritz 2007]. The time-varying excursion of the water surface elevation (WSE) at the MCR due to TIDE is shown in terms of an annualized percent exceedance for Astoria 1987-2007, applied to the MCR using a 0.87 modulation factor. The hourly high tide level exceeded 10% of the time during a given year = 3.4 ft NGVD (6.9 ft MLLW). The 1% annual high tide is 4.6 ft NGVD (8.1 ft MLLW). 0 MLLW= -3.5 ft NGVD. The estimate for static storm surge is based on a partial-duration frequency analysis for a 20-yr period of record using data that was recorded at Toke Point, WA (1-hr interval). Results were extrapolated to a 100-yr frequency of occurrence and are presented in Figure A1- 78 in terms of a cumulative distribution. The 10-year (0.9) static storm surge = 4.7 ft. Storm-induced Infragravity transient results are based on an estimated cumulative distribution. The 10-year (0.9) estimate for 50 ft water depth = 5 ft. Each component for water level was defined in terms a probability density function (PDF), which was used to for generating a randomized total water level when simulating the life-cycle of MCR jetties within the SRB model (Appendix A2).

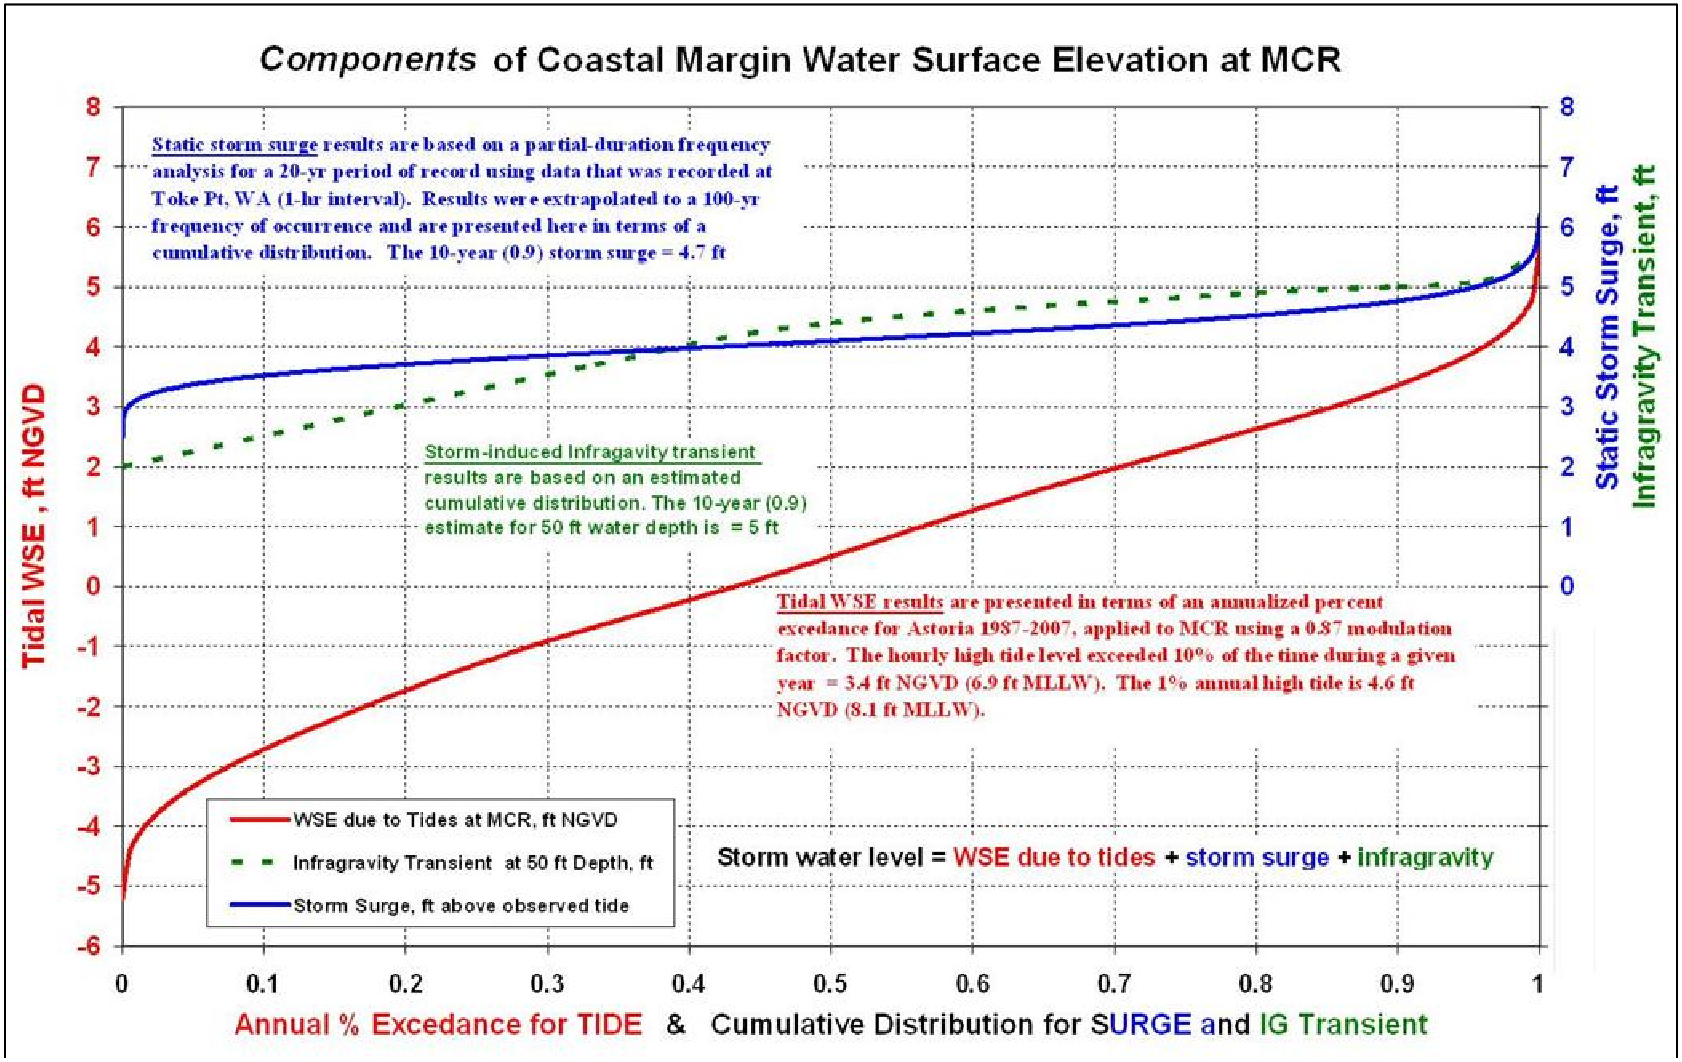

Figure A1- 78. Components of Water Level at MCR

3. Potential for Sea Level Rise

The effect sea level rise was included for assessments of *future* jetty performance at MCR. Future sea level rise estimated within the SRB model as outlined in EC-165-2-211 [USACE 2011]. The EC prescribes a method for defining three future projection curves which are used to bound the estimate for sea level rise over time. The sea level projections (curves) are site specific and are derived based on the historical sea level trend blended with the eustatic effect. EC Curve #1 defines the lowest expected bound for sea level rise, EC Curve #2 defines a "prudent" expected trend, and EC Curve #3 defines the highest expected bound. The sea level projections that were used within the SRB model were based on the NOS station at Astoria, Oregon. Within the SRB model, each jetty life-cycle realization (extending 50 years beyond the base year 2012) was assigned a randomly generated sea level rise trend, which is bounded by EC Curve #1 (-0.2 ft) and EC Curve #3 (1.8 ft; see Figure A1- 79). A total nearshore water level is estimated for each storm by adding the estimated sea level rise (for a given year, i) to the nearshore storm-induce water level, described above. Sea level rise effects were not included within the historical assessment of jetty performance (hindcast).

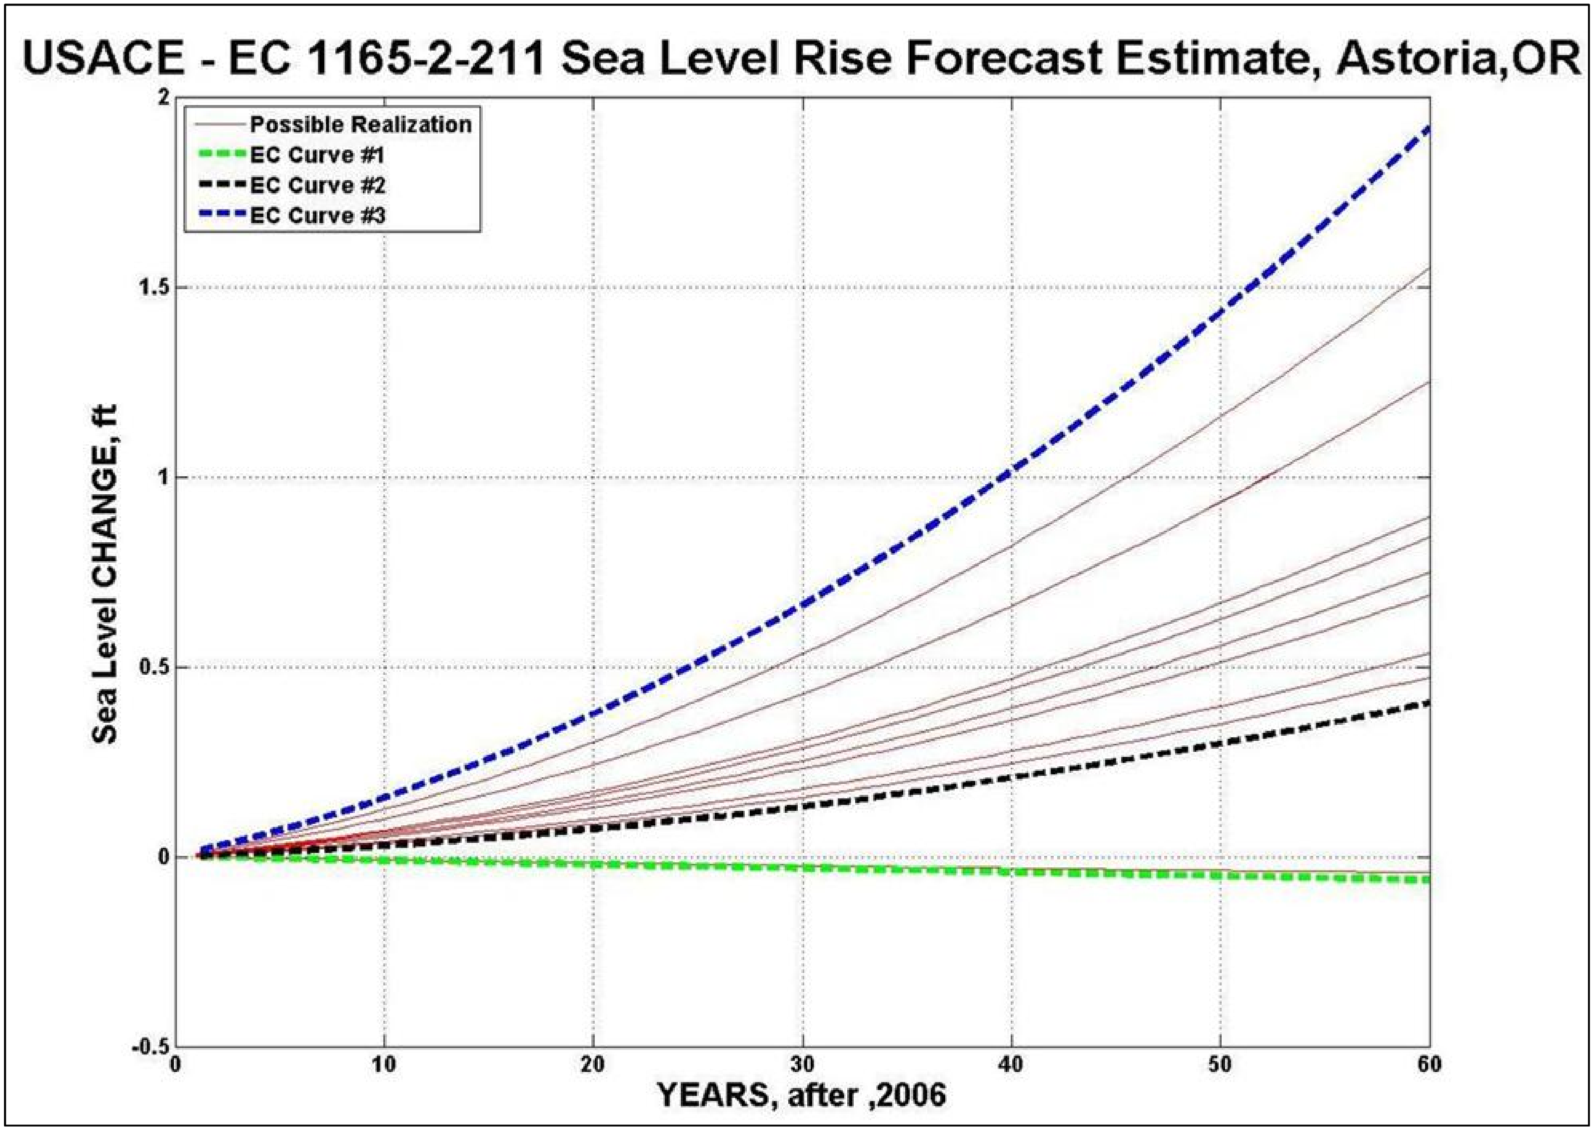

Figure A1- 79. Example of Sea Level Rise Realizations used in Life Cycle Analysis

c. Definition of Wave Climate at the Jetties

The storm wave "climate" affecting each MCR jetty was estimated by synthesizing the offshore storm wave environment in terms of a series of observed wave events. Each offshore wave event was described in terms of a directional wave spectrum. A phased-average spectral wave model was used to transform the candidate offshore wave events to various locations along each jetty, for a range of water levels.

1. Selection of Offshore Wave Events

For this analysis, the candidate storm events were defined when the wave heights within each storm 'block' exceed a threshold (7.0 meters). The largest 84 storms on record were identified for the period spanning 1984 to 2008. A peak over threshold analysis determined that storms having wave height ≧ 7 meters occur 1-11 times per year, having a MLE (Maximum Likelihood Estimate) of 4.5 times per year. A peak over threshold analysis focuses the extremal analysis on only those events which cross the defined threshold. The re-occurrence for offshore wave height (Hsig) > 7 meters was emulated using a GEVD (Generalized Extreme Value Distribution) PDF. Years in which no extreme storm events were recorded were omitted from the PDF estimate. The reason for this is that some years did not include a complete data record for the year. An extreme storm still may have occurred that year, but was not recorded.

Out of a total of 84 candidate storms, a total of 52 peak wave height events were recorded in terms of reliable directional spectra (input used for modeling the transformation of offshore waves to the nearshore). Each spectrum was tagged to a specific modal wave height (Hmo), wave period (Tp), and wave direction (Dp). Figure A1- 71 summarizes the 52 selected storms. All events with a return period greater than 1-year were utilized. The buoy data was synthesized to produce a data-base of candidate storm wave events, used to emulate the annual offshore storm wave climate. Each candidate storm event was portrayed by an observed "real world" offshore directional wave spectrum, using the NDBC spectral amplitude and Fourier coefficients. Each directional wave spectrum (52 events) was described by a wave frequency range spanning 0.03 to 0.35 Hz (using a frequency increment of 0.01). Directional resolution of each wave spectrum was defined by 5-degree increments spanning 185 to 355 degrees AZ (TN). STWAVE [Smith et al 2001] was used to simulate the propagation of each candidate wave event, from the offshore observation point (NDBC buoy) to specific points along each jetty.

To account for the effect that water level can have on nearshore wave height, total nearshore water level was developed from a superposition of variably-correlated random components featuring tide, static storm surge, and infra-gravity transient. STWAVE simulations were performed for each offshore wave event using two nearshore storm-induced water levels: An extreme low (0.4 m MLLW), a median (8.5 ft), and extreme high water level (4.8 m MLLW) were used. The low water level (used for wave modeling) was based on: 10% annual exceedance for astronomical tide WSE = -2.7 ft NGVD + a value of 0 ft for static storm surge = 0 ft + a sub-annual exceedance for infragravity transient = 0.5 ft. The median water level is based on 50% annual exceedance of astronomical tide which is 4.5 ft NGVD, a sub-1 year value of static storm surge (2.5 ft) and a sub-one year value for infragravity surge (2 ft). The high water level (used for wave modeling) was based on: 90% annual exceedance for astronomical tide WSE = 3.4 ft NGVD + a 10-year value for static storm surge = 4.8 ft + a 2-year value for infragravity transient = 4 ft.

2. STWAVE - Wave Transformation Modeling

The wave environment incident *at* the MCR north and south jetties was estimated using a numerical model, STWAVE [Smith et al., 2001]. STWAVE (STeady-State spectral WAVE) is a computer model used to simulate the two-dimensional propagation of a wave field as it travels through winds and current, and encounters variable bathymetry. STWAVE simulates depth-induced wave refraction and shoaling, current-induced refraction and shoaling, depth- and steepness-induced wave breaking, wind-wave growth, wave-wave interaction, and white capping that redistribute and dissipate energy in a growing wave field [Smith et al., 2001]. STWAVE use the wave action conservation equation, solved in the frequency domain using phase averaging to simulate wave propagation. This means that STWAVE neglects changes in wave phase and superposition of waves having different phases is not performed; results for wave height (hmo at a specific x,y location) are phase averaged. Phase-averaging limits these models from directly solving for wave diffraction and reflection caused by bathymetric features and surface piercing structures. However, approximation methods have been incorporated into STWAVE to indirectly account for wave diffraction and reflection. STWAVE has been applied at various inlets in the Pacific northwest with excellent agreement between model results and prototype data. Refer to Smith et al. (2003) for additional details.

Applying STWAVE requires several steps: A) create the model's computational "domain" by adapting the bathymetry of interest to form a numerical grid, B) obtain directional wave spectra to "force" the offshore boundary of the STWAVE model, C) run the STWAVE model; the offshore wave data is transformed through the model domain to estimate the nearshore wave conditions throughout the domain and at specified points of interest, and D) post-process the STWAVE output, if needed.

3. Bathymetry

The bathymetry data used in any wave modeling effort is the primary factor that controls the accuracy and legitimacy of model output. Imposing the correct and best bathymetry is a necessary condition to achieve reliable wave model results. Strict attention to detail and much effort was expended to develop a bathymetry data set for use in the subject STWAVE model. Bathymetry for the area surrounding the MCR was compiled from different sets of survey data, based on the most recent and detailed surveys available. A composite bathymetry data set was produced from data collected using three different survey methods during 2003-2007 (as mentioned in Section 6(b)).

1. Conventional single beam fathometry was used to survey bathymetry within and outside the main inlet of the MCR. The conventional bathymetry survey was controlled using DGPS and NOAA tidal corrector.
2. Multi-beam fathometry was used to survey the submerged areas of the jetties. The multi-beam survey was controlled using RTK-DGPS.
3. Controlled aerial topographic mapping was used to survey the exposed (subareal) areas of the jetties. The aerial photography that was used for topographic mapping of the jetties was controlled using ground reference points with the aircraft camera being tracked using RTK-DGPS with an inertial measurement unit.

The average resolution for bathymetry surveys conducted within and outside the inlet was 70 m, having horizontal and vertical accuracy of ± 0.5 m and ± 0.3 m, respectively.

The bathymetry data was adapted to an STWAVE grid to form a highly resolved computational domain of 33 km x 37 km (offshore distance x alongshore distance). The cell size used to generate the STWAVE grid domain was 20 meters (making the STWAVE grid dimensions = 1650 cells x 1850 cells). The overall area for which STWAVE was applied, is shown in Figure A1- 70 and Figure A1- 80. The vertical datum of STWAVE bathymetry was based on NGVD.

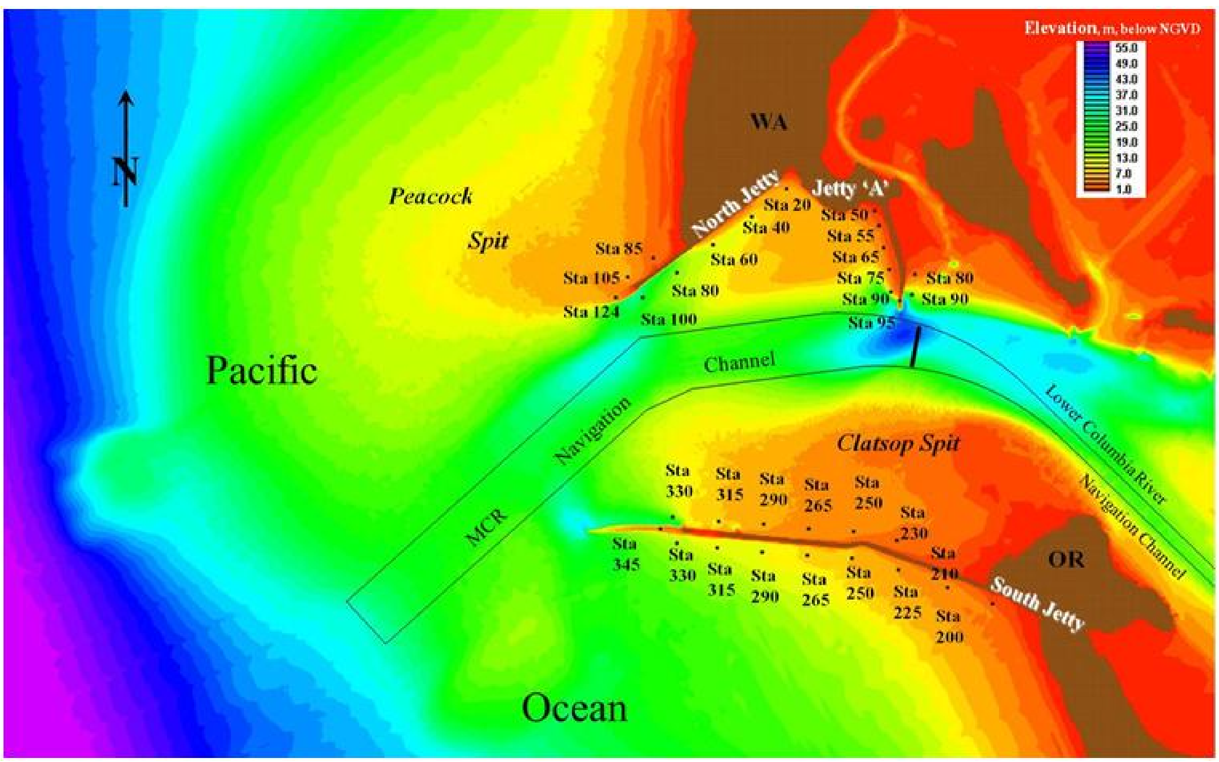

Figure A1- 80. Close-up View of MCR Bathymetry as Described in STWAVE Model

Area shown is 10 km (north-south) x 15 km (east-west). Distance between north and south jetties is 3 km. Survey data is a composite from 2003-2007. Figures A2- - show STWAVE results obtained for each of the 52 wave conditions. Figures A-10 & A-11 specify the wave height, at each of the "points" shown along the jetties, for the 52 storms modeled using STWAVE.

The markers shown in Figure A1- 80 (along the jetties) were used as "observation points" to record wave height output from each STWAVE run. Each observation point is 300-400 ft away from the jetty. Fifty-two (52) different STWAVE runs were made, each using a different offshore wave (boundary) condition and two water levels, as described above. The effect of current was not included in the STWAVE modeling. The presence of a strong ebb current (2 m/sec) can cause opposing waves with short period (less than 9 seconds) to increase in height, through steepening. However, large storm waves (design waves used for jetty design) have periods greater than 14 seconds, are depth limited at the MCR jetties, and are not susceptible to significant steepening in the presence of an ebb current of 2 m/sec. Ebb currents occur near the time of low point tide, which means that water depth is reduced, restricting depth-limited waves more than during a high-tide water elevation.

4. Offshore Wave Field - STWAVE Boundary Conditions

Fifty-two wave fields were selected to represent the range of storm wave conditions offshore of the MCR (Figure A1- 71). The wave fields were used to "force" the offshore boundary condition for the STWAVE model. The range in characteristics of wave energy (wave period, height and direction) that affects the MCR was included in the candidate wave fields. The intensity of modeled offshore wave conditions ranged from a 50-year wave (2% offshore wave event) to an event that occurs approximately 5 times, on average, every winter. Each selected wave condition represents a distinctive type of wave field as described by its directional spectrum (example shown in Figure A1- 81). Some of the candidate wave fields describe conditions that have been generated primarily by large storms far offshore, creating "swells" that come from a specific direction with high energy and low frequency. Other wave fields represent conditions that are dominated by locally generated "seas," waves with a larger range of frequency and direction. Most are a combination of these two sources, with varying degrees of influence from each. This diversity of storm characteristics in the different wave scenarios ensures that all wave events likely to occur at the MCR have been considered.

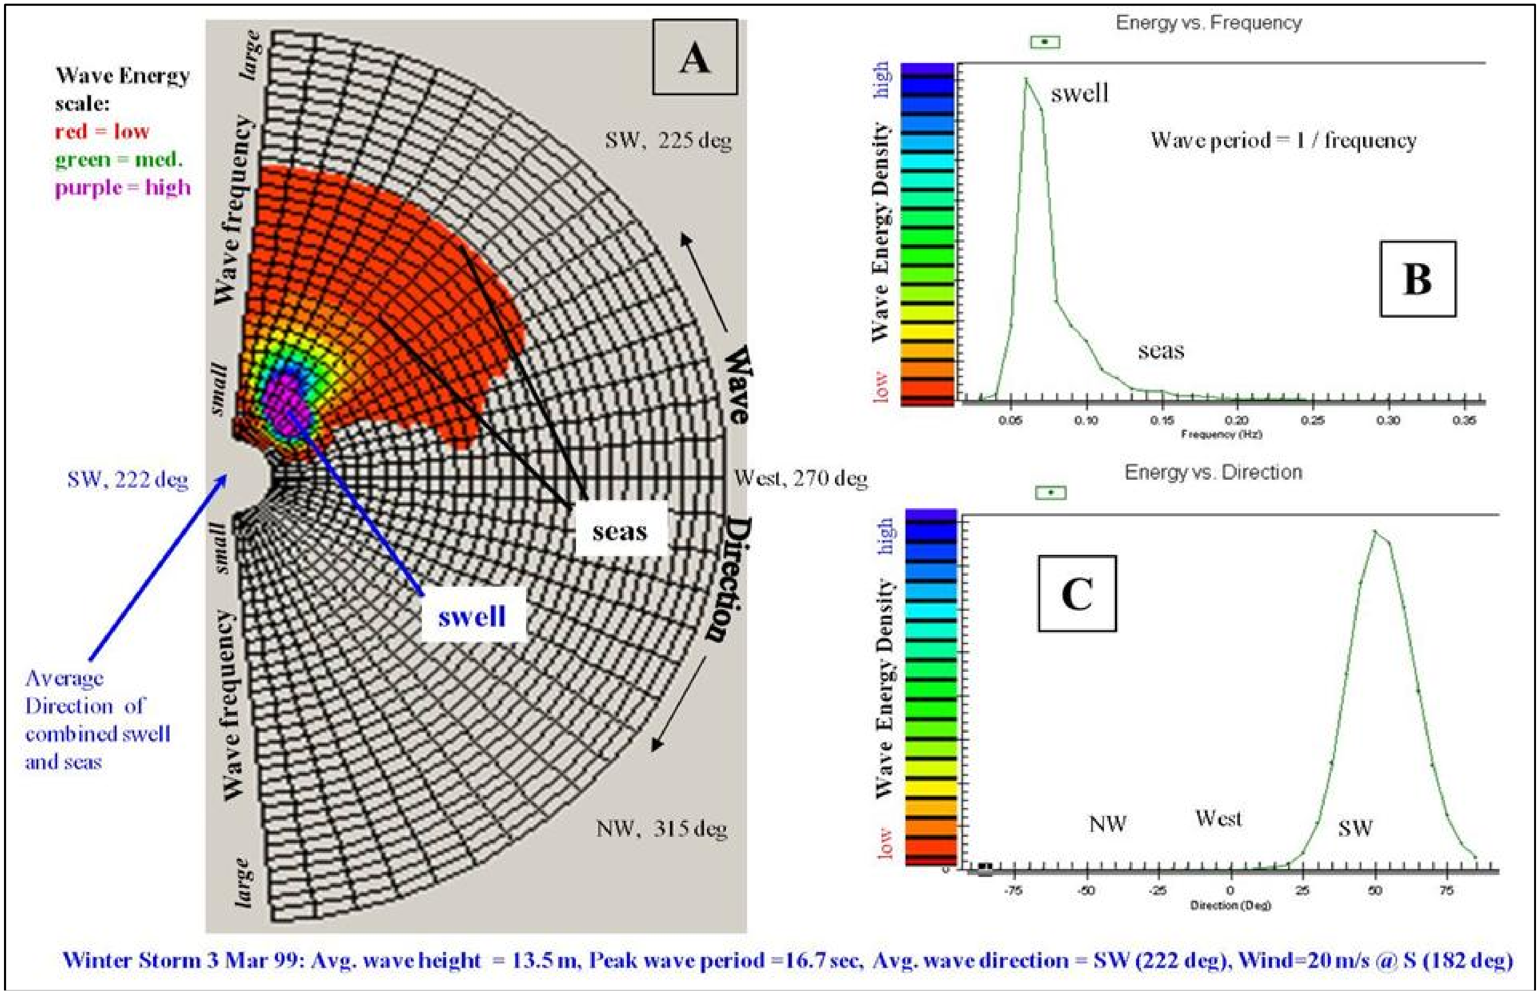

Figure A1- 81. Offshore energy spectrum for waves composed of swell and seas (NDBC 46029)

Graphic (A) shows the wave energy distribution in terms of wave direction and frequency. Graphic (B) is a x-section thru the areas of maximum energy, along the frequency axis in (A), to show where the most energy is in terms of frequency. Graphic (C) is an x-section thru the areas of maximum energy, along the direction axis in (A), to show where the most energy is in terms of wave direction. The wave field is dominated by swell within a narrow frequency range (wave period = 15-20 seconds) from the Southwest.

5. STWAVE Results

STWAVE transformed each offshore wave field (boundary condition) through the model domain, to generate nearshore wave conditions based on the bathymetry and water level that was imposed within the model. The computed nearshore wave environment is a function of the offshore wave boundary condition and bathymetry within the model domain. It must be emphasized that the wave conditions inshore (say at a water depth of 60 ft) are not the same as offshore (200 ft) due to wave shoaling, wave-wave interaction, wind and wave interaction, and wave breaking. The 10-year wave height incident at a specific jetty location may conform to a sub-annual offshore wave event. This is the case in reality and it is also simulated by STWAVE. In some cases, the wave height along specific areas of the MCR jetties is depth limited, especially for low storm event water levels. Wave height provided by STWAVE is Hmo (wave height at the peak of the spectral density), whereas the wave height normally used in design of coastal infrastructure is Hs (average of the highest 1/3 wave heights). Several post-processing steps were applied to reconcile Hmo to Hs. At each of the STWAVE observation points (32), the local wave conditions (zero-eth moment wave height, H_{mo}, peak wave period, T_p, wave direction and wave breaking index) were extracted from the STWAVE output. The wave breaking index determines if a wave is breaking based on the following wave steepness computation:

$$H_{mo_{max}} = 0.1L\tanh(kd) \qquad [1]$$

where L is the wavelength, k is the wave number and d is the water depth at that location and accounts for water level variations.

Additional processing of the data yielded the significant wave height, H_s, and the depth limited breaking wave height, H_b. The significant wave height is the average of the largest 1/3 waves observed at a location. The depth limited breaking wave height is a function of the water depth, typically presented as $H_b = \gamma * d$, where γ can vary, but is 0.78 in this analysis. A value for γ of 0.78 is typically used for long, mild slope beaches. The final wave heights selected from this analysis, H_{final}, were chosen from H_{mo}, H_s and H_b. This was a two-step process. First, if the wave was determined to be breaking using the STWAVE criteria, then $H_{final} = H_{mo}$ for that wave case and location. Second, if the wave was not breaking, then H_s was computed from H_{mo} using equation 2:

$$e^{0.00136\left(\frac{d}{9.8/Tp^2}\right)^{-0.834}} \qquad [2]$$

H_s was further examined to ensure that it did not exceed H_b at that location. In this situation, H_{final} = minimum $[H_s, H_b]$. The H_{final} wave heights were ranked in ascending order and probability of non-exceedance plots were produced for each side of each jetty, for a total of six probability plots.

Example results of nearshore computed wave height estimates are shown Figure A1- 82(A) and (B). Note the protected areas on Clatsop Spit, in the lee of the South Jetty during southerly storm wave events. The opposite is true for waves approaching from the NNW. The windward areas along the South Jetty are subject to larger incident waves. The situation along the North Jetty (south side) is more complex due to the local bathymetry of the inlet. Peacock Spit protects the northern half of MCR from significant nearshore wave activity by causing waves to break before making landfall, during large offshore wave events. During events when offshore wave action is less severe, Peacock Spit causes waves to shoal and grow as they approach landfall. Depending upon the wave direction and period (and location at the MCR), there can be times when a "lesser" offshore wave condition can produce larger nearshore waves than a severe offshore wave condition. This is the reason for a detailed wave transformation model (like STWAVE) using a variety of offshore wave conditions when trying to define design wave conditions nearshore (incident to the jetties).

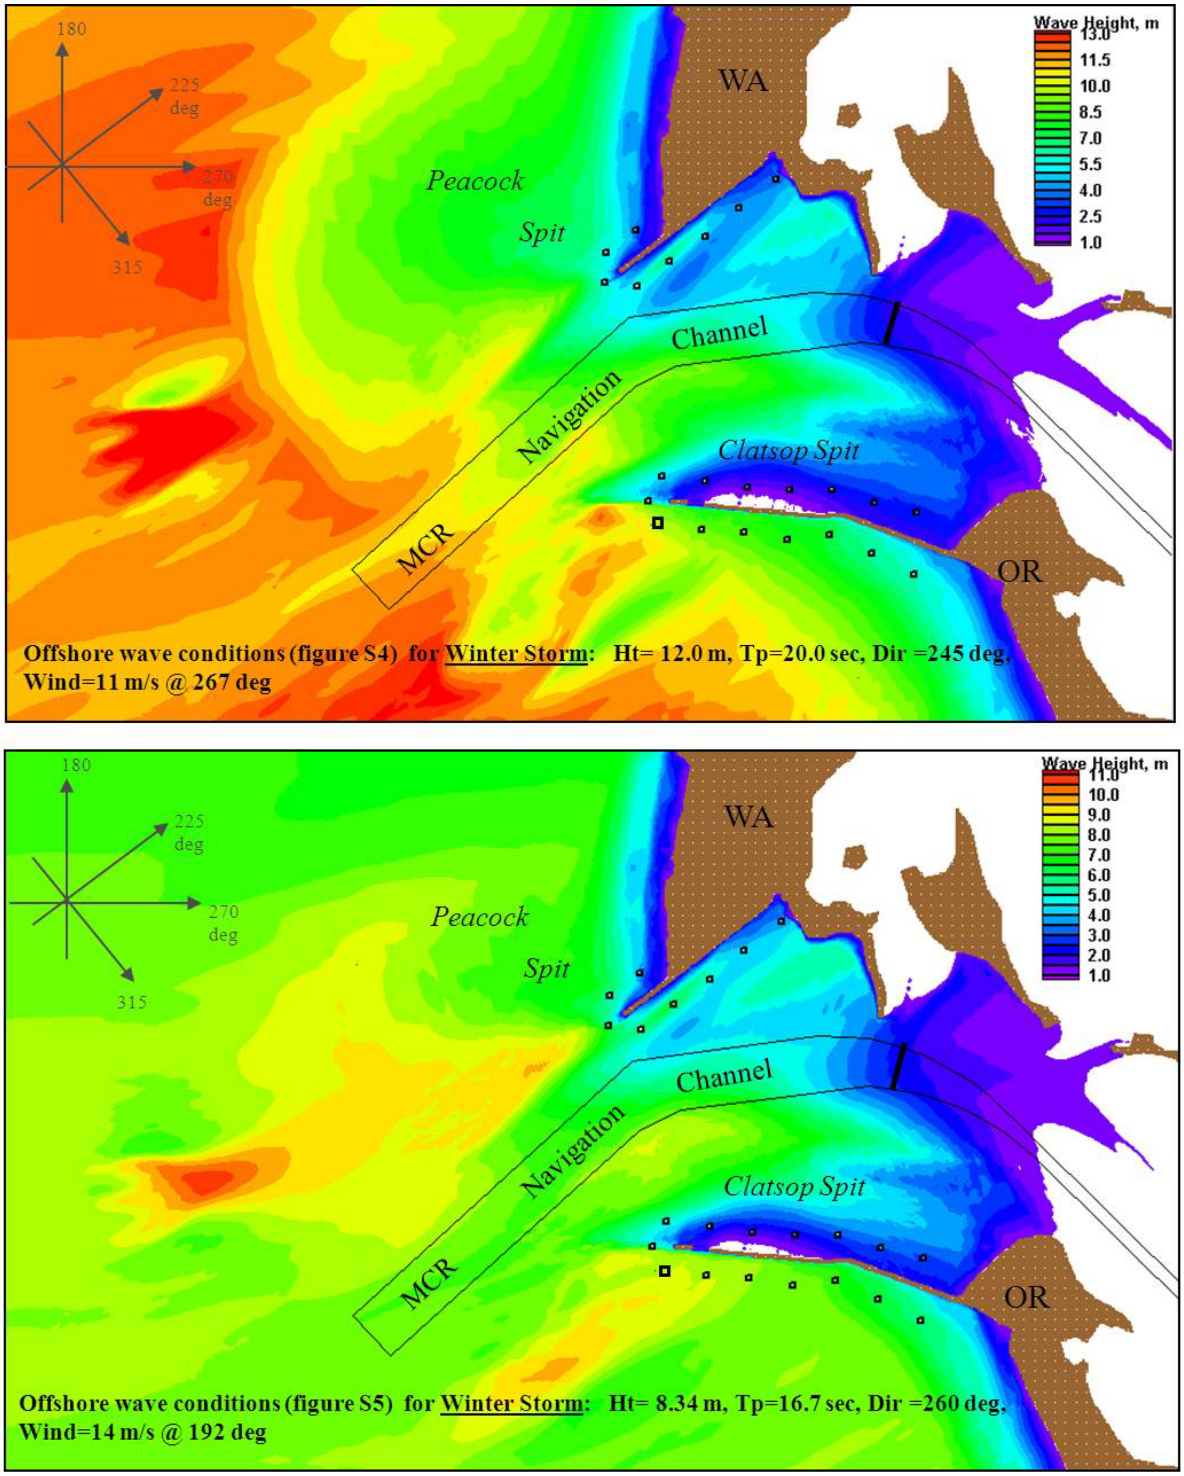

Figure A1- 82. STWAVE Model Simulation of Nearshore Wave Height at MCR for 2 of the 52 Wave Events

Note depth limitation (by breaking) of waves offshore Peacock Spit and south of south jetty. North side of south jetty is protected large swells

d. Summary of Wave Environment Estimated for MCR Jetties

STWAVE-based estimates for wave height were made for each of the 32 observation points located along the North and South jetties for each of the 52 offshore wave conditions and three water levels. Rather than presenting meaningless and confounding tabular results, the results for each observation point were rank-ordered and presented in terms of a cumulative distribution (Figure A1- 83 through Figure A1- 88). The cumulative distribution allows one to view the data in terms of a percent exceedance reference. Design values for nearshore wave height can be selected, in the same manner as offshore waves can be selected. Recall that the 52 offshore wave boundary conditions included a range between a 25-year event and sub-annual (<1-year) event, and that the expected life-cycle for interim repairs is 10-25 years. The design wave heights along each jetty (to be used for calculating armor stone sizes for future repairs) were selected based on the 0.7 to 0.9 value of exceedance (cumulative distribution). Rehabilitation elements affected by incident wave height were designed using a CD (Cumulative Distribution) of 1.0. Results are shown in Table A1- 4.

e. Life-Cycle Simulation of Annualized Wave and Water Level Environment

Stochastic Risk-based (SRB) life-cycle modeling was performed for each jetty, as described in Appendix A2. The SRB model utilized STWAVE results as summarized here. For each storm event within a given simulation year, the SRB model uses appropriate PDFs to generate random estimates for offshore wave height, period, and direction. A best match realization is selected from the data-base of candidate storms. The nearshore transformations of offshore candidate storms to the jetties were performed a priori for extreme high, median, and low total water levels. The SRB model applies appropriate water level components PDFs to generate a randomized total nearshore water level which is associated with the realized storm event. The event-based water level is used to interpolate from within the range of STWAVE solutions for extreme water levels associated with candidate storm. This series of steps produces the combined wave and water level environment along the jetty for a given storm event. The calculated storm wave environment along the jetty is modified based upon the present morphological stage within the jetty life-cycle being simulated. The wave event is used to estimate jetty damage by accessing the appropriate damage function and reliability is calculated. This process is repeated for each storm event within a given year. Recall, that there can be 1 to 11 storm events randomly occurring per year. The above stochastic approach accounts for variation of: A) annual storm climate (numbers of storms per year), B) individual storm wave parameters (height, direction, period), C) the superposition of water level components (tide, storm surge, and infra-gravity transients), and D) the evolving morphological stage of the inlet which was estimated using historical bathymetry data.

8. Engineering Considerations

a. General

The engineering analysis of the rehabilitation plans covered two primary areas: (1) jetty cross section repair, and (2) engineering features which addressed larger process deterioration of the structures. Tools used for design analysis in this study included historical performance at the MCR, other case studies, 2-dimensional physical modeling, and hydrodynamic numerical modeling. The South Jetty and Jetty A were evaluated for cross section repair options, spur groins to reduce jetty scour, and jetty head reconstruction as shown in Figure A1- 89 and Figure A1- 90. The North Jetty was evaluated for cross section repair options, spur groins to reduce jetty scour, stabilization of backfill area along the jetty root and jetty head reconstruction as shown in Figure A1- 90.

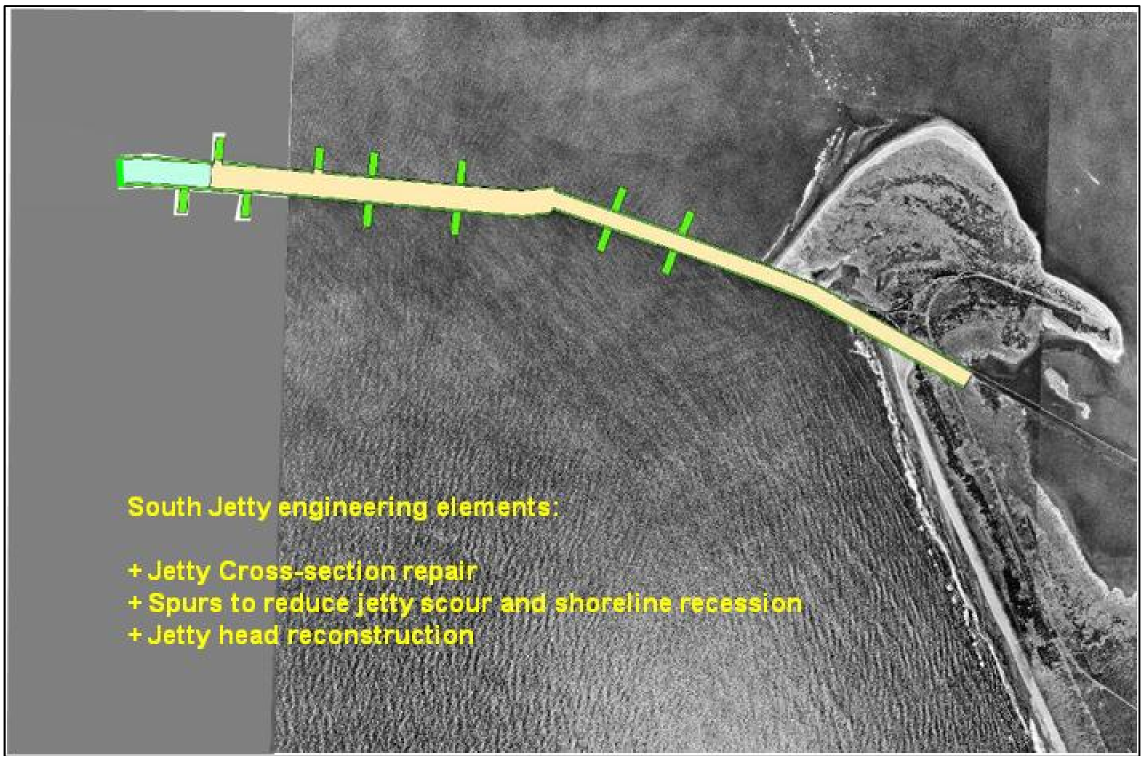

Figure A1- 89. South Jetty Life Cycle Engineering Elements

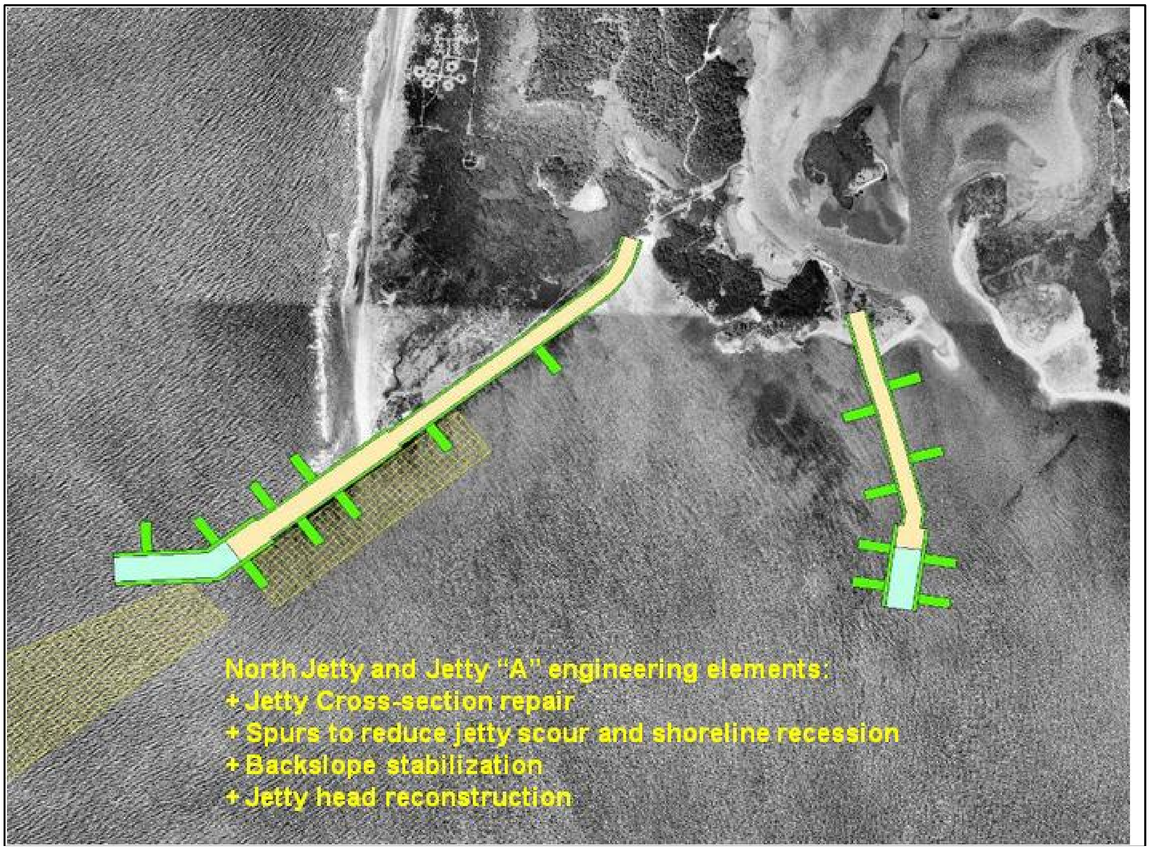

Figure A1- 90. North Jetty and Jetty A Engineering Elements

Jetty structure reliability can be separated into above and below water areas controlled essentially by wave-driven and erosion-driven processes. An effective and long term rehabilitation effort needs to address both sets of damage processes.

b. General Failure Modes for Jetties

Structural performance modes for a rubblemound jetty can be characterized in terms of its ability to: A) remain stable during wave attack (dynamic stability), and B) maintain a stable footprint/slope configuration on the seabed foundation (static stability). These performance modes are described below and shown conceptually, as failure modes, in Figure A1- 91.

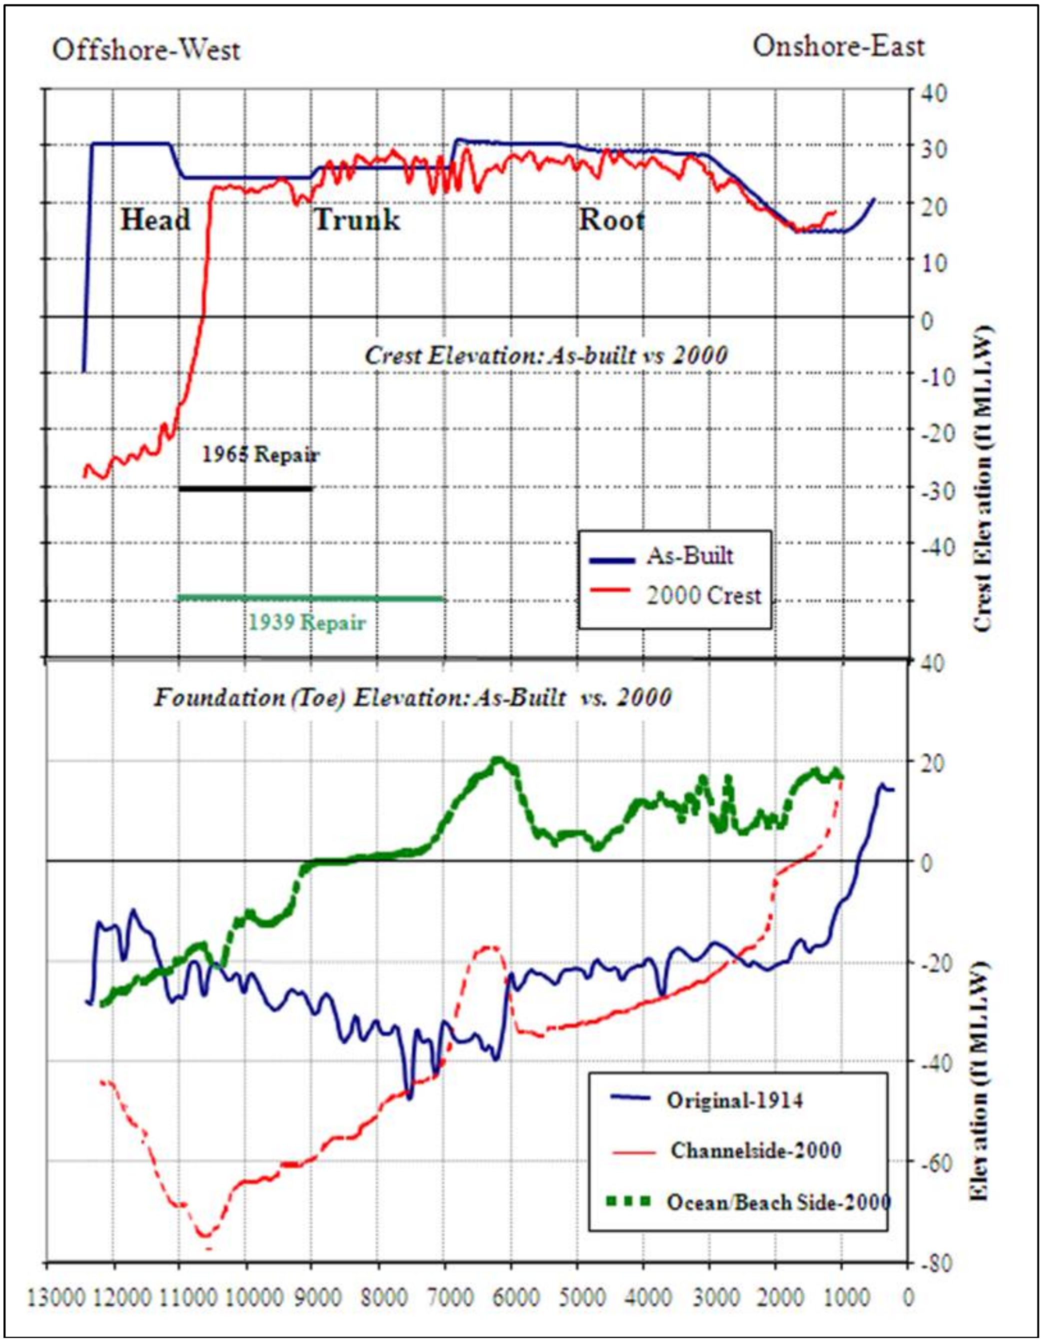

Figure A1- 91. Structural Performance Modes for Jetties at MCR

Dynamic Stability. This affects the upper part of a jetty cross-section as a result of wave action, generally from -5 ft MLLW up to the jetty crest, on the ocean side and channel side of a jetty. On the side of the jetty directly exposed to ocean waves, dynamic stability is manifest by the direct impact of waves on the jetty and the resultant displacement of individual armor units. On the lee side of the jetty, dynamic stability addresses the effect of waves overtopping the jetty crest and displacing armor units down slope, off of the jetty cross-section.

Static Stability. This affects the lower part of the jetty cross-section, generally below -5 ft MLLW, on the ocean side and channel side of the jetty. Static stability addresses the susceptibility of the jetty toe to wave-current scour, and resistance of the jetty slope to sliding down grade along a slip-plane. Damage due to static stability issues propagates up-slope to affect the upper region of the jetty cross-section.

c. Delineation of Structure Design Reaches

Utilizing the design climate for each structure, the existing condition of each structure, as well as the identified potential process impacts along each jetty length, key design reaches are outlined as shown in Figure A1- 92 and Figure A1- 93 and Table A1- 5 for the North Jetty. South Jetty is illustrated in Figure A1- 94 and Figure A1- 95 and Table A1- 6. Jetty A is shown in Figure A1- 96 and Figure A1- 97 and Table A1- 7. The design parameters provided in Table A1- 5 through Table A1- 7 are for existing conditions only. These parameters will change in the future based on progressive morphological changes and damage to the jetties. Basic categories of design concern can be grouped in the following categories:

- Frontslope wave attack
- Backslope overtopping wave attack
- Foundation loss
- Adjacent shoreline recession
- Backside foundation loss.

Table A1- 5. North Jetty Design Input Parameters

Station	Crest Elevation	Crest Width	Design Wave Height Ocean	Design Wave Height Channel	Depth at Toe Ocean	Depth at Toe Channel	Design Issue
	(ft, MLLW)	(ft)	(ft)	(ft)	(ft, MLLW)	(ft, MLLW)	
10 to 40	15 to 25	10 to 30	0	10 to 14	+4 to +15	-10 to -20	Minor frontslope wave attack (1) Backside foundation
40 to 60	20 to 27	10 to 30	0	14 to 17	+3 to +11	-9 to -13	Moderate frontslope wave attack (1) Overtopping (1) Backside foundation
60 to 80	20 to 25	20 to 35	5 to 21	17 to 18	-1 to +15	-15 to -55	Moderate frontslope wave attack (2) Overtopping (2) Foundation loss (1) Shore erosion
80 to 100	17 to 25	10 to 40	21 to 25	18 to 20	-2 to -15	-55 to -65	Extreme frontslope wave attack (2) Heavy overtopping (2) Foundation loss (1)
Head	19 to 20	15 to 40	26	20	-10 to -17	-65 to -75	Extreme frontslope wave attack (3) Heavy overtopping (3) Foundation loss (3)

Note: These design input parameters are valid only for the existing condition.

1. North Jetty Design Reaches

The North Jetty is divided into 5 reaches. Half of the jetty is backed by accreted land on the north side. The seaward half of the jetty, while it does not have land behind it, is backed by the substantial underwater shoal in the form of Peacock Spit. The North Jetty as well as its significant submerged jetty head functions to hold back this significant shoal from the navigation channel. These features can be clearly seen in Figure A1- 93. Benson Beach is located on the north side of the jetty at the transition between above and below water features of the spit. Also visible on Figure A1- 93 are the deepening contours on the channelside of the jetty. Figure A1- 98 illustrates crest and foundation changes over time along the North Jetty. Figure A1- 99 through Figure A1- 107 show pictures of the different reaches of the North Jetty and Figure A1- 108 through Figure A1- 111 illustrate the respective cross sections.

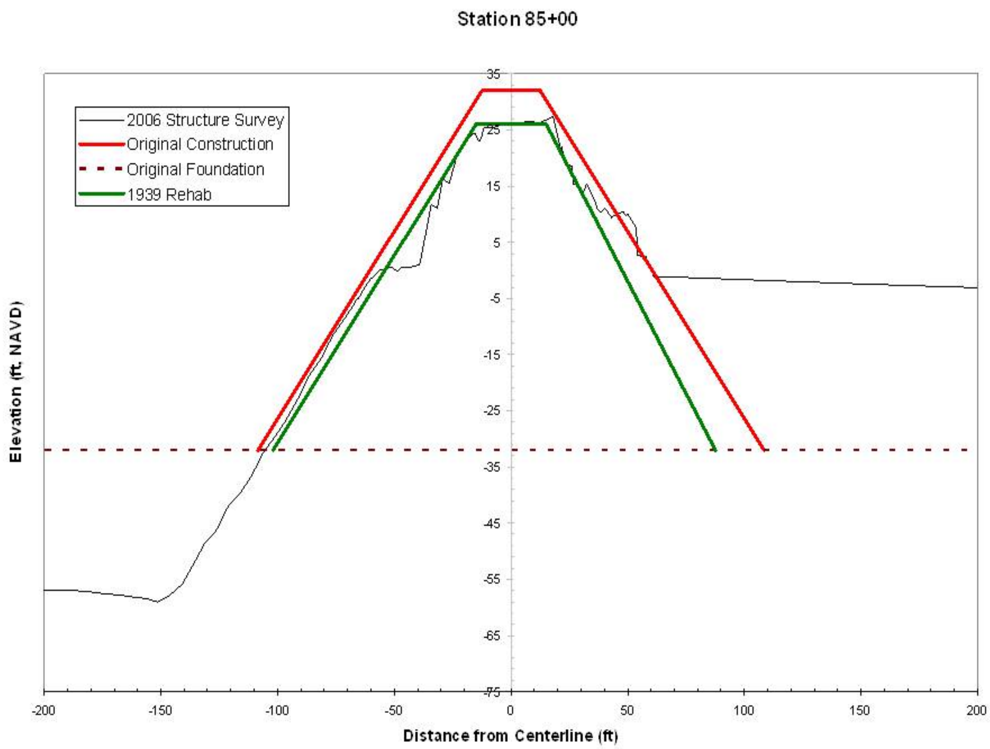

Figure A1- 110. North Jetty Cross Section Templates - Trunk

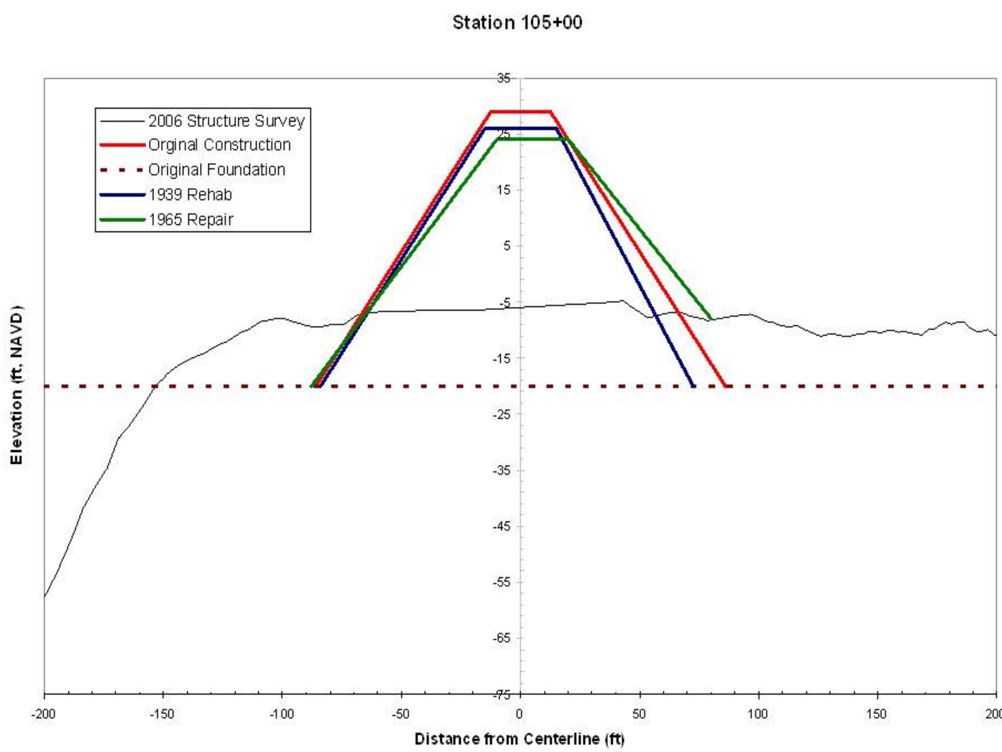

Figure A1- 111. North Jetty Cross Section Templates - Head

The most landward design reach for the North Jetty extends from Station 10 to Station 40 (Figure A1- 112). Depths noted in the table include depths at the toe of the jetty as well as depths at 400 ft away from the jetty, which is representative of the design wave height measurements. Foundation depths along this reach range from -10 to -20 on the channelside and +4 to +15 on the land side. The maximum channelside wave height is projected to be approximately 14 ft and the oceanside of the jetty is protected from wave attack. An eroded area on the backside of the jetty root has developed over time produced by a combination of overland flow channeled toward the jetty as well as tidal flow through the deteriorated jetty structure. This portion of the jetty has never been repaired since its original construction in 1917 (92 years) and it currently exists in a much deteriorated condition. Crest elevations range from +15 to +25 ft with crest widths of 10 to 30 ft wide. The jetty in this reach is in a jumbled state with little rock to rock interlocking as evidenced by the tidal flow allowed through the structure. Primary design issues for this reach are just basic need for structure repair as well as backside undermining of foundation.

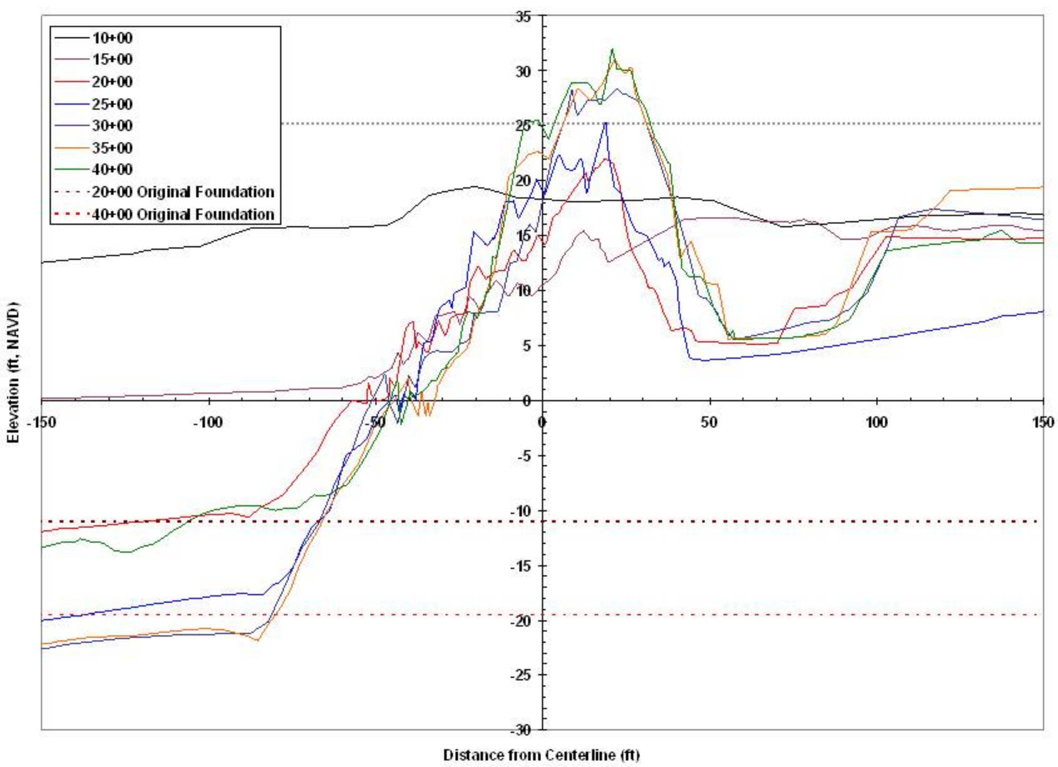

Figure A1- 112. North Jetty – Reach 1

The second design reach extends from Station 40 to Station 60 and, except for 500 ft repaired in the 2005 Interim Repair effort, also has never been repaired since 1917 (Figure A1- 113). Foundation depths range from -9 to -13 ft, MLLW on the channelside and +3 to +11 on the land side. Design wave heights are expected to range from 14 to 17 ft on the channelside. The ocean or north side is protected by land. This reach is also impacted by the hydraulic flow through the jetty to the eroded area behind the jetty. Some wave overtopping may occur in this reach, however, it is not expected to be significant. Primary design issues for this reach are just basic need for structure repair as well as backside undermining of foundation.

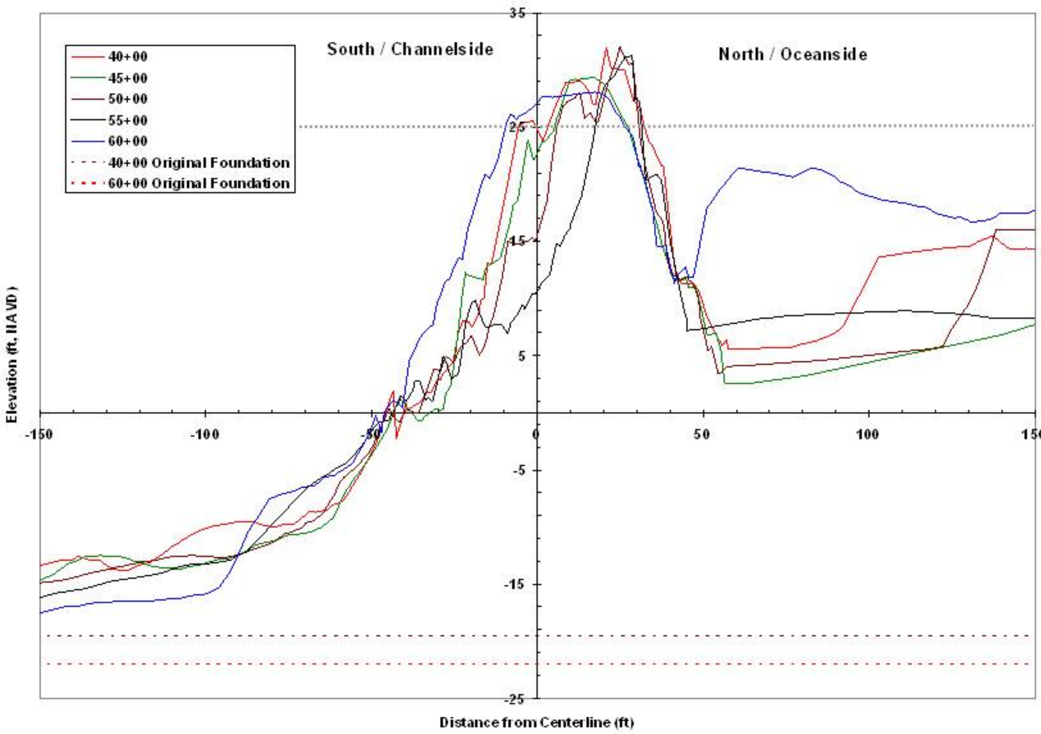

Figure A1- 113. North Jetty – Reach 2

The third design reach extends from Station 60 to Station 80 (Figure A1- 114). Channelside foundation depths increase along this reach (-15 ft to -55 ft, MLLW) impacting the static stability of the entire cross section. On the north side, foundation depths range from -1 to +15 ft, MLLW. This reach extends into the portion of the structure which is exposed to both channelside as well as oceanside wave attack, though the oceanside attack is significantly reduced by the presence of Peacock Spit. Oceanside design wave heights are expected to range from 5 to 21 ft and channelside design wave heights are expected to range from 17 to 18 ft. An additional concern in this reach is the progressive recession of the shoreline which results in increased exposure of the deteriorated jetty root structure as well as increasing the likelihood of hydraulic flow path connection of the ocean wave/surge processes with the tidal flow area which parallels the jetty root. This reach of jetty was recently addressed in the 2005 Interim Repair action which provided some additional short-term stability to the reach. Crest elevations and crest widths achieved during that repair action were +25 ft and 30 ft wide.

Design issues for this reach include moderate wave attack and overtopping, foundation loss and instability, and shoreline recession on the north side.

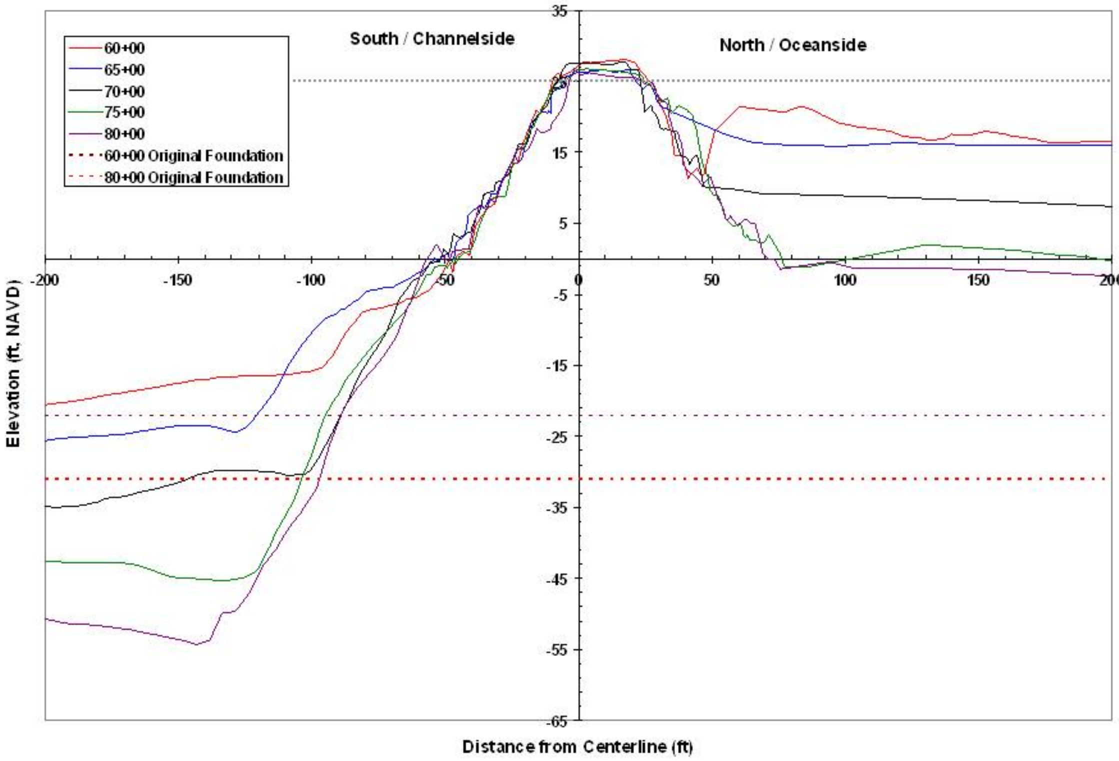

Figure A1- 114. North Jetty – Reach 3

The fourth design reach extends from Station 80 to 100 and represents the most vulnerable reach of the North Jetty at this time, primarily due to its high level of exposure to wave attack from both the oceanside and the channelside (Figure A1- 115). Design wave heights are expected to range from 21 to 25 ft on the oceanside and 18 to 20 ft on the channelside. Both sides of the jetty are exposed to frontslope wave attack as well as significant overtopping forces. Partial repairs were conducted to Station 85 during the Interim Repair effort although this work was not the full Interim Repair section. The last repair conducted in this reach was in 1964, 45 years ago. Crest elevations range from 17 to 25 ft and crest widths range from 10 to 40. Foundation depths along the channelside are significant ranging from -65 ft to -75 ft, MLLW. Scour and upslope stabilization of the cross section are concerns. Primary design issues for this reach include extreme wave attack and overtopping from 2 directions as well as foundation loss.

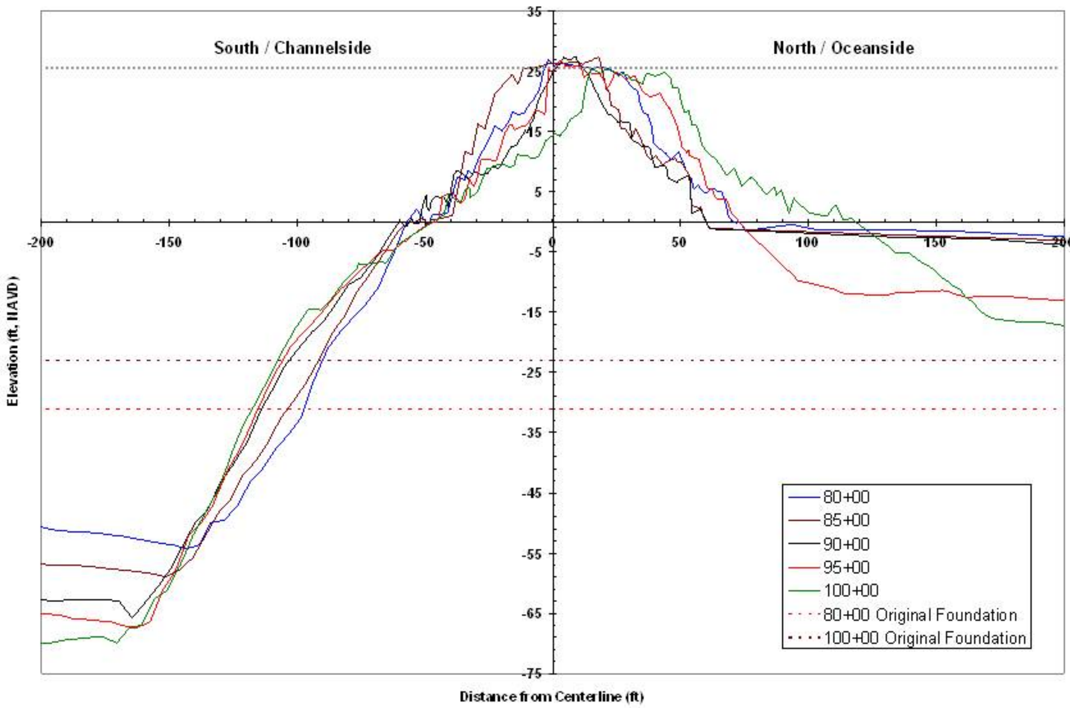

Figure A1- 115. North Jetty – Reach 4

The final design reach on the North Jetty extends from Station 100 to the reconstructed head position, expected to be constructed around Station 103 (Figure A1- 116). Wave exposure on this jetty feature is extreme since it is exposed to 3 different directions of frontslope wave attack and overtopping. Design wave heights are estimated to range from 20 to 26 ft. Foundation depths on the channelside are severe (around -70 ft) and the design of the jetty head stabilization is tailored to be constructed on top of the relic stone base of the existing jetty. Primary design issues for this reach include extreme wave attack and overtopping from 3 directions as well as foundation loss.

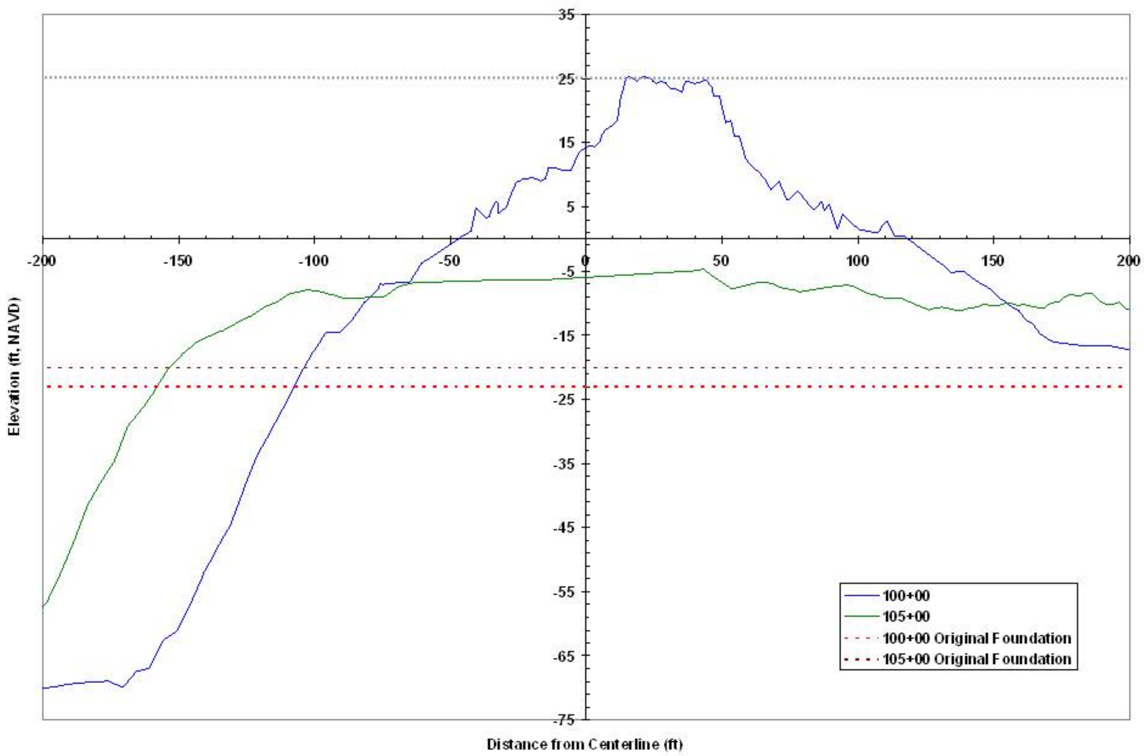

Figure A1- 116. North Jetty – Reach 5

2. South Jetty Design Reaches

The South Jetty is divided into six reaches and is shown in Figure A1- 117 and Figure A1- 118 and Table A1- 6. The design parameters provided in Table A1- 6 are valid only for the existing condition. These parameters will change in the future due to morphological changes and future damage to the South Jetty. Only the first reach of the South Jetty is backed by above water accreted land. The remainder of the structure is exposed to environmental forces from both sides of the structure. The significant underwater shoal on the north side of the South Jetty provides protection both in terms of foundation stabilization as well as reduced wave height exposure. Although the South Jetty extends out into fairly deep water depths, the portion being proposed for this rehabilitation effort is located shoreward of the greatest water depths. Figure A1- 119 illustrates crest and foundation changes over time along the South Jetty. Figure A1- 120 through Figure A1- 129 show pictures of the different reaches of the South Jetty and figures Figure A1- 130 through Figure A1- 133 illustrate the respective cross sections.

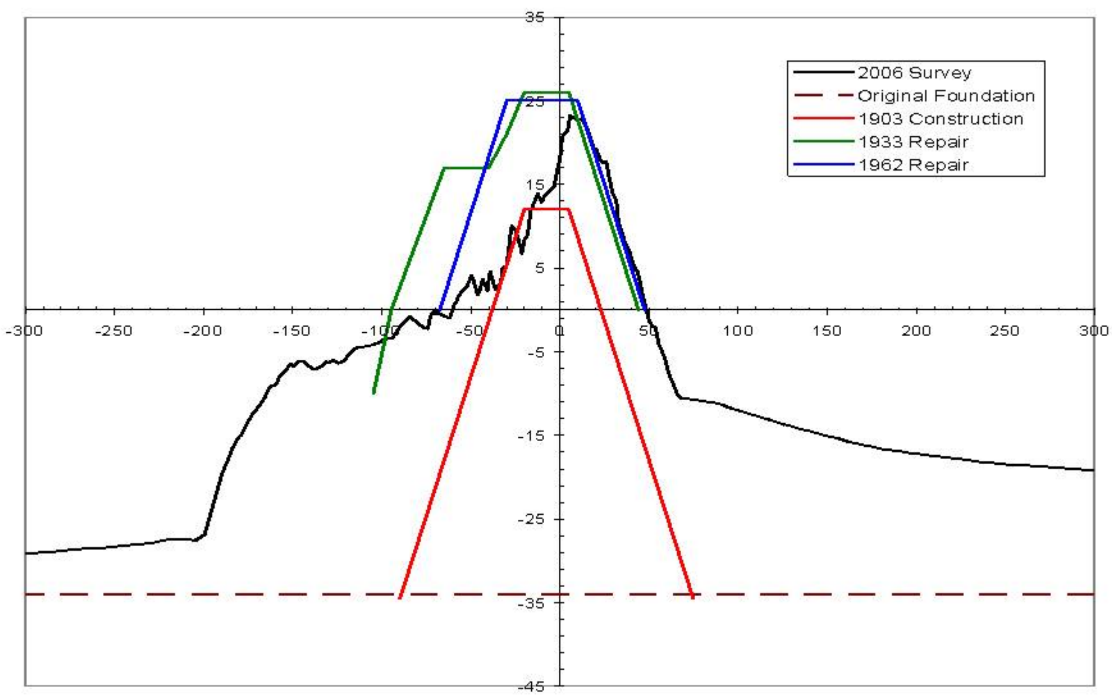

Figure A1- 131. South Jetty Cross Section Templates - Trunk

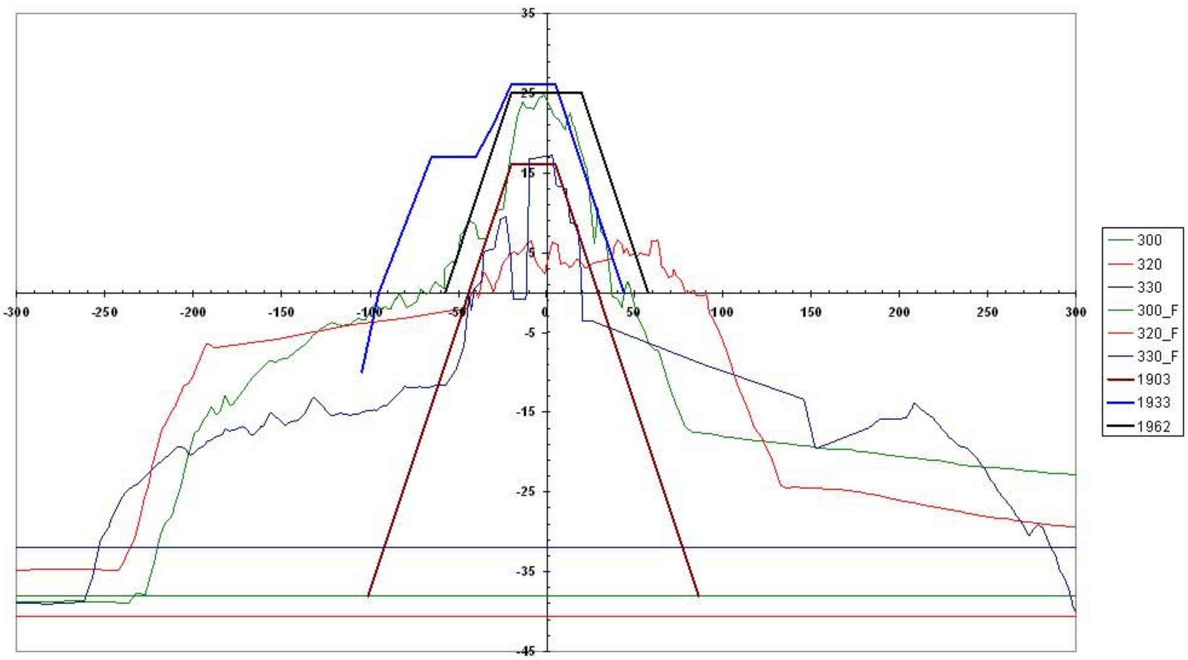

Figure A1- 132. South Jetty Cross Section Templates –Seaward Trunk

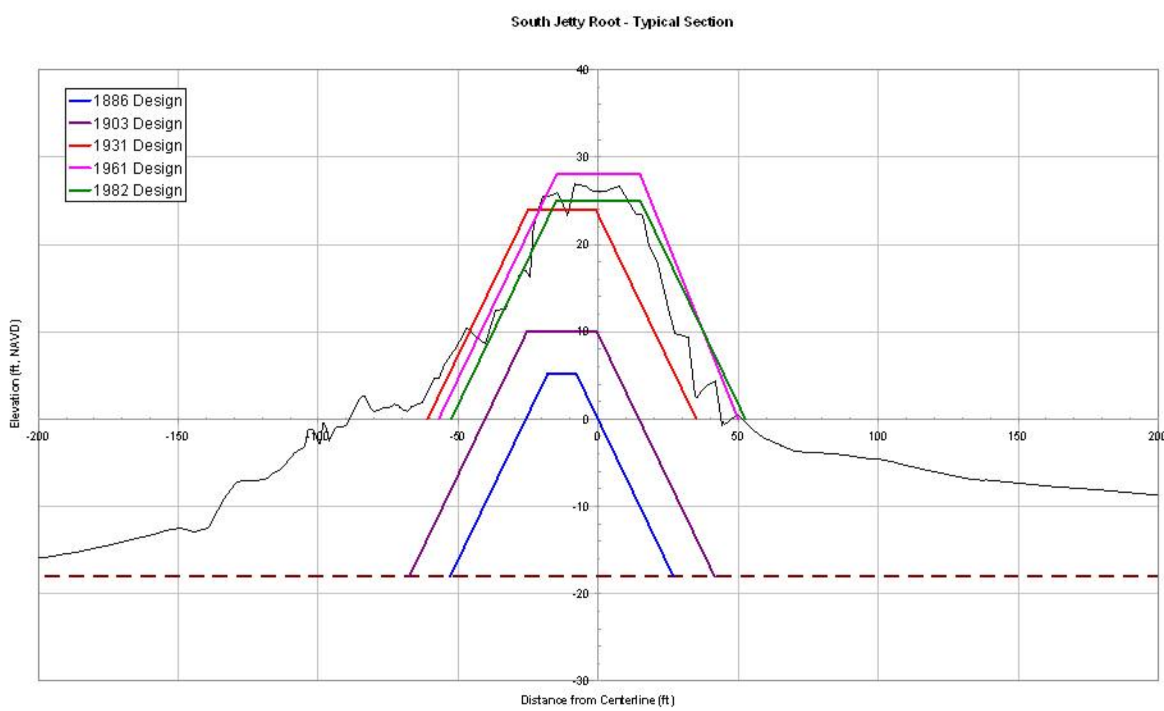

Figure A1- 133. South Jetty Cross Section Templates - Head

The first reach of the South Jetty extends from Station 155 to Station 190 with the northern side of this reach backed by accreted land (Figure A1- 134). A portion of this reach of the

South Jetty has never been repaired since original construction in 1886, 123 years. Foundation depths on the south side of the jetty range from -2 to -15. The shoreline adjacent to the south side of the jetty root has been experiencing successive erosion eastward toward the old jetty root structure. Figure A1- 120 ad Figure A1- 121 show the proximity of the shoreline to Trestle Bay which is on the eastern side of the spit. Action is being taken separate from the rehabilitation study to add sediment to this reach of shoreline. Design wave heights incident to the south side of the structure range from 10 to 16 ft. The crest elevation and crest width along this reach range from 13 to 20 ft and 4 to 20 ft, respectively. Primary design issues for this reach are just basic need for structure repair as well as shoreline erosion eastward.

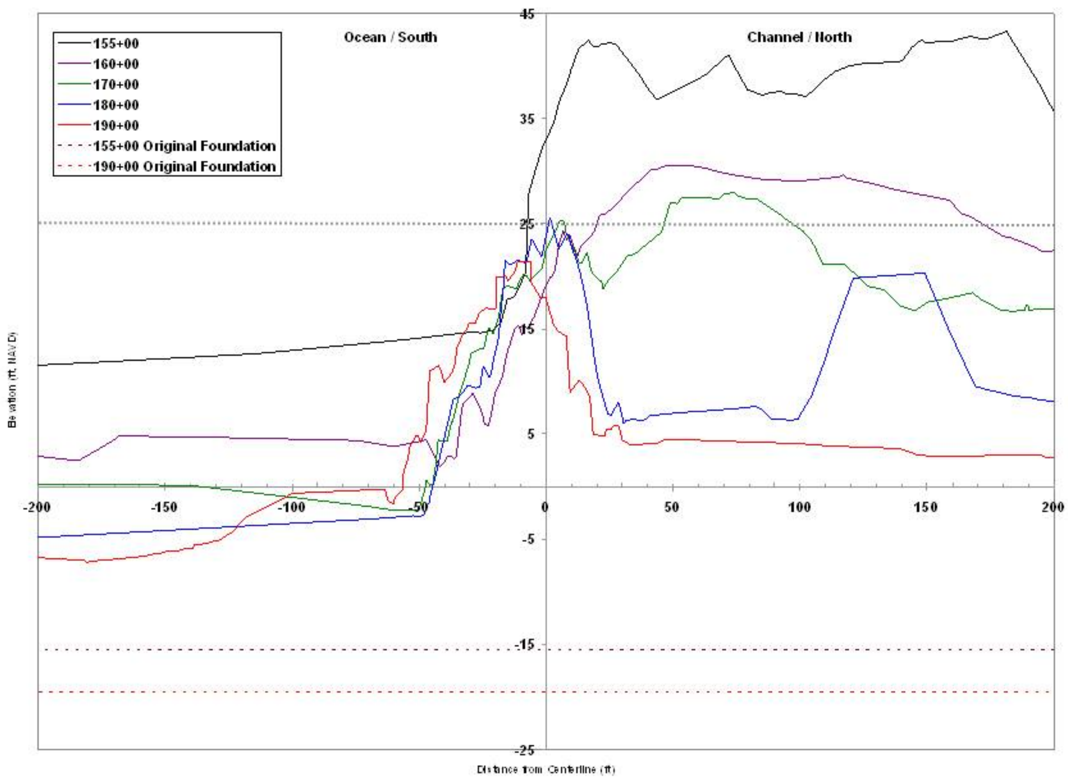

Figure A1- 134. South Jetty – Reach 1

Table A1- 6. South Jetty Design Input Parameters

Station	Crest Elevation	Crest Width	Design Wave Height		Depth at Toe		Design Issue
			Ocean	Channel	Ocean	Channel	
	(ft, MLLW)	(ft)	(ft)	(ft)	(ft, MLLW)	(ft, MLLW)	
155 to 190	13 to 20	4 to 20	10 to 16	0	-2 to +15	+4 to +37	Minor frontslope wave attack (1) Minor overtopping (1) Shore erosion
190 to 220	14 to 25	4 to 37	16 to 25	16 to 18	-2 to -10	-4 to +4	Moderate frontslope wave attack (1) Overtopping (1) Shore erosion
220 to 250	20 to 25	20 to 30	25 to 32	18 to 20	-10 to -22	-5 to -8	Moderate fronslope wave attack (1) Overtopping (1) Foundation loss (1)
250 to 280	20 to 25	25 to 40	32 to 35	20 to 21	-23 to -32	-8 to -15	Extreme frontslope wave attack (2) Heavy overtopping (2) Foundation loss (2)
280 to 310	15 to 25	14 to 40	35 to 36	20 to 21	-32 to -39	-15 to -22	Extreme frontslope wave attack (2) Heavy overtopping (2) Foundation loss (2)
Head	7 to 20	6 to 30	36	21	-33 to -39	-23 to -30	Extreme frontslope wave attack (3) Heavy overtopping (3) Foundation loss (3)

The second reach of the South Jetty extends from Station 190 to Station 220 (Figure A1- 135). This reach is exposed to moderate wave attack from the south side (16 to 25 ft) and minor wave attack from the north side (16 to 18 ft). On the north side or channelside of the structure, the subaerial part of Clatsop Spit is receding eastward exposing more of the older jetty. Foundation depths along this reach vary from -10 to -2 on the seaside and -4 to +4 on the channelside. Existing crest elevation and crest width along this reach vary from 14 to 25 ft and 4 to 37 ft, respectively. Primary design issues along this reach include the shore erosion on the north side and basic need for repair.

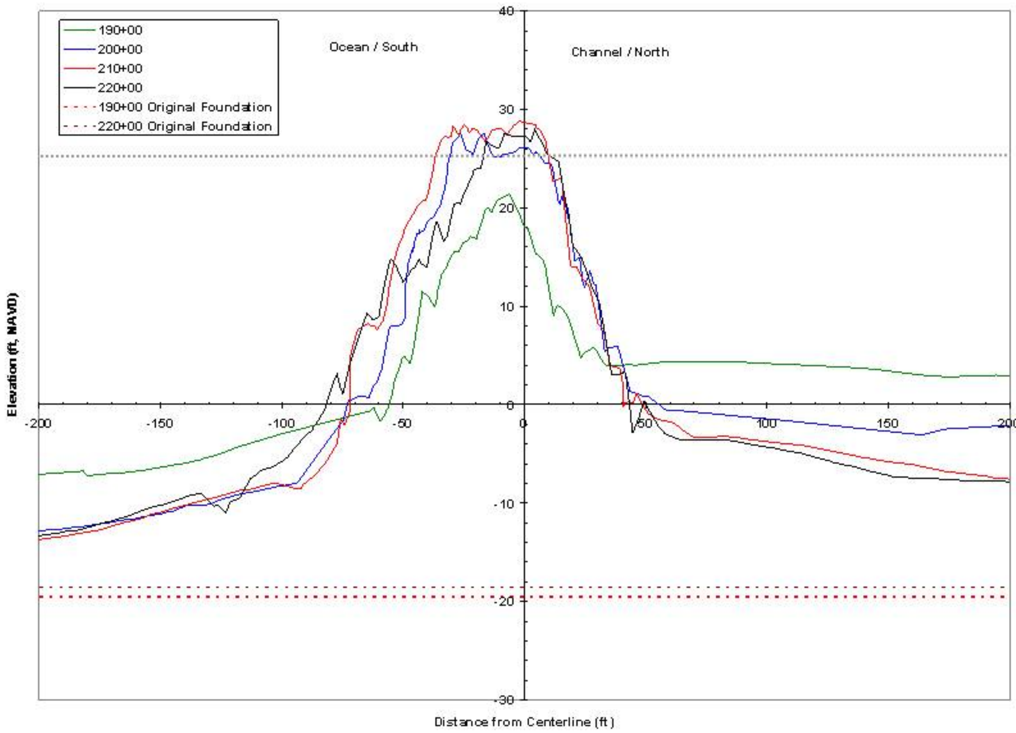

Figure A1- 135. South Jetty – Reach 2

The third reach of the South Jetty extends from Station 220 to Station 250 (Figure A1- 136). The majority of this reach (224 to 245) was addressed with an Interim Repair in 2006. This reach is exposed to design waves of 25 to 32 ft from the oceanside and 18 to 20 ft from the channelside. Existing crest elevations and crest widths are controlled by the most recent Interim Repair effort, 20 to 25 ft elevation and 20 to 30 ft crest widths. This reach of jetty has been repaired 3 times during its lifetime, two of those times to prevent a complete breach of the jetty. Foundation elevations range from -22 to -10 on the oceanside and -8 to -5 on the channelside. Primary design issues for this reach include maintaining the underwater shoal on the channelside of the structure and providing stability against wave attack and overtopping.

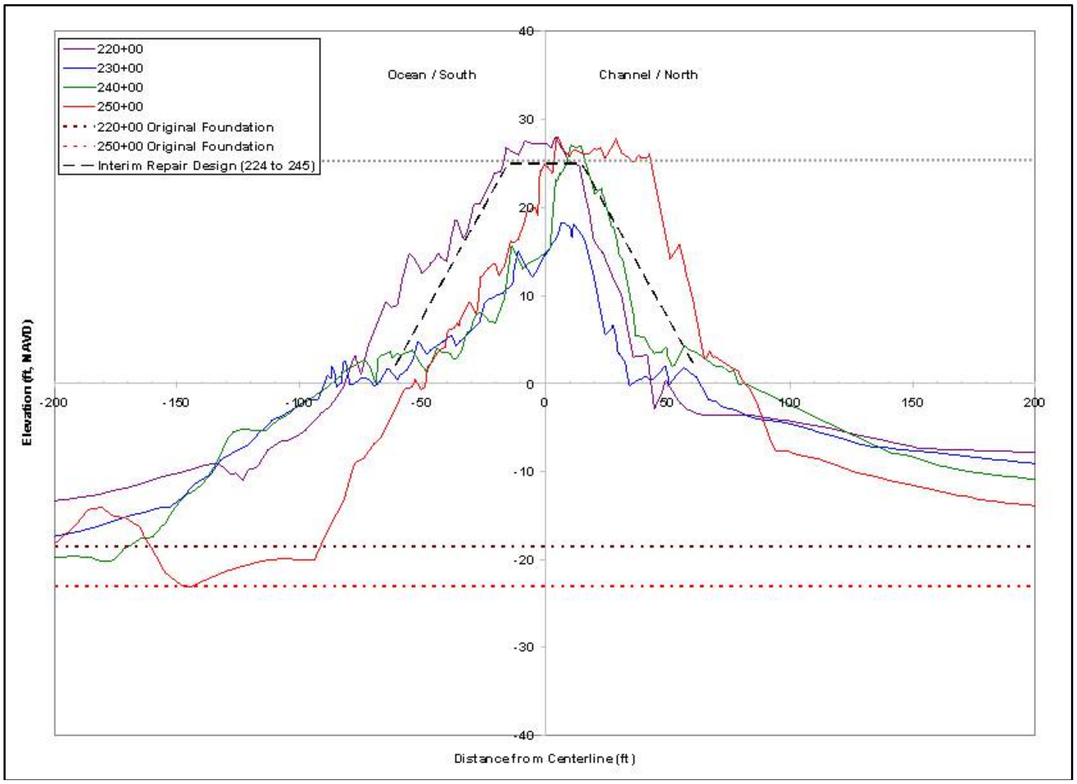

Figure A1- 136. South Jetty – Reach 3

The fourth reach extends from Station 250 to Station 280, a majority of which was addressed in a 2007 Interim Repair effort to prevent a breach of the jetty (Figure A1- 137). Design waves of 32 to 35 ft attack the oceanside of the jetty while 20 to 21 ft waves attack the channelside. Foundation depths range from -23 to -32 on the oceanside and -15 to -8 on the channelside and have exhibited increasing trends on both sides. Subsequent to the 2007 Interim Repair, the crest elevation varies from approximately 20 to 25 ft with crest widths ranging from 25 to 40 ft. Primary design issues for this reach include maintaining the underwater shoal on the channelside of the structure and providing stability against wave attack and overtopping.

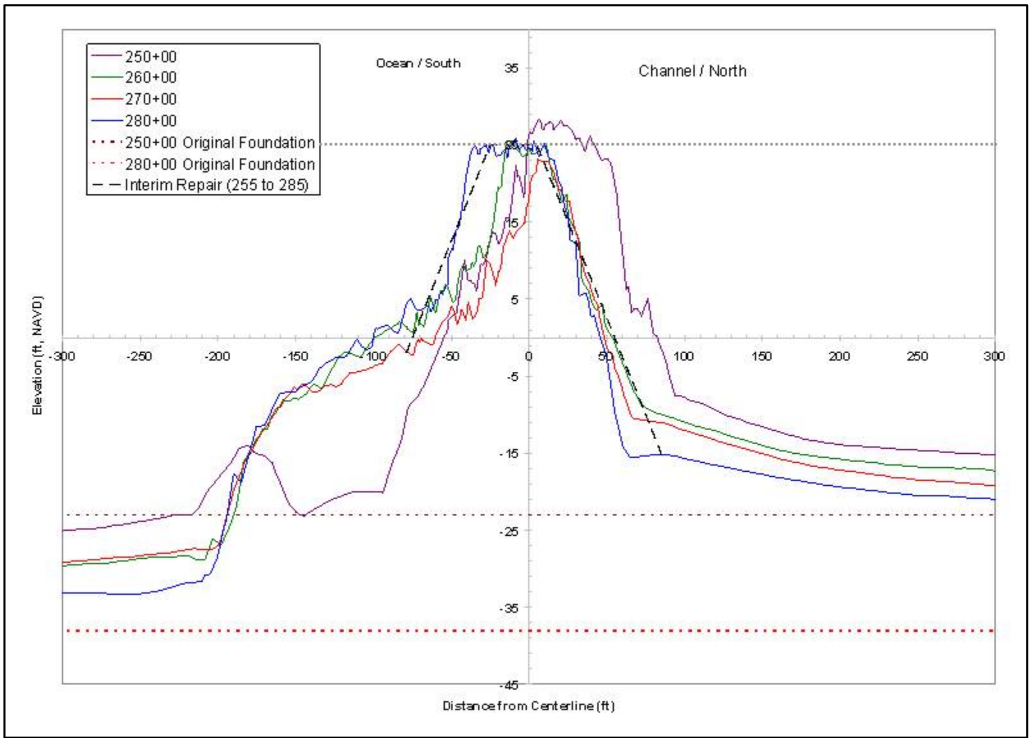

Figure A1- 137. South Jetty – Reach 4

The fifth reach of the South Jetty extends from Station 280 to 310 (Figure A1- 138). This reach has been repaired twice since the original construction in 1913. Foundation depths range from -39 to -32 on the oceanside and -22 to -15 on the channelside and are increasing. Design wave heights are estimated at 35 to 36 ft for the oceanside and 20 to 21 ft for the channelside. The presence of the underwater shoal on the channelside of the South Jetty serves to reduce the wave heights impacting this length of structure. Existing crest elevations and crest widths for this reach range from 15 to 25 ft and 14 to 40 ft, respectively. Primary issues for this reach including the high degree of wave attack from both sides of the structure and the gradually increasing foundation depths.

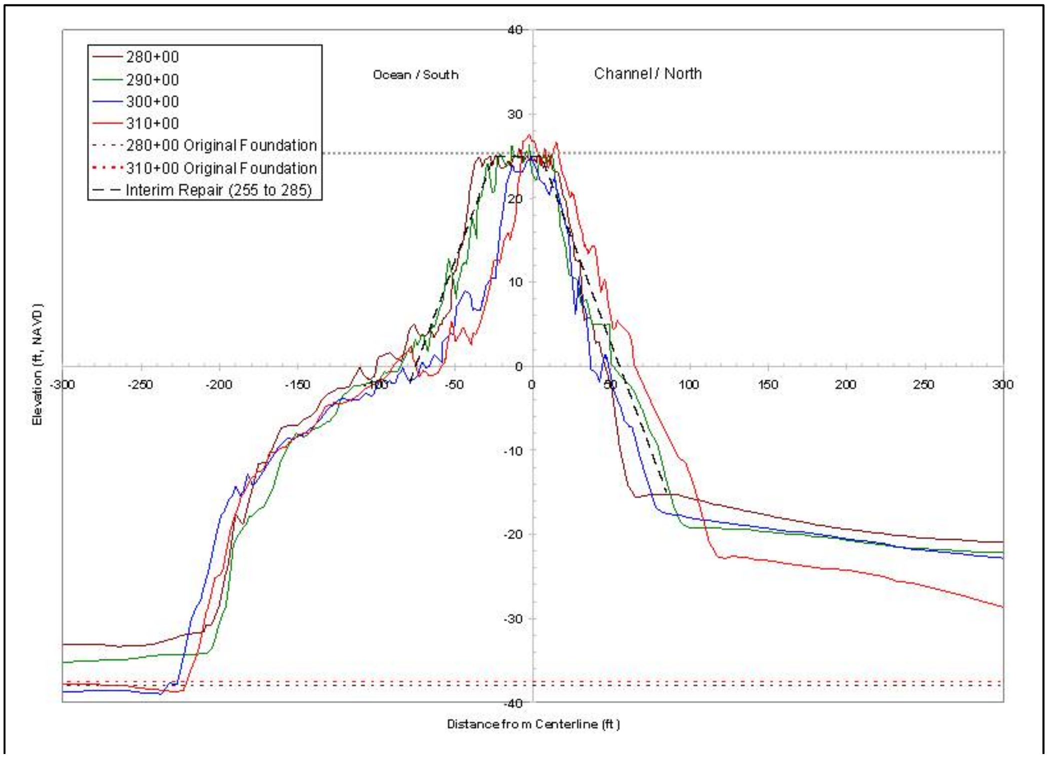

Figure A1- 138. South Jetty – Reach 5

The final design reach for the South Jetty is the head of the structure which is proposed for reconstruction to Station 313 to 315 (Figure A1- 139). Existing crest elevations and crest widths for this reach range from 7 to 20 ft, MLLW and 6 to 30 ft, respectively. A large relic base exists which will provide the base to construct the new jetty head. Primary design concerns include the 3 directions of severe wave attack and overtopping as well as the need to maintain the underwater shoal evolution.

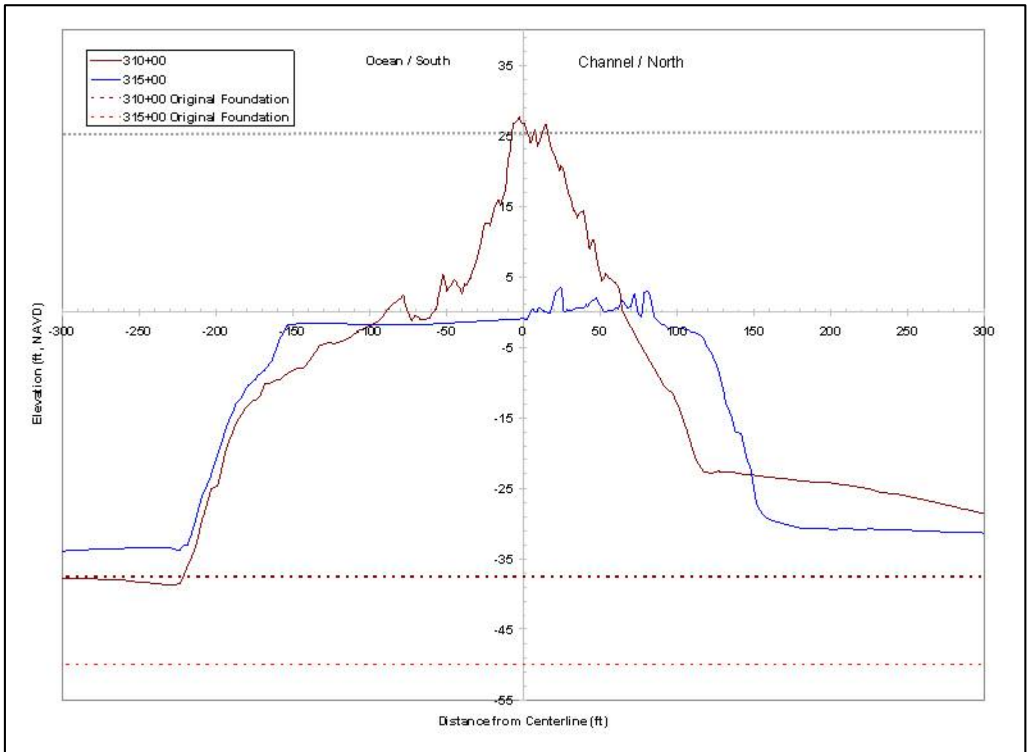

Figure A1- 139. South Jetty – Reach 6

3. Jetty A Design Reaches

Jetty A is divided into four reaches and is shown in Figure A1- 96 and Figure A1- 140 and Table A1- 7. The design parameters provided in Table A1- 7 are valid only for the existing condition. These parameters will change in the future due to morphological changes and future damage to the Jetty A. Jetty A was constructed as a very large spur groin directed perpendicularly into the Columbia River to help train the navigation channel away from the North Jetty foundation. While it is exposed to a lesser wave climate than the other two primary jetties, it has suffered severe scour at its southern tip which has contributed to its recession. In addition, wave modeling at the MCR entrance has identified an area of increased wave attack at the center part of the jetty length. Wave attack on this jetty is limited to the ocean or western side of the structure. Similar to the other two jetties, Jetty A was constructed on top of a large underwater shoal, the continued erosion of which will undermine the structure as it has already done on the southern end. Figure A1- 141 and Figure A1- 142 illustrate crest elevation and foundation changes for Jetty A. Figure A1- 143 through Figure A1- 146 show pictures of the different reaches of the Jetty A and Figure A1- 147 through Figure A1- 154 illustrate the respective cross sections.

The first design reach for Jetty A extends from Station 40 to Station 50 (Figure A1- 155). A portion of this reach is backed by land and is protected. Design wave heights along this reach are expected to range from 5 to 12 ft. Existing crest elevations and crest widths range from 20 to 22 ft, MLLW and 40 to 45 ft, respectively. Primary design issues along this reach deal with basic maintenance.

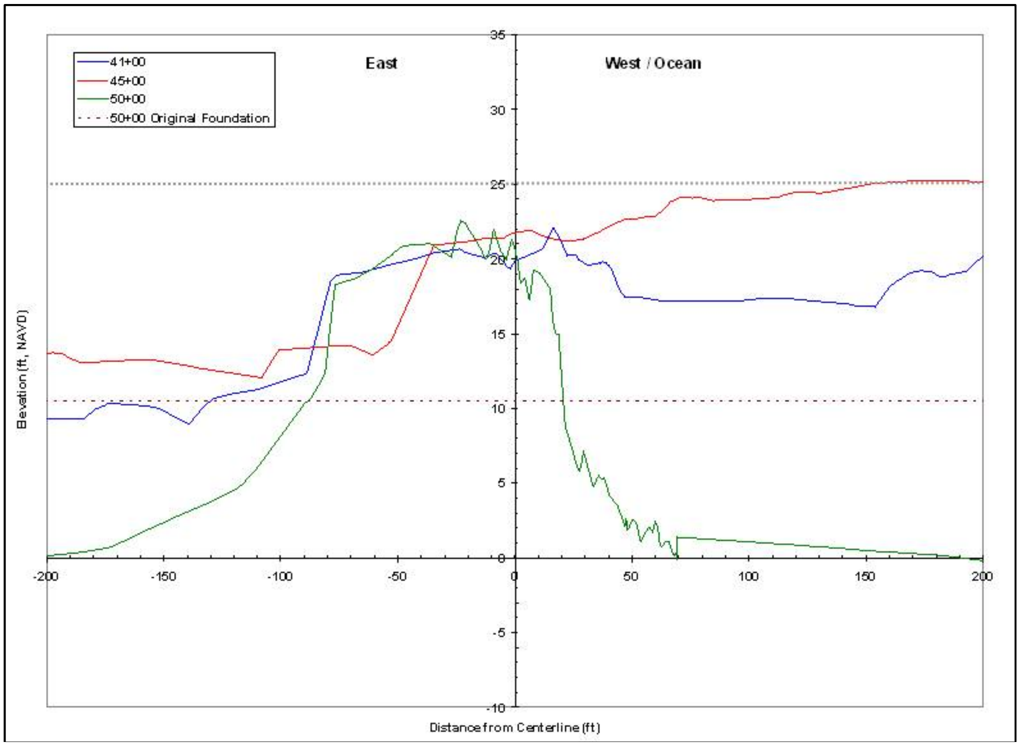

Figure A1- 155. Jetty A - Reach 1

Table A1- 7. Jetty A Design Input Parameters

Reach/ Stations	Crest Elevation (ft, MLLW)	Crest Width (ft)	Design Wave Height (ft)		Depth at Toe (ft, MLLW)		Design Issue
			Ocean	Channel	Ocean	Channel	
Reach 1 (Stations 40 to 50)	20 to 22	40 to 50	5 to 11.5	0	+2 to +18	0 to +14	Minor frontslope wave attack (1)
Reach 2 (Stations 50 to 75)	20 to 25	20 to 50	11.5 to 22.5	3.5	0 to -8	0 to +2	Major frontslope wave attack (1), Overtopping (1),
Reach 3 (Stations 75 to 90)	18 to 25	15 to 50	17 to 20	5.5	-8 to -20	0 to -75	Moderate frontslope wave attack (1), Overtopping (1), Foundation loss (2)
Reach 4 (Head)	-2 to 20	NA	20	5.5	-15 to -50	-75 to -105	Moderate frontslope wave attack (1), Overtopping (1), Foundation loss (2)

Note: These design input parameters are valid only for the existing condition

The second design reach extends from Station 50 to Station 75 (Figure A1- 156). Modeling has shown that this reach of the jetty is exposed to the largest wave heights along the structure ranging from 12 to 23 ft in height. Foundation depths along the oceanside range from -8 to 0 and from 0 to +/-2 on the channelside. Existing crest elevations and crest widths range from 20 to 25 ft MLLW and 20 to 50 ft. Primary design issues along this reach deal with the heightened wave attack and overtopping.

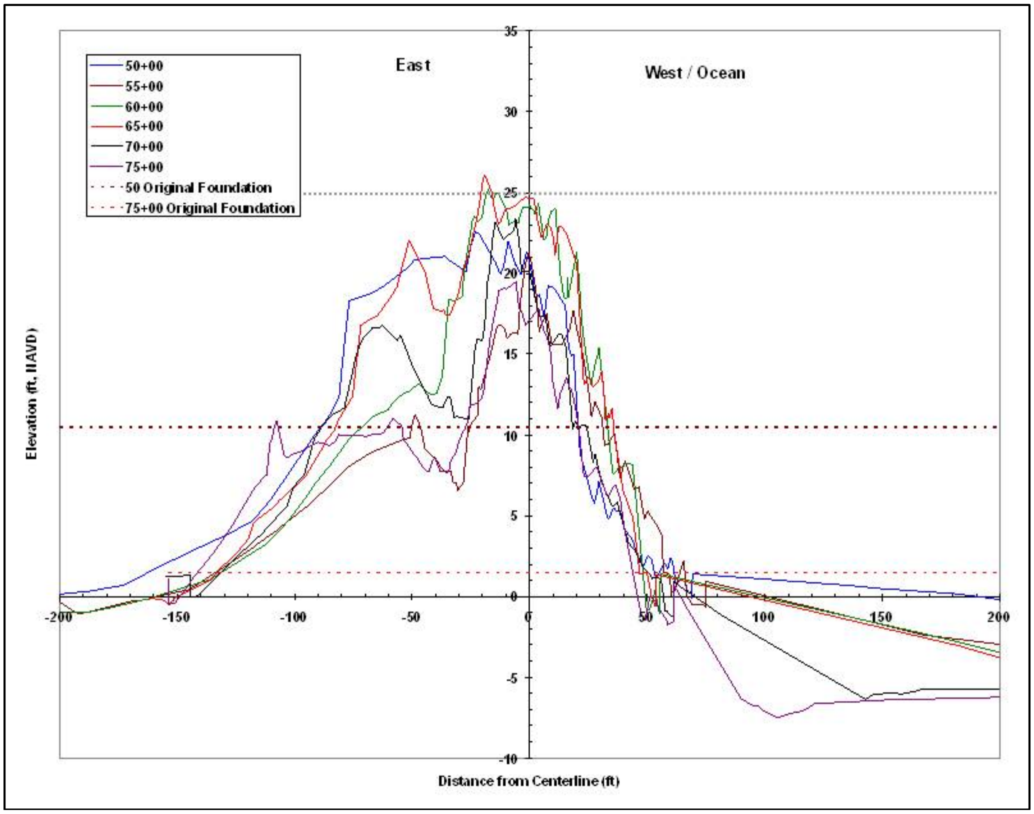

Figure A1- 156. Jetty A – Reach 2

The third reach along Jetty A extends from Station 75 to Station 90 (Figure A1- 157). Design wave heights are expected to range from 17 to 20 ft. This reach currently has oceanside and channelside foundation depths ranging from-20 to -8 and -75 to 0, with increasing rates of erosion on both sides. Attempts to stabilize the underwater shoal could help stabilize this reach of the jetty. Primary design issues include the moderate wave attack and overtopping and the foundation loss.

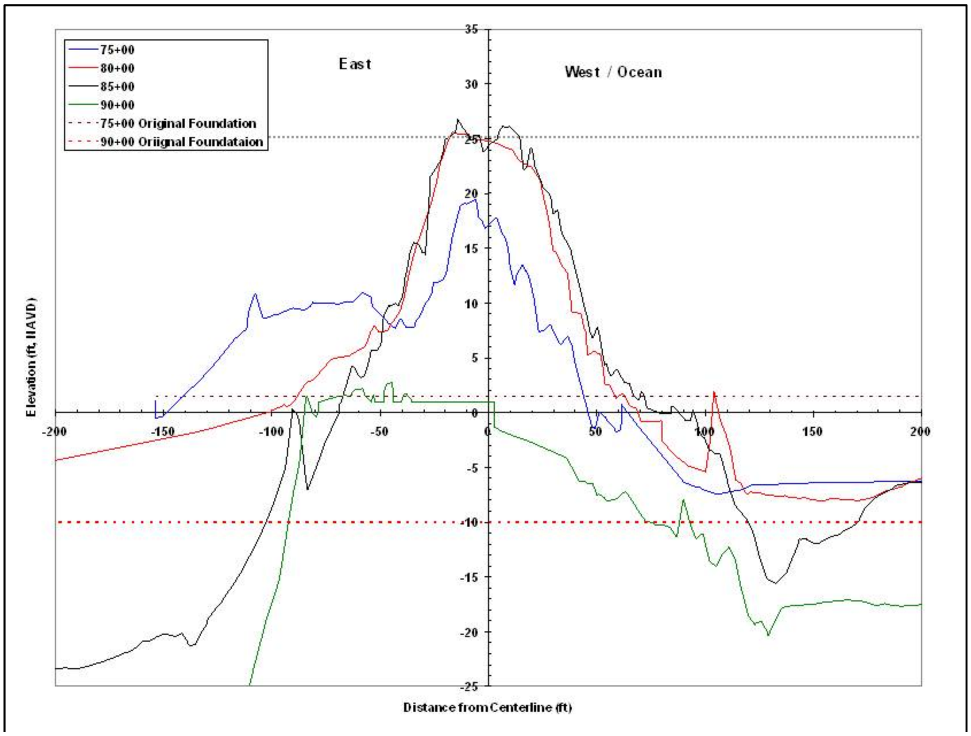

Figure A1- 157. Jetty A – Reach 3

The final reach for Jetty A is reconstruction and stabilization of the head of the structure, expected to occur from Station 90 to 93 (Figure A1- 158). Current crest elevations along this reach range from -2 ft to +2 ft MLLW.

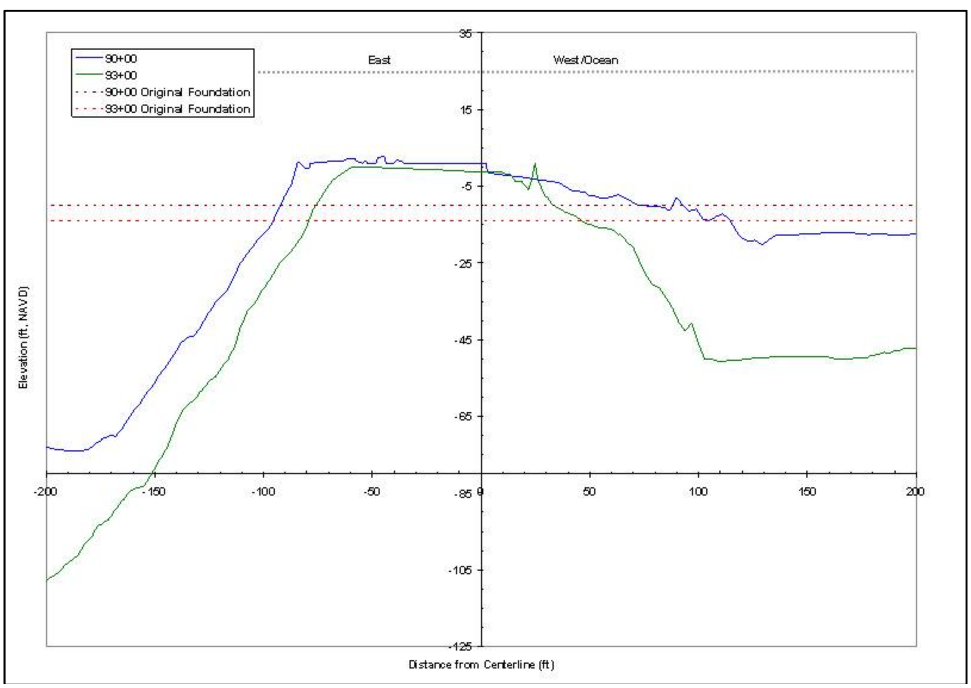

Figure A1- 158. Jetty A – Reach 4

9. Design of Jetty Cross Section Repair

a. Cross Section Intent and Design Philosophy

Cross section development for jetty repairs was guided by the following constraints. The repair template must be cost-effective in terms of construction materials as well as quantity of material, to allow the maximum repair within funding limitations. Quarried stone is expected to be used for the majority of the work. The vast majority of the repair stone which will be needed for the jetty repair will be within the easily acquired stone size range. Quarried armor stone is available from numerous sources in the Pacific Northwest. Concrete armor units are considered as an option for only the most extreme part of each structure. The repair template must be constructible. In order to limit potential impacts to the surrounding environment, the minimum modification to the jetty footprint is desirable. The jetty repair should be structurally consistent with the present jetty configuration and future rehabilitation scenarios. There should be no dissimilar attributes between the present jetty section and the repair template. Areas of the jetty that are repaired, using the repair template, must be able to be augmented later if necessary. Each action taken should be directed toward improving the long-term reliability of the jetty system and its function to protect the navigation channel. Table A1- 1 to Table A1- 3 summarizes the design cross section history for the three jetties.

Early in this investigation it was determined that portions of both the North Jetty and the South Jetty were close to failure. Interim repairs which address only the upper part of the cross section damage and are only expected to last 10 to 15 years, were recently constructed (2005 to 2007) on approximately 25% of the length of both the North and South jetties. Interim Repair actions were executed for Stations 55 to 85 on the North Jetty and Stations 224 to 245 and 255 to 285 on the South Jetty (Figure A1- 159 through Figure A1- 161). The intent of the Interim Repair was to address the loss of jetty cross section above -10 ft MLLW due to slope failure and direct wave action in order to address short term stability problems. Figure A1- 162 contrasts the Interim Repair template with a more substantial template which addresses the full jetty cross section.

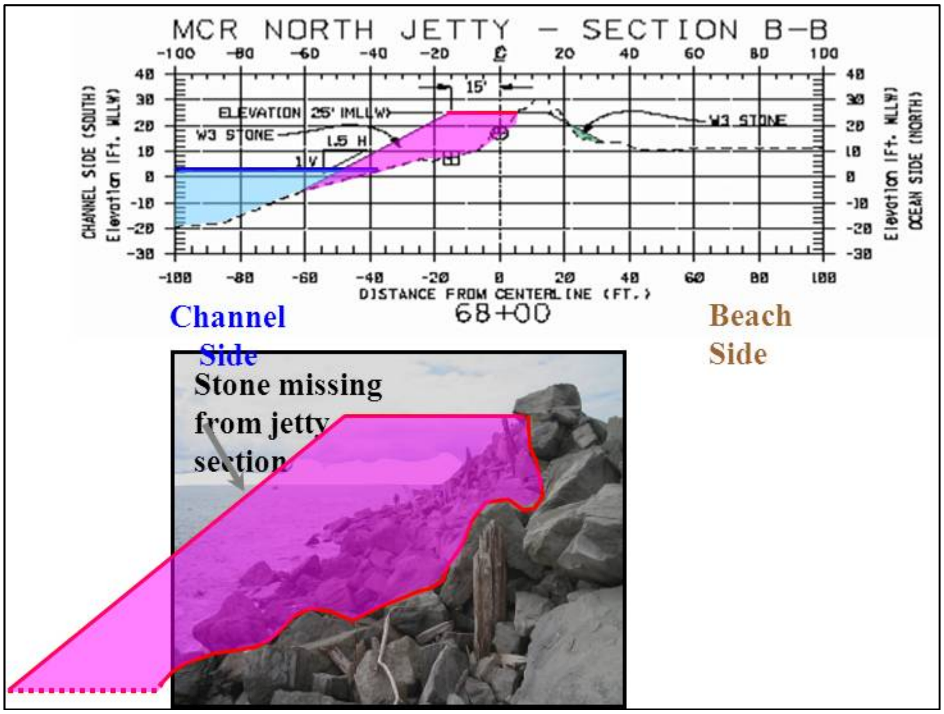

Figure A1- 161. Typical Cross Section – Interim Repair

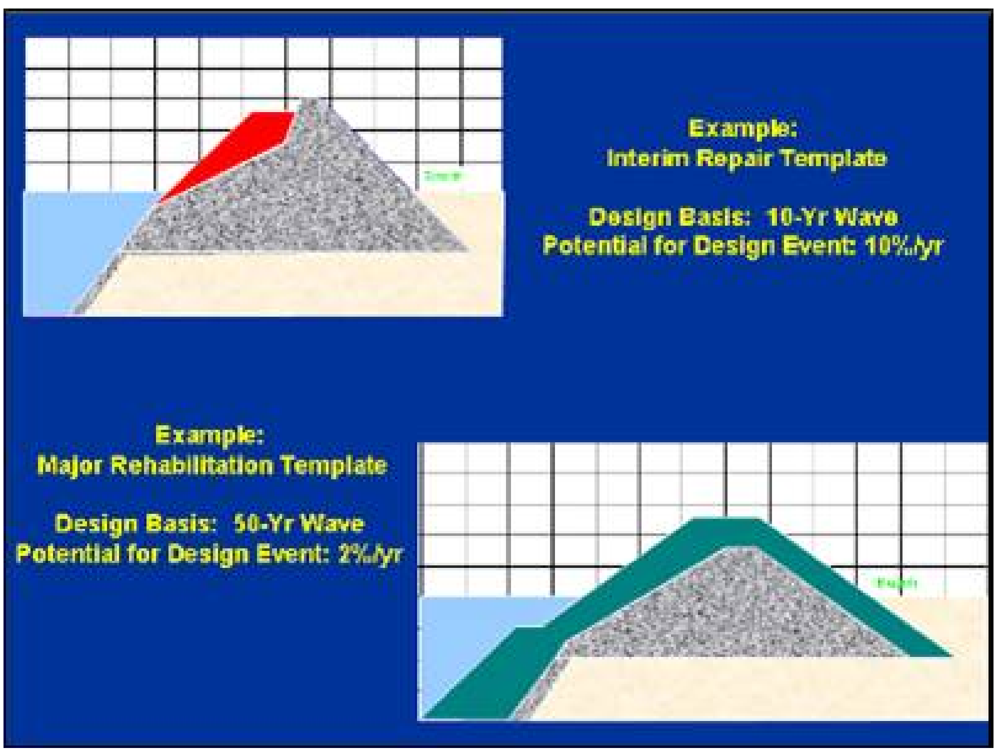

Figure A1- 162. Contrast between Interim Repair and Rehabilitation Templates

b. Design Cross Section Repair Development

Design template attributes for future repair alternatives are selected to minimize the cost of repairs while achieving sufficient stability and life-cycle restoration for each portion of the jetty. Due to the variability in design climate and repair history, alternatives vary between the three structures, and along the length of each structure. Jetty cross section options for future repair examined crest elevation, crest width, and sideslope adjustments. The location along the jetty alignment was important to the degree of robustness needed for each design parameter. Figure A1- 163 illustrates a typical jetty layout with its respective design and consequence concerns. In addition, for those jetty reaches where foundation stability was a concern, special designs were developed for the toe berm area of the cross section in order to stabilize the upper portion of the section over the long term. Above and below water adjustments were made in cross section design to address both variability in design forcing and accuracy and expected method of construction. Two-dimensional physical modeling was used to assess and fine tune the cross section designs. After the cross section refinement in the modeling, each cross section was tested for long term reliability in the life cycle analysis model for the rehabilitation study.

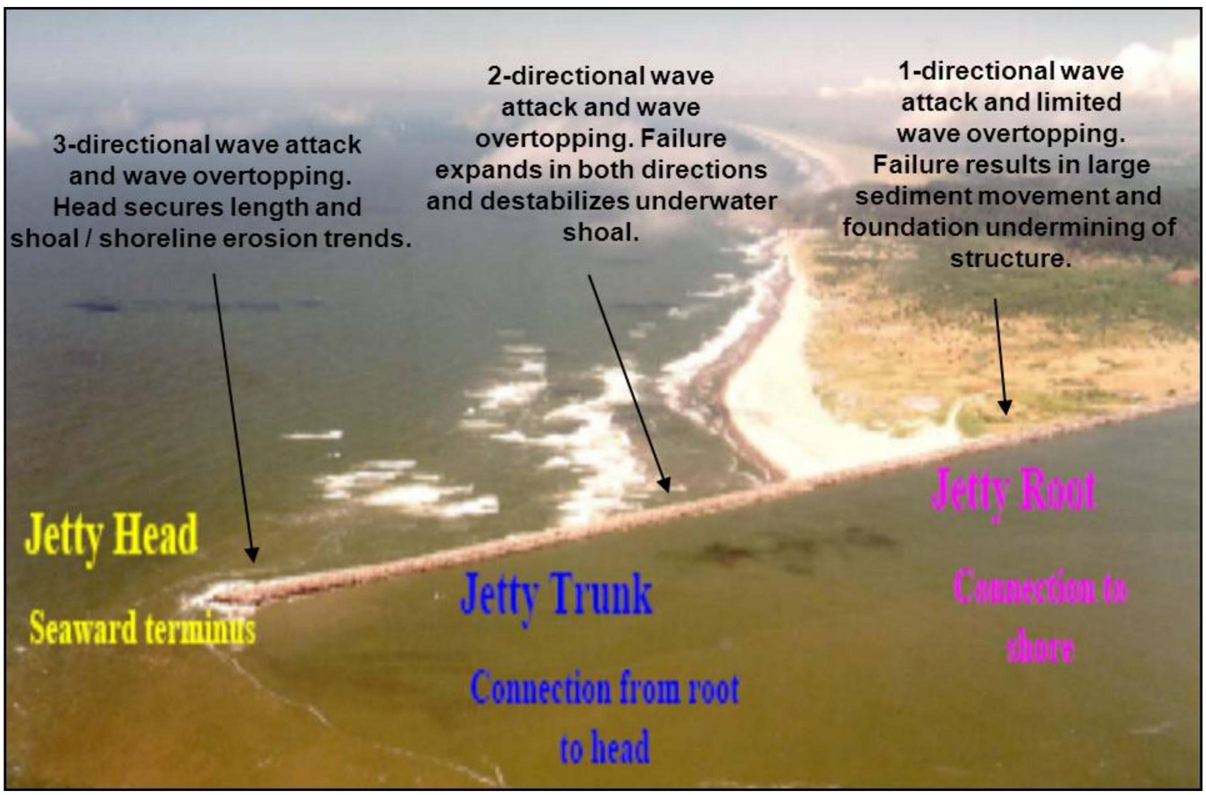

Figure A1- 163. Typical Jetty Design / Exposure Reaches

Historical performance of previous jetty designs, expected and feasible construction techniques, as well as existing structure configuration were considered when specifying structure design parameters. Verification of proposed design cross section elements in the project environment was conducted in the 2-dimensional physical model. Due to the extreme wave climate along the northern Oregon coast, the design of a rubblemound structure to eliminate overtopping is infeasible. In addition, the crest width and to some extent the crest elevation for these structures is related to construction method. Early original construction of Northwest coast jetties in the 1800s was attempted using similar construction methods as east coast jetty construction of the time by floating marine plant. After several notable failures due to the Pacific Ocean working environment, it was soon determined that the Northwest coast would require another construction approach. Since that time, the predominant method of construction for the Oregon coast jetties has been from the top of the crest of the structure down. Using this method of construction has necessitated a crest width that is wide enough to safely accommodate the necessary construction equipment. In addition, especially for the exposed area of construction, the crest elevation is required to be high enough for the equipment to be safely out of the wave attack area.

c. Crest Elevation

Key issues to consider when assessing the crest elevation of a rubblemound jetty are the sensitivity of the established crest elevation to cross section stability as well as the significant impact on cost as a function of crest elevation. Referring to Figure A1- 163, depending on where the design section is located, the structure may be exposed to 1- 2-, or 3-sided overtopping forces. A general reference to assess overtopping forces on the backside of a structure is the work conducted by Walker, Palmer and Dunham as shown in Figure A1- 164 (Walker et al., 1975). Since backside armor exposed to overtopping waves has no jetty section to push up against (as the front side armor does), those armor stones are more easily dislodged. The relationship illustrated in the figure shows how the parameter of freeboard over wave height impacts the ratio of weight required of backside armor to front side armor. A crest elevation design (or freeboard) which starts to increase the backside armor stone weight needs to be evaluated carefully. The figure displays approximately where the 3 jetties fall using a 25 ft crest elevation and a high water level of +12.2 ft MLLW for a range of incident design waves. While both Jetty A and the North Jetty are predominantly on the stable side of the figure using a 25 ft crest elevation, the South Jetty toward the seaward end is exposed to heavy overtopping forces. Figure A1- 165 illustrates how the freeboard over wave height parameter is related to the incident wave height with respect to three different crest elevations (+20, +25, and +30). The vertical dotted line indicates the stable location for equal back-side to front-side armor size.

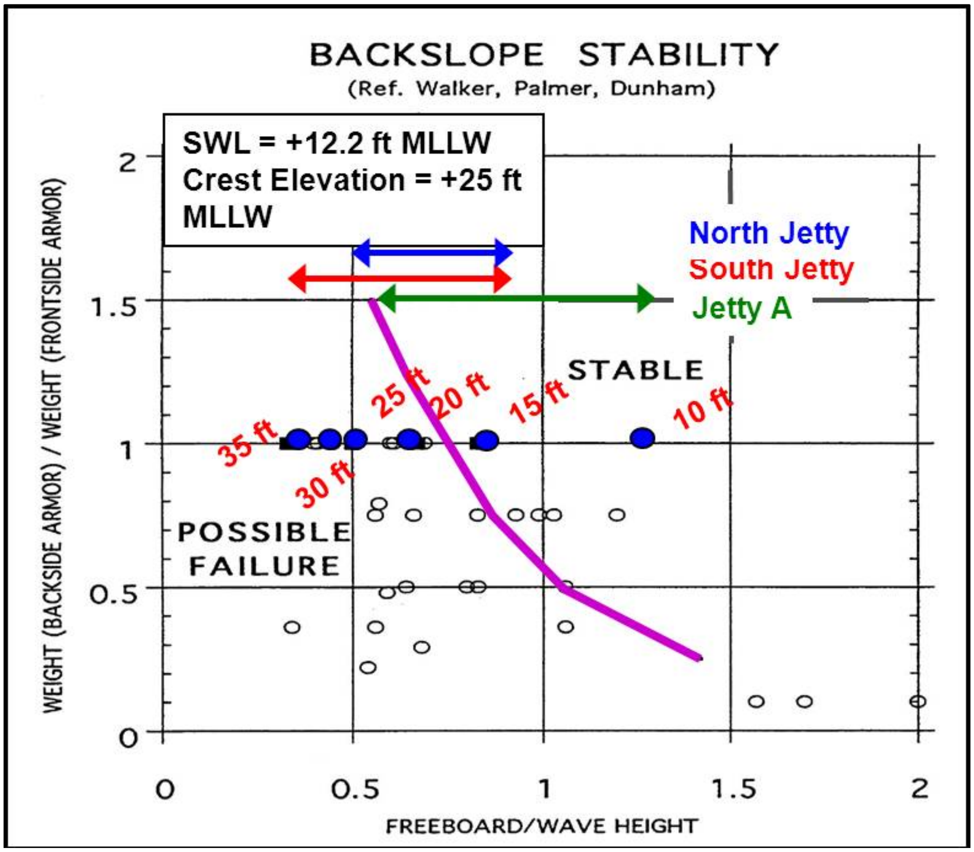

Figure A1- 164. Backslope Stability Relationship

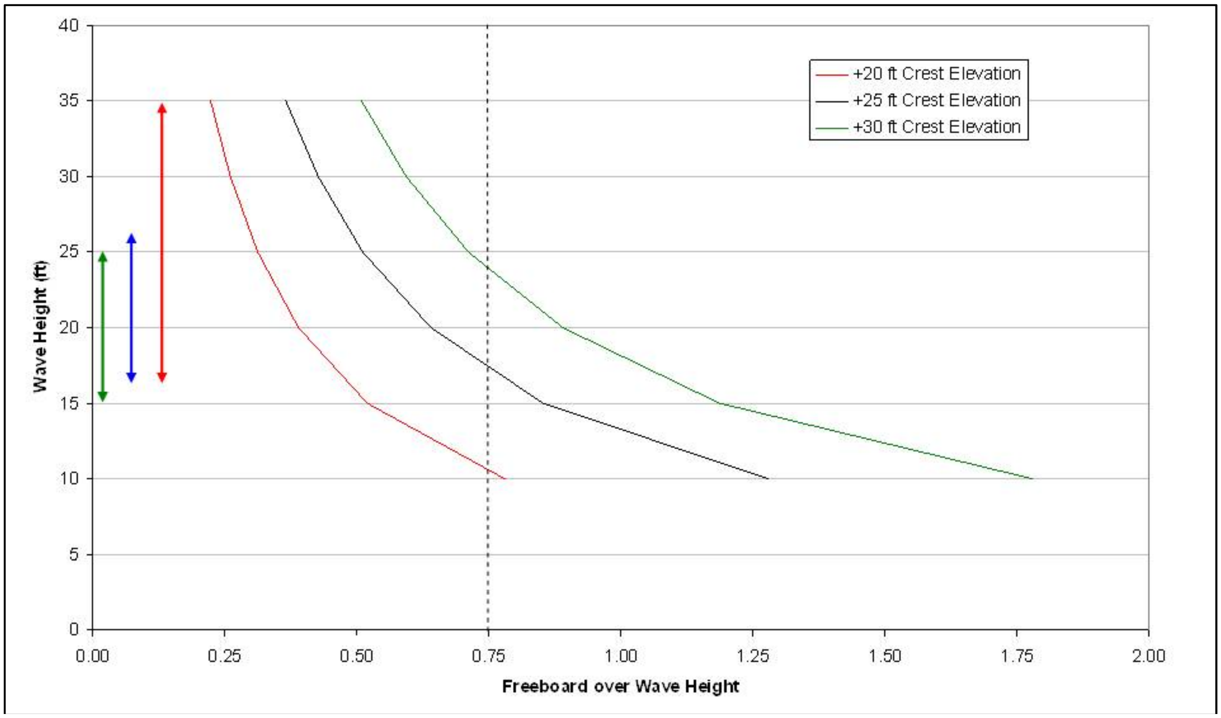

Figure A1- 165. Incident Wave Height vs Overtopping Parameter

Other issues considered while determining proposed crest elevations included the existing configuration of the jetty as well as the goal of minimizing any modifications to the jetty footprint. Working in an optimized manner with the existing structure is part of a cost-effective design. This involves minimal re-working of the structure, particularly tearing down portions of the structure that currently exist. On the design reach cross section figures it can be seen that consistently, substantial jetty sections currently exist along much of the three structures. Establishing a crest elevation lower than the existing and/or historical elevations would need to be supported by substantial justification, since reducing crest elevation can have serious impacts to overall section stability in addition to the cost to achieve it.

Initial crest elevations for the South Jetty were established in 1913 ranging from +10 ft to +24 ft MLLW. Repairs since that time have utilized crest elevations of +20 to +30 ft MLLW. Current crest elevations along the jetty range from +14 to +25. One added feature that the South Jetty can take advantage of with future repairs is the very wide relic base that is the product of numerous historical jetty repairs. While structure width is not as efficient at reducing overtopping as increased elevation, a wide structure can provide further reduction in those forces. This effect is born out in the 2-dimensionsal physical modeling results. Initial crest elevations for the North Jetty were established in 1917 ranging from +15 ft to +32 ft MLLW. Subsequent repair work has been conducted on the seaward half of the jetty utilizing crest elevations of +24 to +26 ft MLLW. Current crest elevations along the jetty range from +14 ft to +27 ft, MLLW. Initial crest elevations for Jetty A were established in 1939 ranging from +16 ft to +20 ft MLLW. Repairs occurring since original construction have utilized crest elevations of +20 to +24 ft MLLW. Existing crest elevations along Jetty A range from 18 to 25 ft MLLW.

A +25 ft MLLW crest elevation was chosen for the majority of the North and South jetties to work within the existing structure and provide long term stability to the design reaches without increasing jetty footprint. The heads of both the North and South Jetties were set at a crest elevation of +20 ft MLLW in order to facilitate construction of the head solely on the relic stone base. The additional width of the head design provided by both the wide adjacent toe berms as well as the wider main body crest width should provide sufficient robustness for the jetty feature to resist the wave overtopping. A similar head design has been employed at the Yaquina North Jetty (constructed in 2001) with positive results.

A +20 ft MLLW crest elevation was chosen for the majority of Jetty A since this jetty is exposed to a much reduced wave climate compared to the other jetties and is only exposed to a 1-directional wave overtopping process. As can be seen in Figure A1- 145, this structure also has a fairly wide overall relic structure which can provide added buffer against overtopping forces. For the head construction at Jetty A, a +15 ft MLLW crest elevation was determined. Again, construction of the jetty head on a precarious relic stone base is a controlling factor for the head cross section dimensions. This jetty head will only be exposed to overtopping from one side and it also has wide toe berms for additional stabilization.

d. Crest Width

Some of the crest width design concerns have been discussed above. Desired output is minimal reworking of the existing structure, minimal stone quantity, minimal modification to the jetty footprint to provide long-term reliability and robustness of the jetty cross section. For the MCR jetties, the minimal 30 ft crest width typically required for equipment access is more than sufficient to meet the typical three armor stone width requirement recommended for rubble mound jetty crest design. A 30 ft crest width would be equivalent to three 83 ton stones in width. Since all of the jetty stone design for this application is smaller than 83 ton, the crest width meets design requirements.

Initial crest widths for the South Jetty were established in 1913 ranging from 10 to 25 ft. Repairs since that time have utilized crest widths of 25 to 40 ft. Existing crest widths along the jetty range from 4 to 40 ft. Once again the added feature of the very wide relic base for the South Jetty is the product of numerous historical jetty repairs. Initial crest widths for the North Jetty were established in 1917 at 25 ft. Original construction of the North Jetty benefited from the lessons learned on the South Jetty construction. Subsequent repair work has been conducted on the seaward half of the jetty utilizing crest widths of 30 ft. Existing crest widths along the jetty range from 10 to 40 ft. Initial crest widths for Jetty A were established in 1939 ranging from 10 ft to 90 ft. Construction of Jetty A and the South Jetty utilized a double trestle setup which impacted final crest width parameters. Repairs occurring since original construction have utilized crest widths of 20 to 30 ft. Current crest width along Jetty A ranges from 20 to 50 ft.

A 30-ft crest width is needed to allow equipment access (if land-based construction is used) and provide a sufficiently thick cross-section with reserve capacity to allow some damage (displacement) of the armor stone by scour-induced settlement or wave action. For the bullnose section at the heads of the three jetties, a 40 ft crest width is used for additional robustness and to withstand the 3-dimensional overtopping forces that occur there.

e. Sideslope

The specification of sideslope impacts three primary cross section elements: stone size required for stability, quantity of stone required and potential size of modified footprint. Since this design effort attempts to minimize stone quantity and footprint modifications, attempts were made to achieve the minimum sideslope feasible for each design reach. In addition, in extremely deep areas along the jetties, flatter sideslopes result in large quantity increases to achieve the cross section. However, per the Hudson armor stone design equation, as the sideslope is steepened, required armor sizes increase.

Historically on the three jetties, sideslopes have ranged from 1V:1.25H to 1V:2H. Some sideslopes were also a function of what was achievable with the equipment being used for construction. Early construction work did not involve individual stone placement but rather achieved the design section by dumping rock from the railroad trestle on top of the jetty.

The minimum side-slope allowed for jetty design is 1V:1.5H [USACE 1984]. Sideslopes of 1V:1.5H to 1V: 3.5H were considered. Steeper slopes are usable along some of the more protected areas of the three jetties, channelside areas with less wave exposure and most landward reaches of the jetties. A 1V:2H to 1V:3.5H sideslope is needed where wave action is more extreme, exposed ocean slopes, seaward reaches of the jetties, and head construction. Another constraint on sideslope occurs for those design templates which attempt to stay completely on top of the existing jetty section, requiring a steeper slope. This can be done either to control the jetty footprint impact or to achieve building on the relic stone base. Construction at the head of the three jetties was a multi-variable tradeoff between sideslope stability and control of size of head feature. More physical modeling will be required to optimize this design in subsequent phases.

Another area of potential variability in sideslope is in areas outside of the wave impact zone. This is typically one wave height below the still water line. Some of the toe berm features designed to help control foundation scour and provide robustness for the upper jetty cross section is proposed using a 1V:1.5H sideslope.

f. Armor Stone Unit Weight

Rock unit weights in the Pacific Northwest typically range from 165 lb/ft^3 to 200 lb/ft^3. A minimum rock unit weight of 167 lb/ft^3 is needed to achieve workable armor stone sizes, based on the wave action incident at the MCR jetties. However, a higher unit weight stone is most desirable. For the same design wave height, armor stone produced from rock with a unit weight of 190 lb/ft^3 is 40% less weight (per armor stone) than armor stone produced from rock with unit weight of 167 lb/ft^3. Although 14% more of the denser armor stone would be needed (190 lb/ft^3 vs 167 lb/ft^3), armor stone with significantly less weight per unit is easier to produce, transport, and place; which translates into net cost savings.

g. Core Stone and Bedding Stone

Repair of 100-year-old structures that have already been repaired multiple times is a significantly different construction activity than building a new jetty. The foundation and mass of the jetty structure is already there. The repair construction activity will involve some rearrangement of the existing section but will consist primarily of adding layers of stone to the outside of the base structure. The candidate areas proposed for repair have varying degrees of damage; from large gaping holes within the jetty cross-section to small but deep scallops. There is too much irregularity within the damage areas to apply a continuous or complete jetty repair section, with attendant bedding, core and armor stone layers. Because of this, very little core or bedding stone is required. Armor stone (large size stone) is used for the majority of the repair template, to ensure that all of the stone placed within the repair areas is effective at preventing excessive wave damage. An exception to this is in areas where the cross section is broadened as it extends down to the seabed for foundation stabilization purposes. For those cross sections, bedding and smaller-size stone is proposed for constructing the toe berm.

h. Above and Below Water Repair Areas

Design of above and below water sections on the jetty are controlled primarily by two factors: variable exposure to wave attack and expected degree of control over placement. An understanding of the feasible and probable construction techniques for the different portions of the jetty cross section is essential to development of a robust and constructible design. Armor stone placement above water can be closely controlled resulting in a higher level of certainty of interlocking parameters. However, areas further down along the cross section slope and further away from the jetty crest (i.e., greater reach length for equipment) are likely to have lesser degrees of control over placement quality. In very deep areas along the jetty toe (e.g., -70 ft MLLW depth along channelside of the North Jetty), construction is likely to be achieved by dumping of material from a marine plant. Stone sizing and structure feature elements need to be adjusted accordingly to allow for uncertainty in final cross section placement.

i. Armor Stone Gradation

The gradation range for armor stone is usually specified as 0.75*W_{50} to 1.25* W_{50} , where W_{50} is the design armor stone weight (per unit) [USACE 1984]. The calculation of W_{50} is an essential element for jetty design and is described below. In terms of quarry operations, the above gradation range is very narrow and much rock must be quarried to produce requisite amounts of the armor stone (the effective % yield of armor stone from the quarry may be 2%-6%). As mentioned in above text, stone acquisition for repair of an existing structure is already skewed toward the higher end of stone sizing specification because of the outer cross section repair characteristics of the design stone.

To improve the quarry production and transport of armor stone and achieve a high degree of stone-to-stone interlocking, the gradation range for armor stone to be used for repair of MCR jetties will be widened to approximately 0.6*W_{50} to 1.5*W_{50}. In addition, 10% of the overall tonnage for each class of armor stone can consist of 0.3*W_{50} to 0.6*W_{50}. The smaller stone within the lower 10% of the gradation range will be used to achieve a tight and well-placed armor stone template. For armor stone used along the South Jetty, stones larger than maximum gradation size are permitted for up to 20% of the total armor stone.

j. Armor Stone Placement

As mentioned above, varying degrees of armor stone placement control can be expected for each jetty and along the length of each jetty. Wherever possible, armor stone should be placed in a controlled method such that all sides of each stone are seated against adjacent stones, except for the outer armor layer. The level of the control will vary, however, in areas above water where significant wave exposure occurs, special placement will be required. The intent of controlled armor stone placement is to achieve maximum interlocking of the armor stone to achieve a solid mass with minimum voids. Target percentage voids (porosity) are 0.25-0.30. Each armor stone should be individually placed. Armor stone should not be dropped into position from a height exceeding 1-2 ft. Refer to Section 18 (Construction

Considerations) for additional details concerning jetty stone placement. The armor stone is assumed to have a rough angular shape.

k. Jetty Armor Size Calculations

Armor unit size (W_{50}) for the repairs of the MCR jetties was determined using the Hudson Equation [USACE 1984]. Comprehensive investigations were made by Hudson and Jackson (1953-61) to develop a formula for determining the stability of armor units on rubblemound structures, in response to direct wave attack. The destabilizing effects of direct wave action on the windward side of a jetty are manifested in the upper region of the jetty (from the jetty crest down to –10 ft MLLW).

The Hudson equation is based on extensive small-scale modeling testing. Verification has been made using prototype data. The Hudson equation is used when the crest of a structure is high enough to prevent overtopping by waves and the armor layer slope is not steeper than 1V:1.5H. Armor layer slopes steeper that 1:1.5 are not recommended by the USACE [USACE 1984]. Median armor stone size (weight, W_{50}) for the wave-ward slope face is determined as follows:

$$W_{50} = \frac{\gamma r * H^3}{K_d * (Sr-1)^3 * \text{Cot}\theta}$$

where

W_{50} = median armor stone — θ = side slope of armor layer from horizontal
γr = armor unit weight — H = incident wave height, $H_{1/3}$ in this case
K_d = stability coefficient — Sr = specific gravity of armor units

The parameters of stone density (γr) and armor layer side slope (θ) were previously defined. Specification of the stability coefficient (K_d) can be problematic. Figure A1- 70 and Figure A1- 166 through Figure A1- 174 show how armor stone size (W_{50}) can vary based on the variation of stability coefficient, sideslope, and armor density. Figure A1- 175 notes potential incompatibility challenges when introducing CAU's to a rubblemound structure. An important consideration for jetty design is to attempt to keep the armor stone weight at or below 35 tons where feasible, to ensure achievable construction, transportation, and placement options. Note that armor stone weight is a function of H^3. Determination of incident wave height (H) is the critical element to get right when calculating the size of armor stone. Significant effort was expended to estimate the design (incident) wave height for various reaches along the jetties. Figure A1- 176 and Figure A1- 177 provide estimates for design stone requirements along the length of the South and North jetties, respectively.

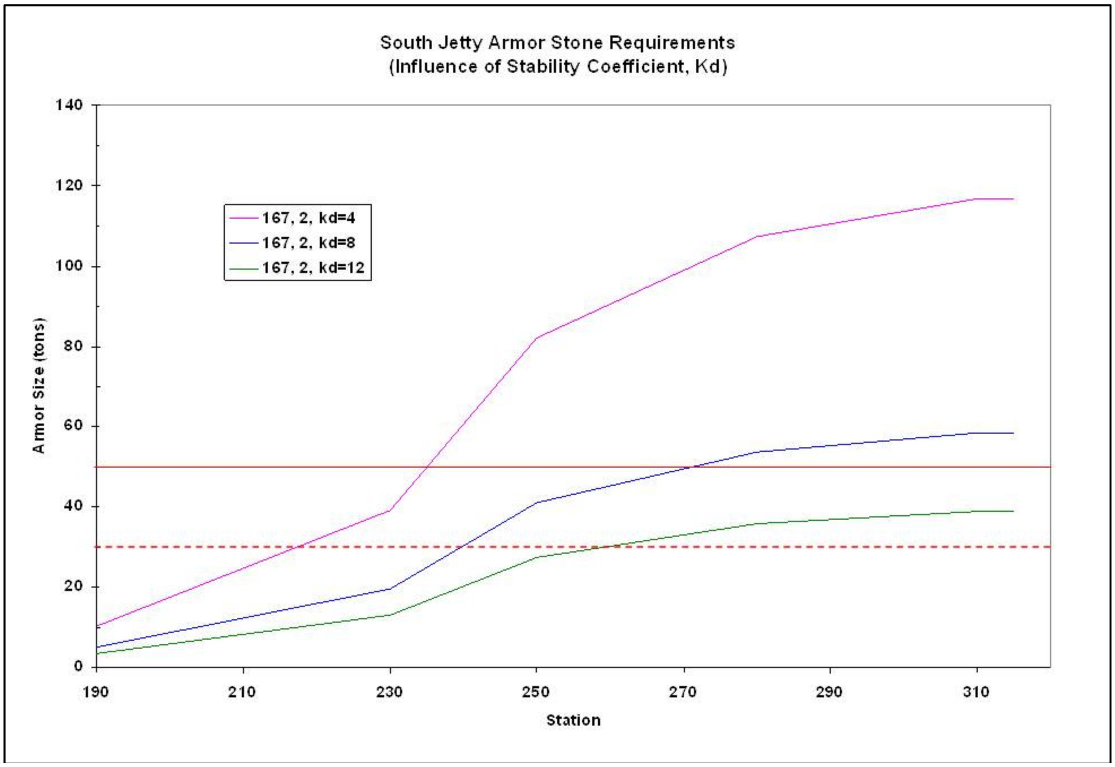

Figure A1- 166. Influence of Stability Coefficient on South Jetty Armor Stone Requirements

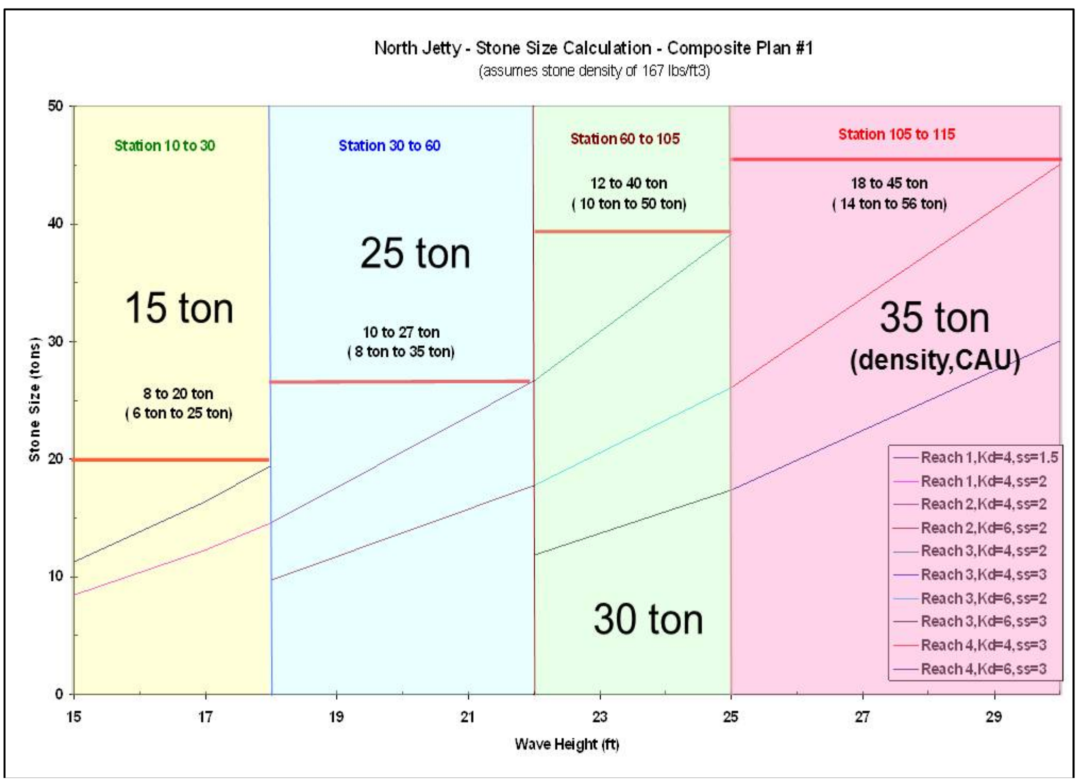

Figure A1- 177. North Jetty – Stone Size Calculation Range

l. Armor Stone Stability (K_d) Number

The stability number located in the denominator of the Hudson equation has a great influence on the calculation of stable design stone weight. It also is the parameter most influenced by the location on the structure and construction technique used. Stability numbers (K_d) of 6.0 and 4.0 (above and below water) were selected for the design templates for this study. These values correspond to rough angular stone placed in a controlled manner. The value of K_d used for the previous repair of the North Jetty (in 1964) was 7.1. The previous repair of the South Jetty (1982) used a K_d of 10 for above MLLW armor stone and a K_d of 5 for armor stone placed below water. Higher values of K_d generate a smaller required armor stone size, for the same wave height as compared to a low-valued K_d; however, over-estimation of this parameter results in an unstable cross section very soon into its constructed life.

m. Summary of Armor Stone Sizes

The median armor stone size (W_{50} , weight) was determined for each candidate jetty reach using the values of incident wave height. Note that for the largest armor stone range, armor stones larger than maximum gradation size are permitted (for up to 20% of the stone). Figure A1- 70 illustrates the sensitivity of armor unit size to wave height, unit weight, sideslope, and stability coefficient. Figure A1- 166 through Figure A1- 174 illustrate the potential range in armor unit sizes along the North and South jetties and Jetty A as a function of armor unit weight, stability coefficient, and sideslope.

n. Armor Stone Quantity Calculations

A high-resolution digital elevation model (DEM) was developed for the MCR and jetties. The MCR DEM describes the present surface of each jetty and the bathymetry of MCR. The DEM of the present jetty condition was used to compare the existing condition of each jetty to the 'as-built' (or as previously repaired) condition. The difference between the two surfaces was used to estimate the volume of armor stone needed to implement the repair template, along candidate reaches of the jetties.

10. Two-Dimensional Physical Model Study

a. General

The primary failure modes impacting cross section design vary along each structure but are generally believed to be a combination of one or more of the following: (1) armor instability due to direct wave impact, (2) armor instability due to overtopping, (3) toe scour de-stabilization, and (4) static instability of underwater slope. The primary issues from the structural design perspective are: (1) technical viability given the condition of the existing structures and the Pacific Ocean environment, (2) risk and/or robustness of design to achieve a minimum 50-year life under extreme annual loading, and (3) reliable constructability of design.

The Corps' Engineering Research and Development Center in Vicksburg, Mississippi was contracted to conduct a 2-dimensional physical model of the jetty cross section design. The range of structural repair types addressed in the model included: crest elevation and crest widths variations, sideslope variations, underwater berms, armor stone and concrete armor unit options. The purpose for the 2-D physical model was three-fold:

1. Assist in defining damage initiation and damage progression relationships (damage function) for existing condition and proposed alternatives to feed into a reliability analysis of the structures.
2. Conduct a qualitative screening of a wide range of alternatives that will bracket potential structural and material-type options that could be applied on the three structures.
3. Assist in cross section optimization and material type design for the range of alternatives to be assessed in the general rehabilitation study.

Both the North and South jetties were tested under low and high water conditions. Incident wave heights up to 35 ft were applied to the jetty cross sections. Armor units tested included quarry stone and dolos concrete armor units. An additional concrete armor unit was tested called a C-roc. The C-roc armor unit is shown in figures Figure A1- 178 through Figure A1-183 and more closely resembles a large rock with interlocking members. Due to its rock-like configuration, it is expected to be less fragile than concrete armor units which have thinner flange-like elements.

Figure A1- 178. Side View of Stone and C-roc 2-Dimensional Model

Figure A1- 179. Front View of Dolos and Stone 2-Dimensional Model

Figure A1- 180. Cross Section Side View of 2-Dimensional Model

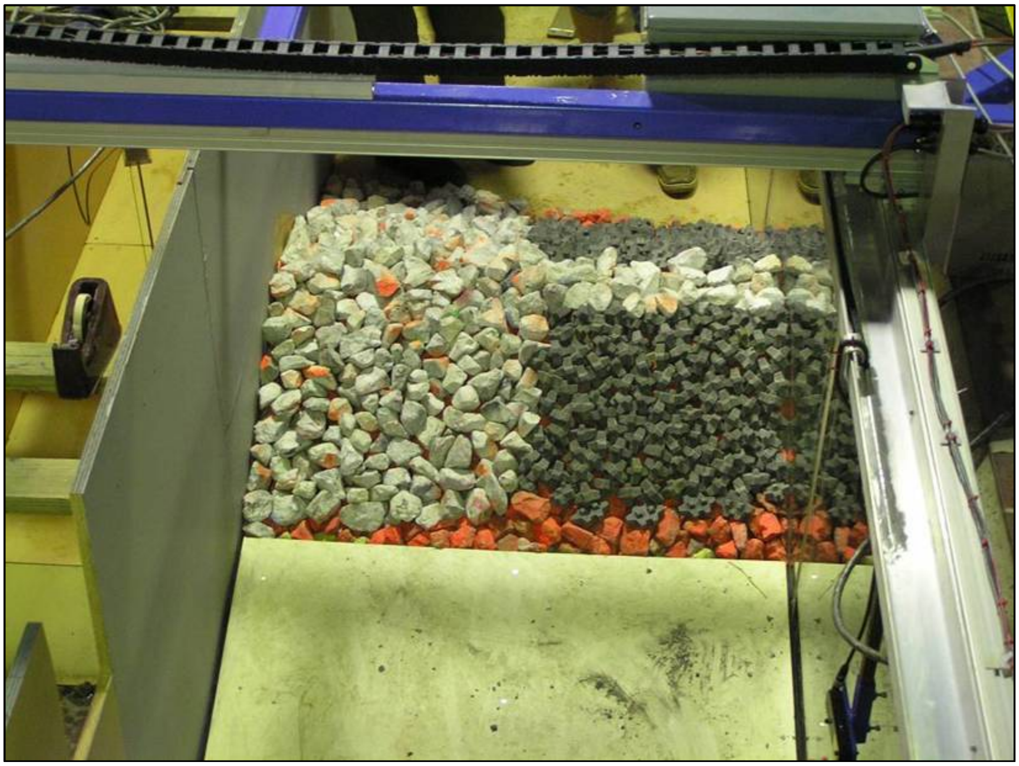

Figure A1- 181. Stone and C-roc Cross Sections in 2-D Model

Figure A1- 182. Overstopping of Cross Section in Model

Figure A1- 183. Stone and C-roc used in Model

Both existing condition and potential design alternative cross sections were modeled. The physical model testing of the jetty cross section resulted in a range of graduated design options that achieve varying levels of structure reliability. These design options were carried forward into the life cycle analysis model of the jetty system. The general categories of plans tested in the physical model included in graduated levels of robustness:

- Existing jetty cross section
- Interim Repair cross section
- Minimum repair cross section possible – encasement
- Increased slope and increased toe berm
- Extended slope cross section
- Combination berm/sideslope cross sections
- Increased crest elevation cross section

b. Model Setup

The Engineer Research and Development Center, Coastal and Hydraulics Laboratory, maintains and operates extensive laboratory facilities used for designing and testing coastal structures. Large two-dimensional wave flumes are used to test designs for rubblemound trunk armor stability and to quantify wave runup, overtopping, and transmission. In addition, these wave flumes are used to explore the physics of water wave propagation, wave transformation and wave-structure interaction. Figure A1- 184 and Figure A1- 185 show the general layout of the 2-dimensional flume used for the study. A 10 ft wide glass-walled flume 208 ft long was used for the MCR jetties study. It is 5 ft deep. The flume is equipped with a computer-controlled electro-hydraulic wave generator. The wave generator was capable of creating irregular waves with a maximum wave height of 0.46 m (1.5 ft), and wave periods of 0.75-10.0 secs. A steady flow system is also an integral part of the flumes. The facility includes an automated data acquisition and control system, extensive fluid measurement instruments and a laser profiling system. To expedite the testing of a large number of jetty cross sections, the 10 ft flume was divided into two 5 ft sections, each containing a separate cross section.

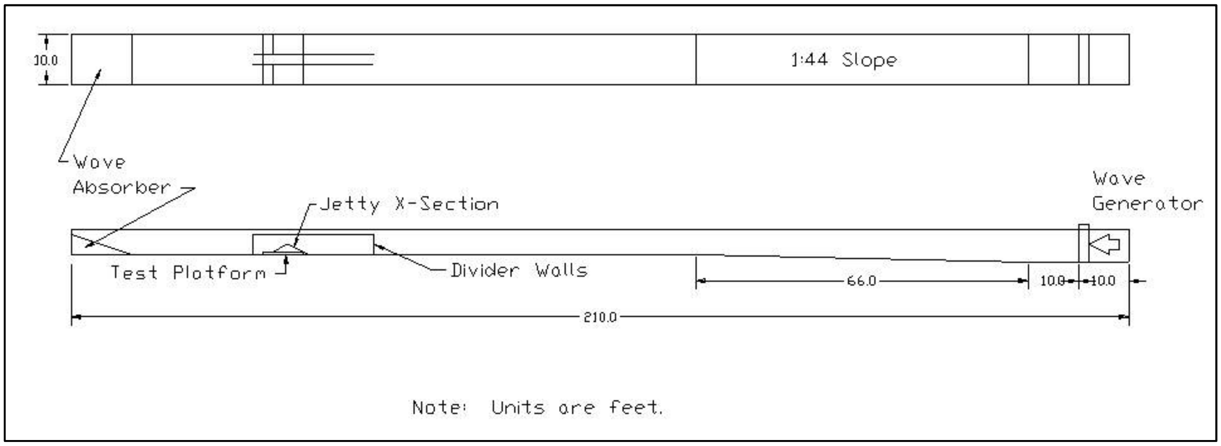

Figure A1- 184. Physical Model Schematic

Figure A1- 185. Physical Model – 10 ft Flume

c. Model Stages

The first task was to evaluate and document the reliability of the existing condition and the interim repair sections for the seaward end of the North and South jetties. Those sections can be seen in Figure A1- 186 and Figure A1- 187. For the North Jetty tests, both existing and interim repair cross sections were conducted with and without a sand lens on the channelside of the structure in place. The intent was to determine if the presence of this transitory sand lens might affect the damage relationship of those sections. Specific damage and performance information was collected in order to define variables for the reliability analysis. Cross sections were tested to identify damage initiation conditions, damage progression and complete failure conditions. Figure A1- 178 through Figure A1- 183 show photos of the model setup.

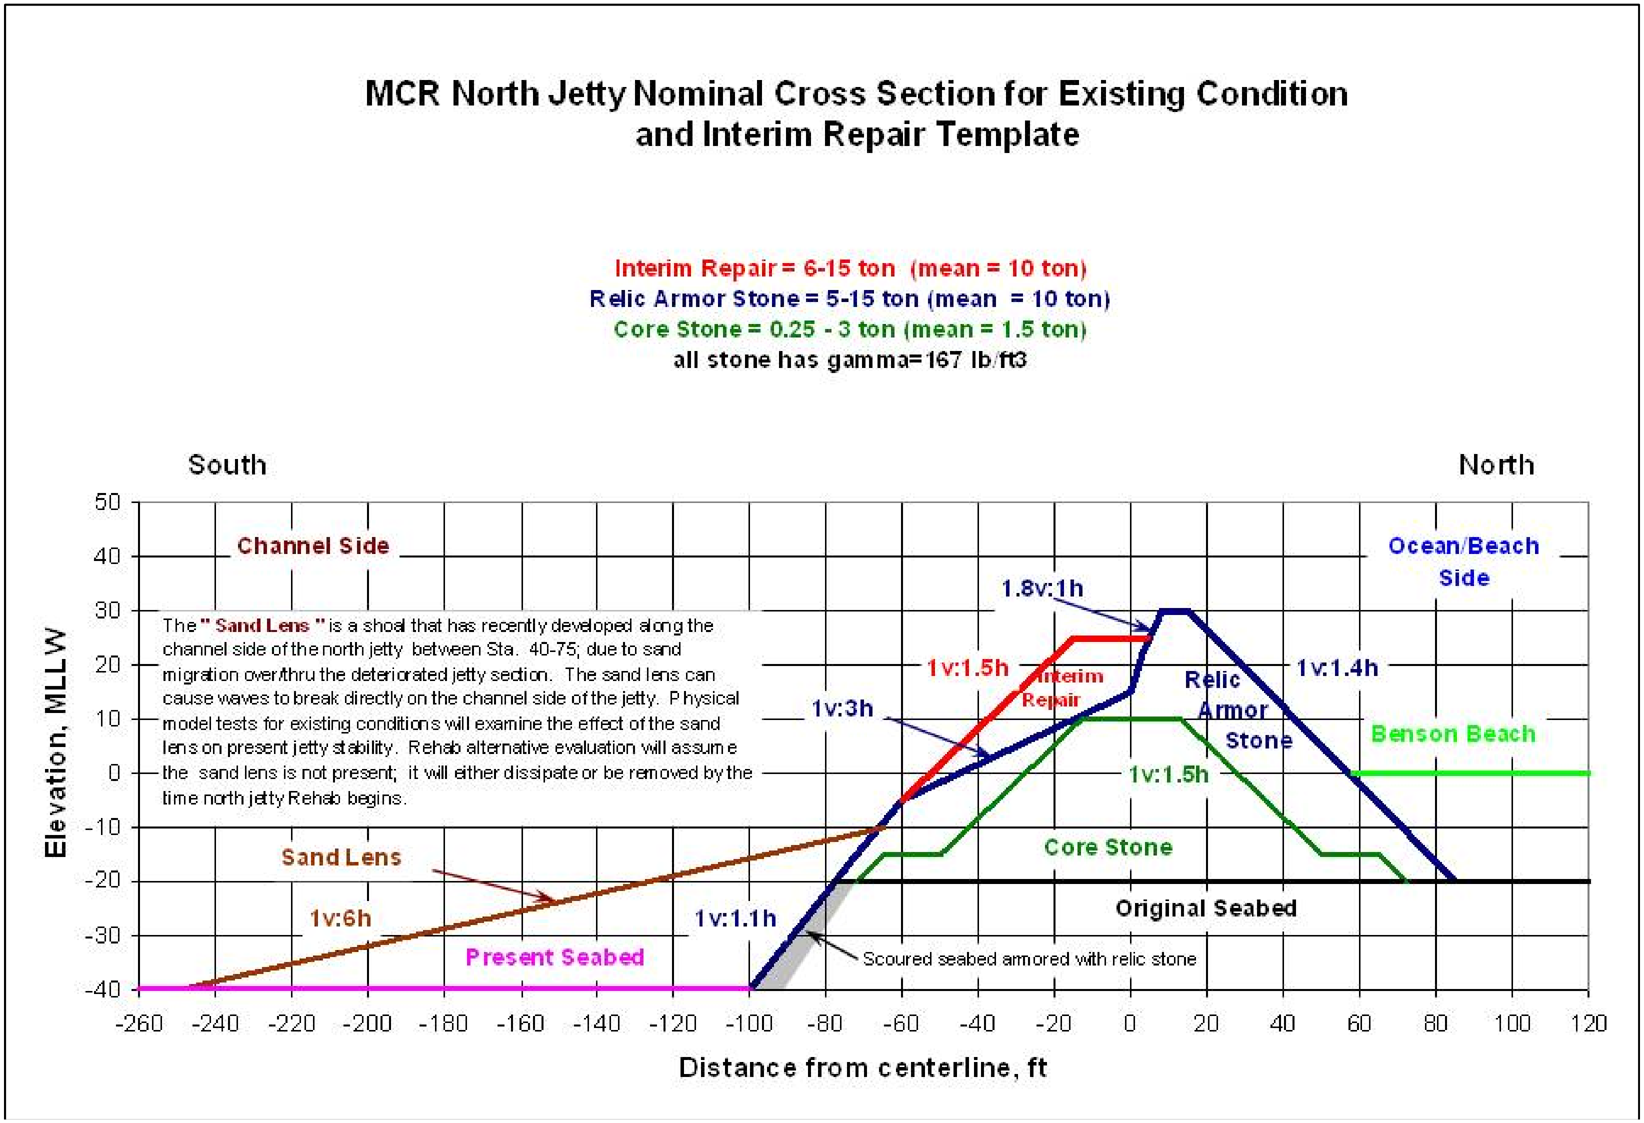

Figure A1- 186. North Jetty Existing and Interim Repair Template

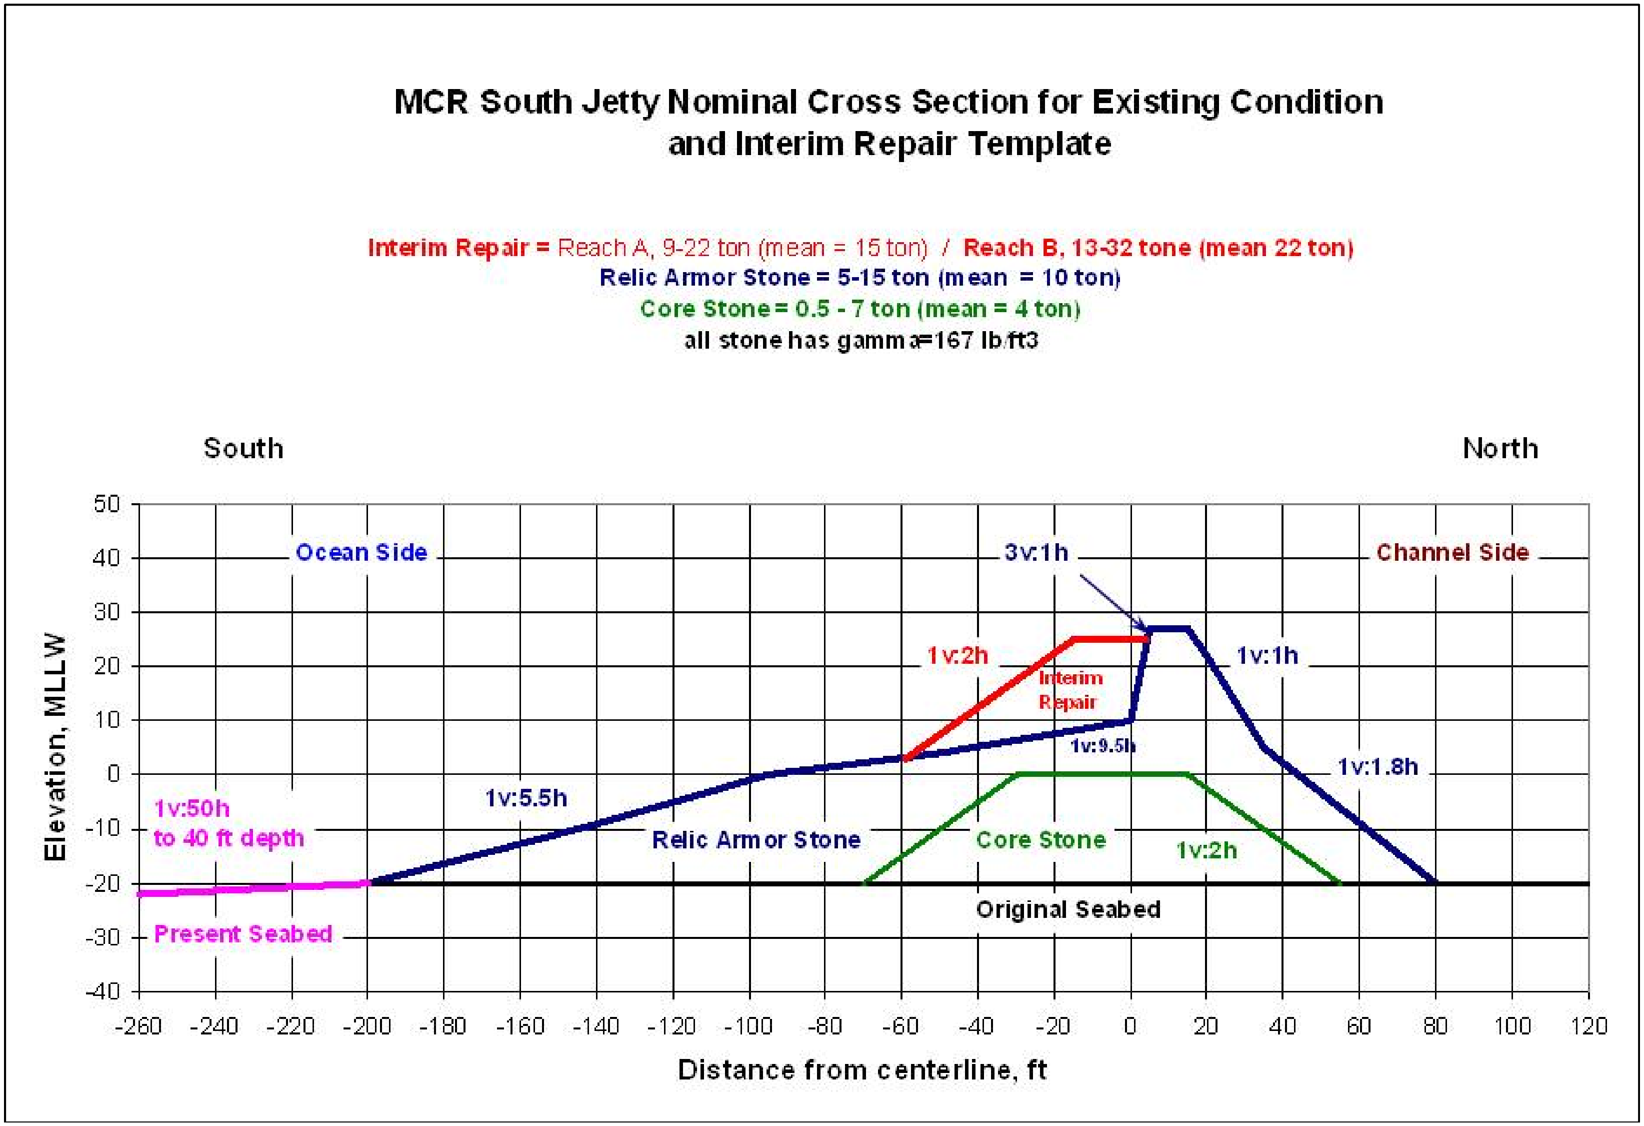

Figure A1- 187. South Jetty Existing and Interim Repair Template

The second task was to quickly run a broad range of potential alternative cross section improvements and material types for the north and south jetties in order to narrow down feasible options for more quantitative testing. The third task was to evaluate and document the reliability of a range of potential alternatives for the seaward end of the north and south jetties. Information obtained from this phase was utilized in the reliability analysis and in development of cross sections for cost estimating purposes.

d. Existing Structure Results

The existing condition is a greatly deteriorated, loosely stacked mound of relic armor stone. The crest has been eroded away to just a single stone width in places. Remaining stones are not well-keyed and are in danger of being displaced. The core stone is thinly covered in places and in danger of becoming exposed. If exposed, core stone is readily washed away and can lead to progressive failure of the structure.

The sand lens shown in Figure A1- 186 is a transient feature. It was necessary to determine if degradation of the jetty was worse with or without the sand lens. Accordingly, tests were conducted with and without the sand lens for both existing and interim repair profiles. With the plywood sand lens removed, the model has a steep 1:1.1 slope from the bottom of the model structure at -20 ft MLLW to the bottom of the flume at -40 ft MLLW. Stability on this slope was not tested. Instead, relic armor stones were glued to a piece of plywood to provide the necessary roughness while the plywood underlayer made an impermeable barrier. The relic stones were loosely placed above -20 ft MLLW following the cross-section. Figure A1-186 shows the model in place for existing conditions without sand lens prior to testing at the high water level. In all cases both a high still water level and a low still water level test were conducted. The model for the existing condition and interim repair (high water without sand lens) were constructed with the aid and assistance of engineers from Portland District.

e. Alternatives Tested

General alternatives and design concepts are summarized below and shown in Figure A1- 188 through Figure A1- 196.

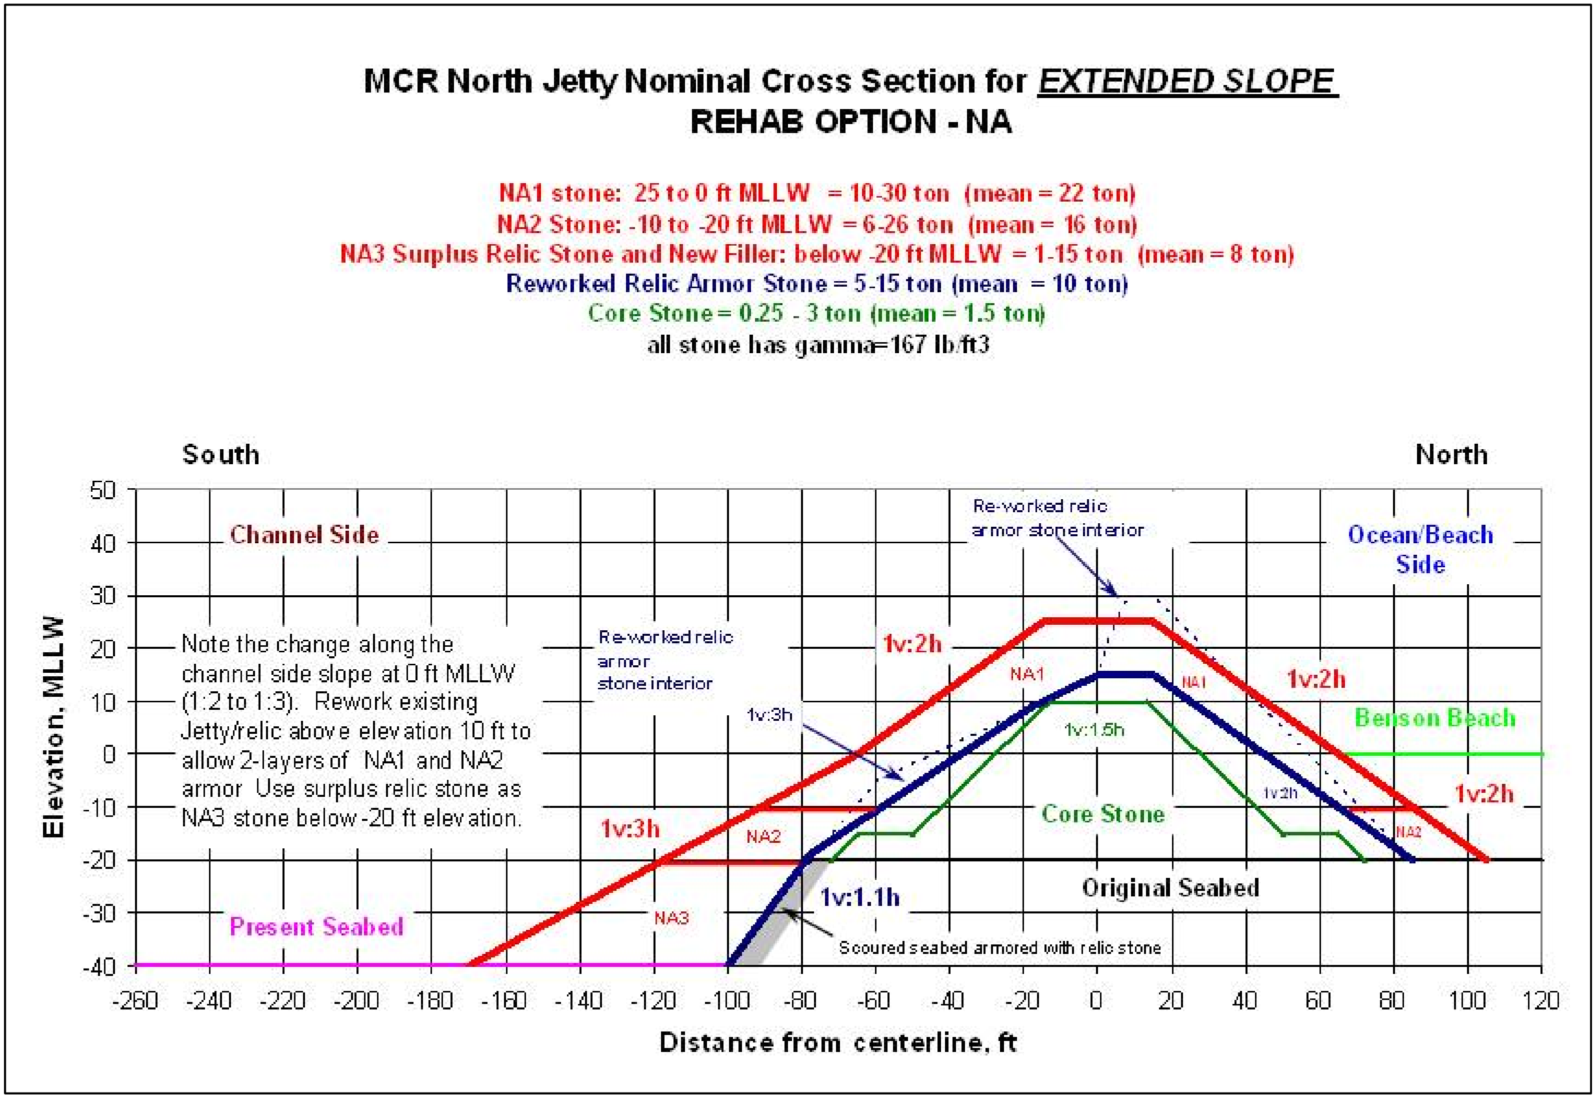

Figure A1- 188. ***North Jetty Extended Slope Section - NA***

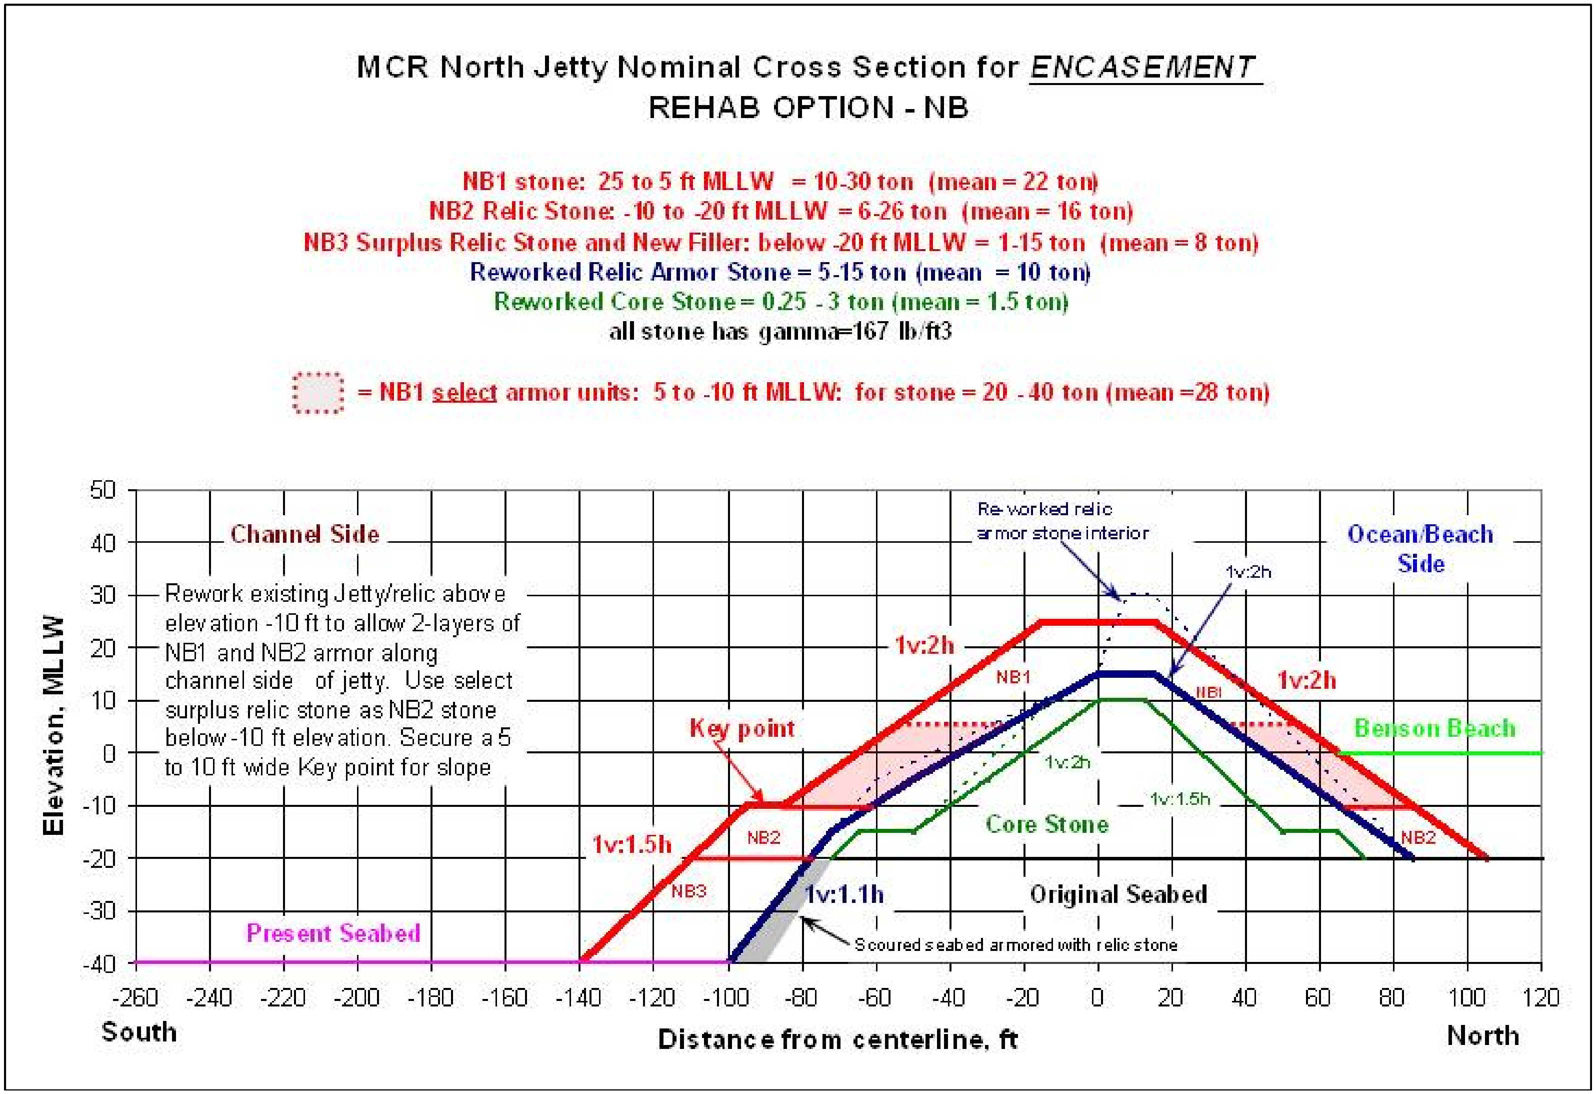

Figure A1- 189. North Jetty Encasement Slope Section - NB

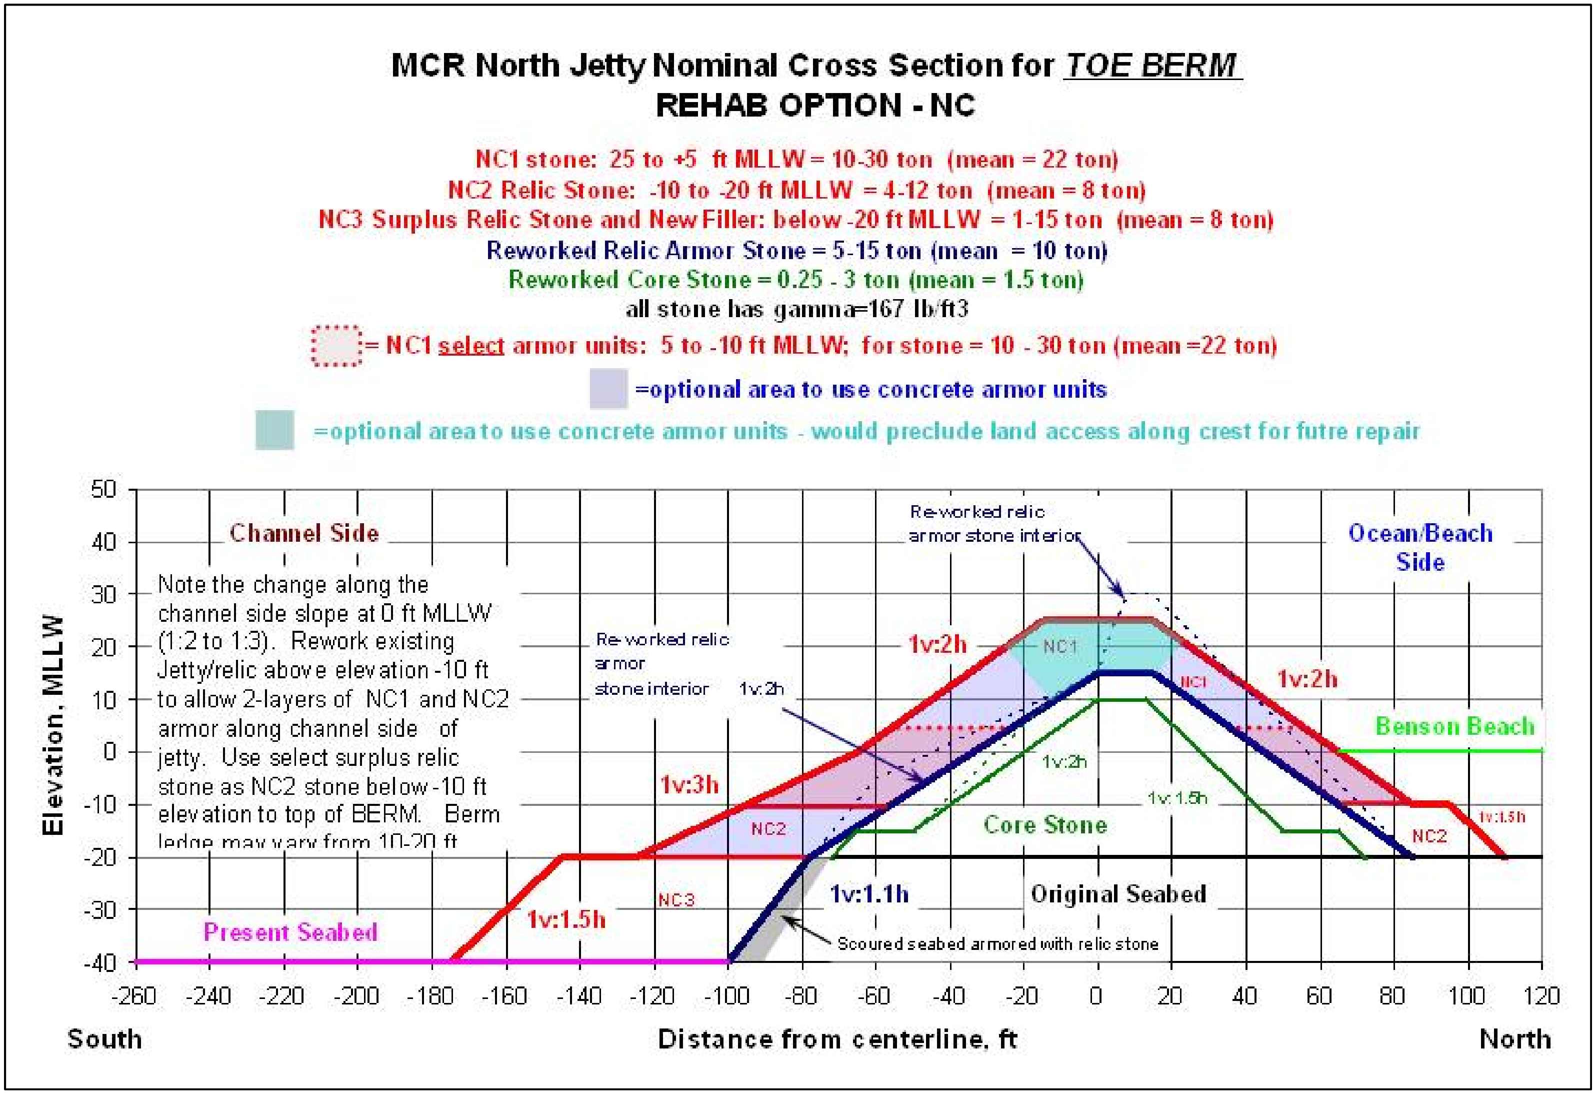

Figure A1- 190. North Jetty Toe-Berm Section - NC

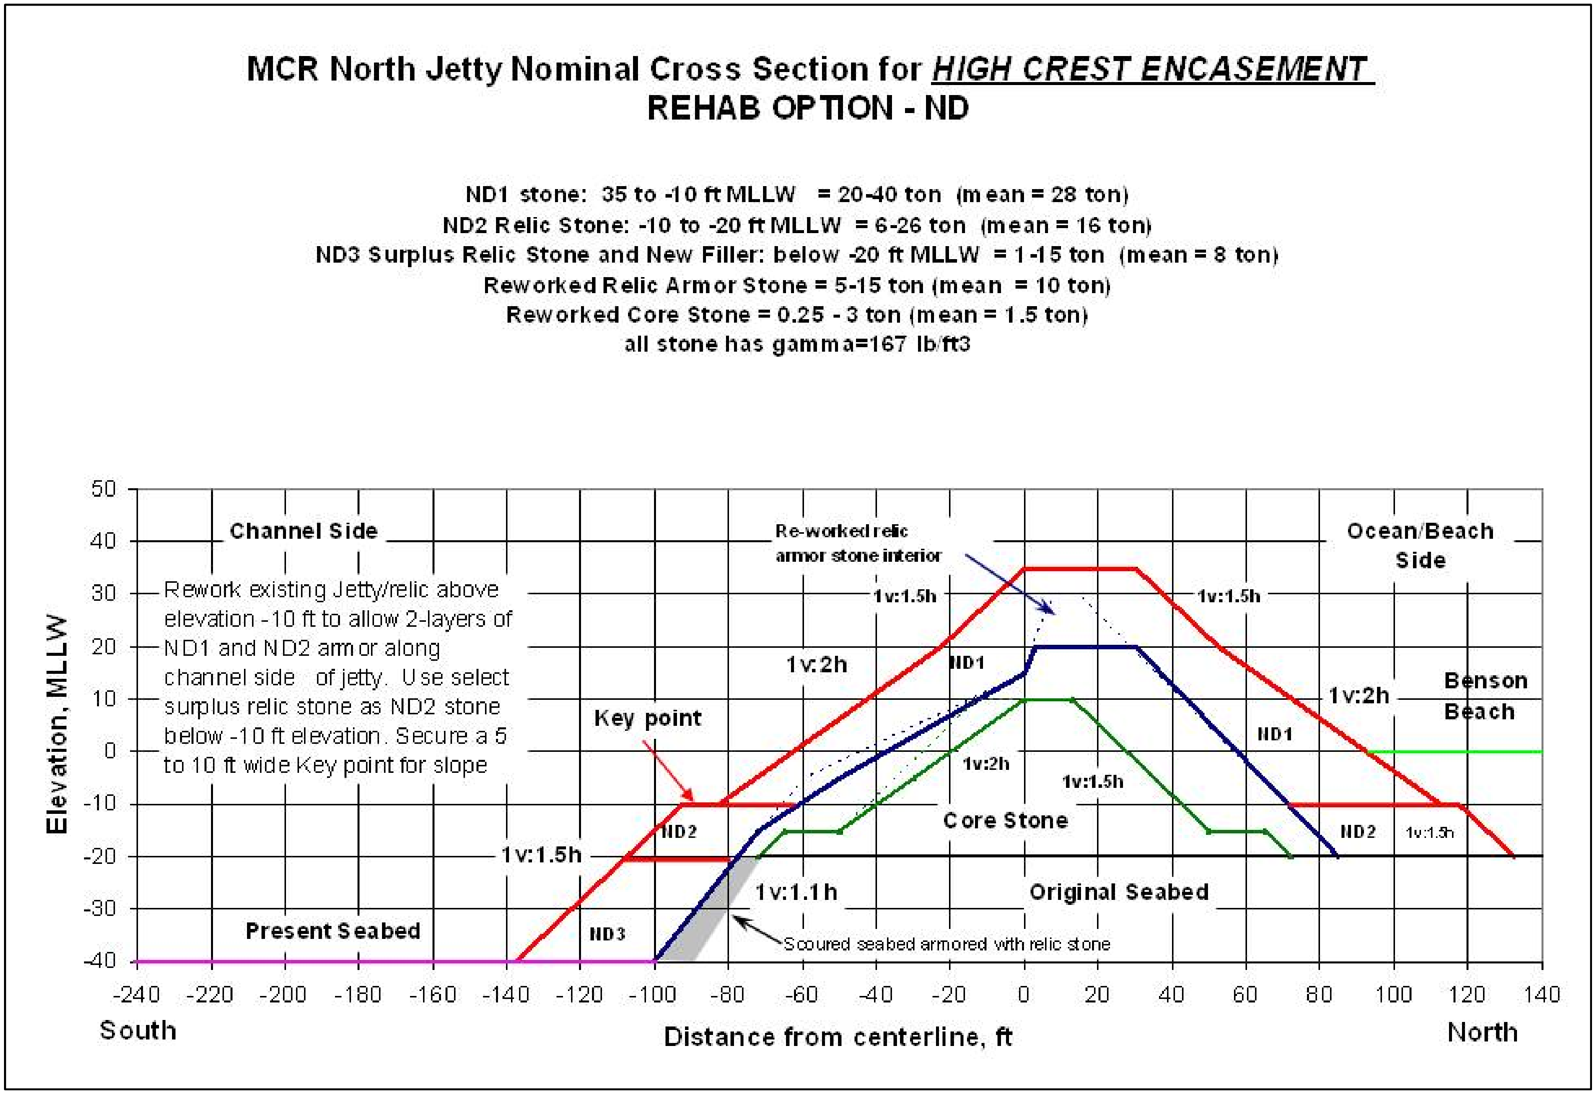

Figure A1- 191. North Jetty Elevated Crest Section

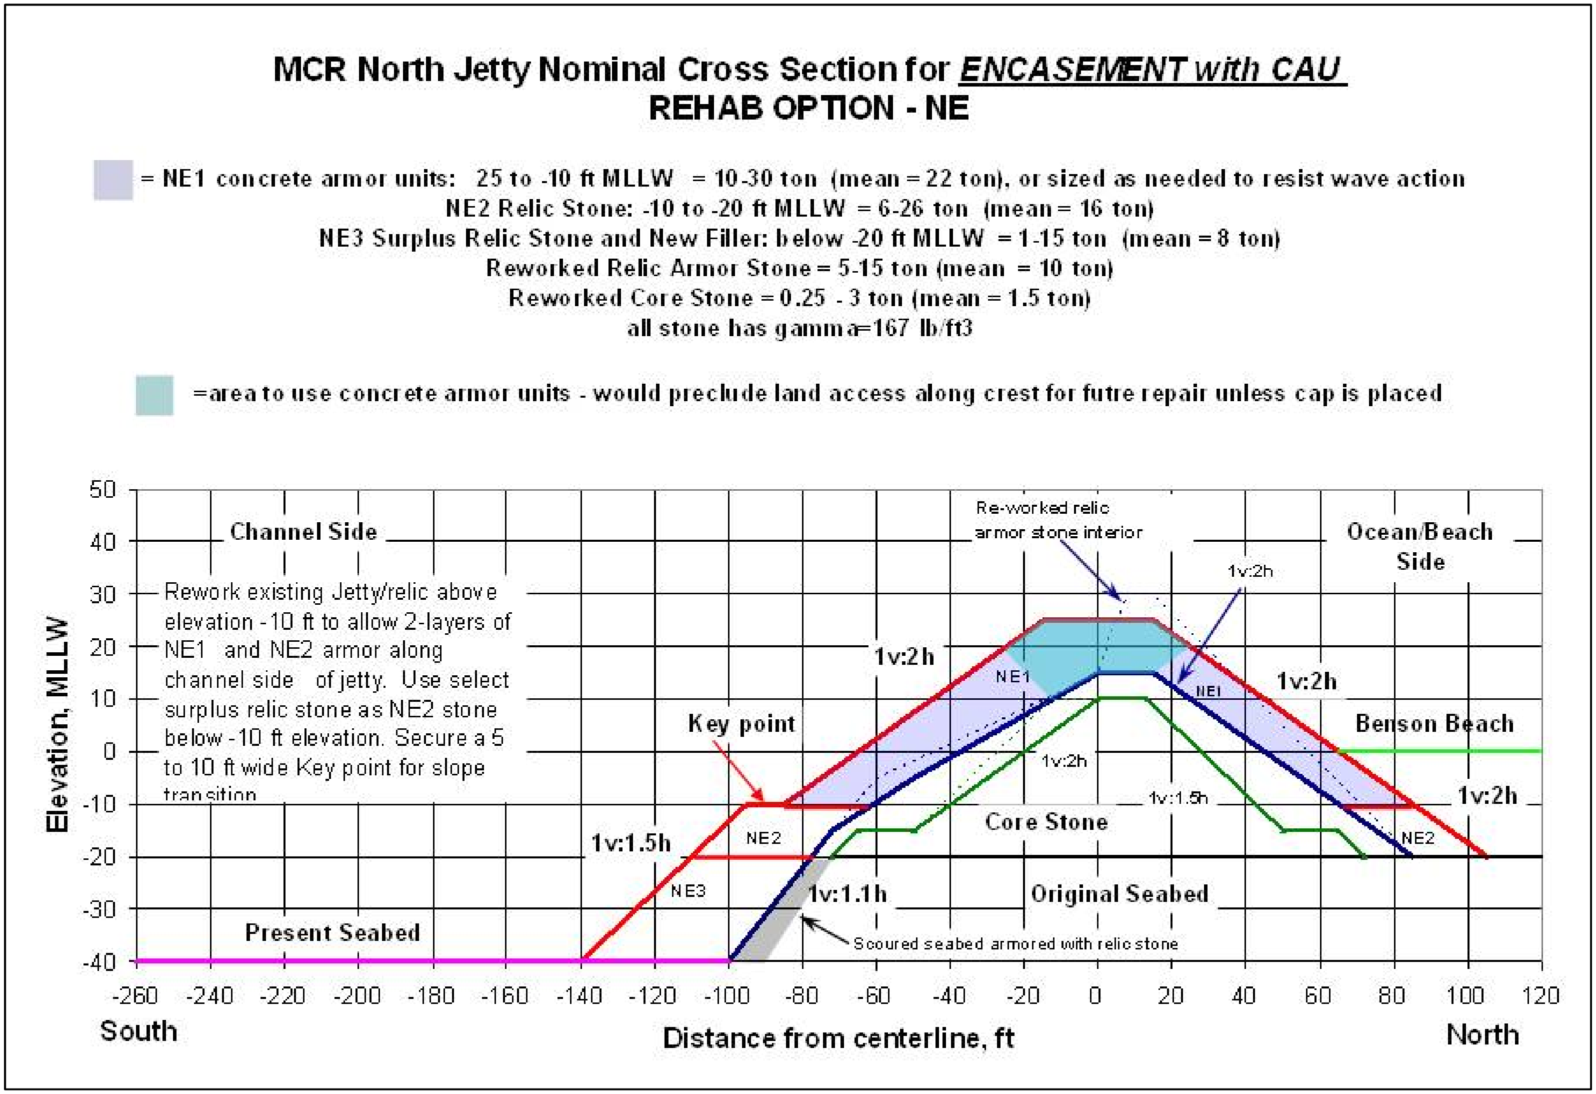

Figure A1- 192. North Jetty Encasement Secton with CAU's

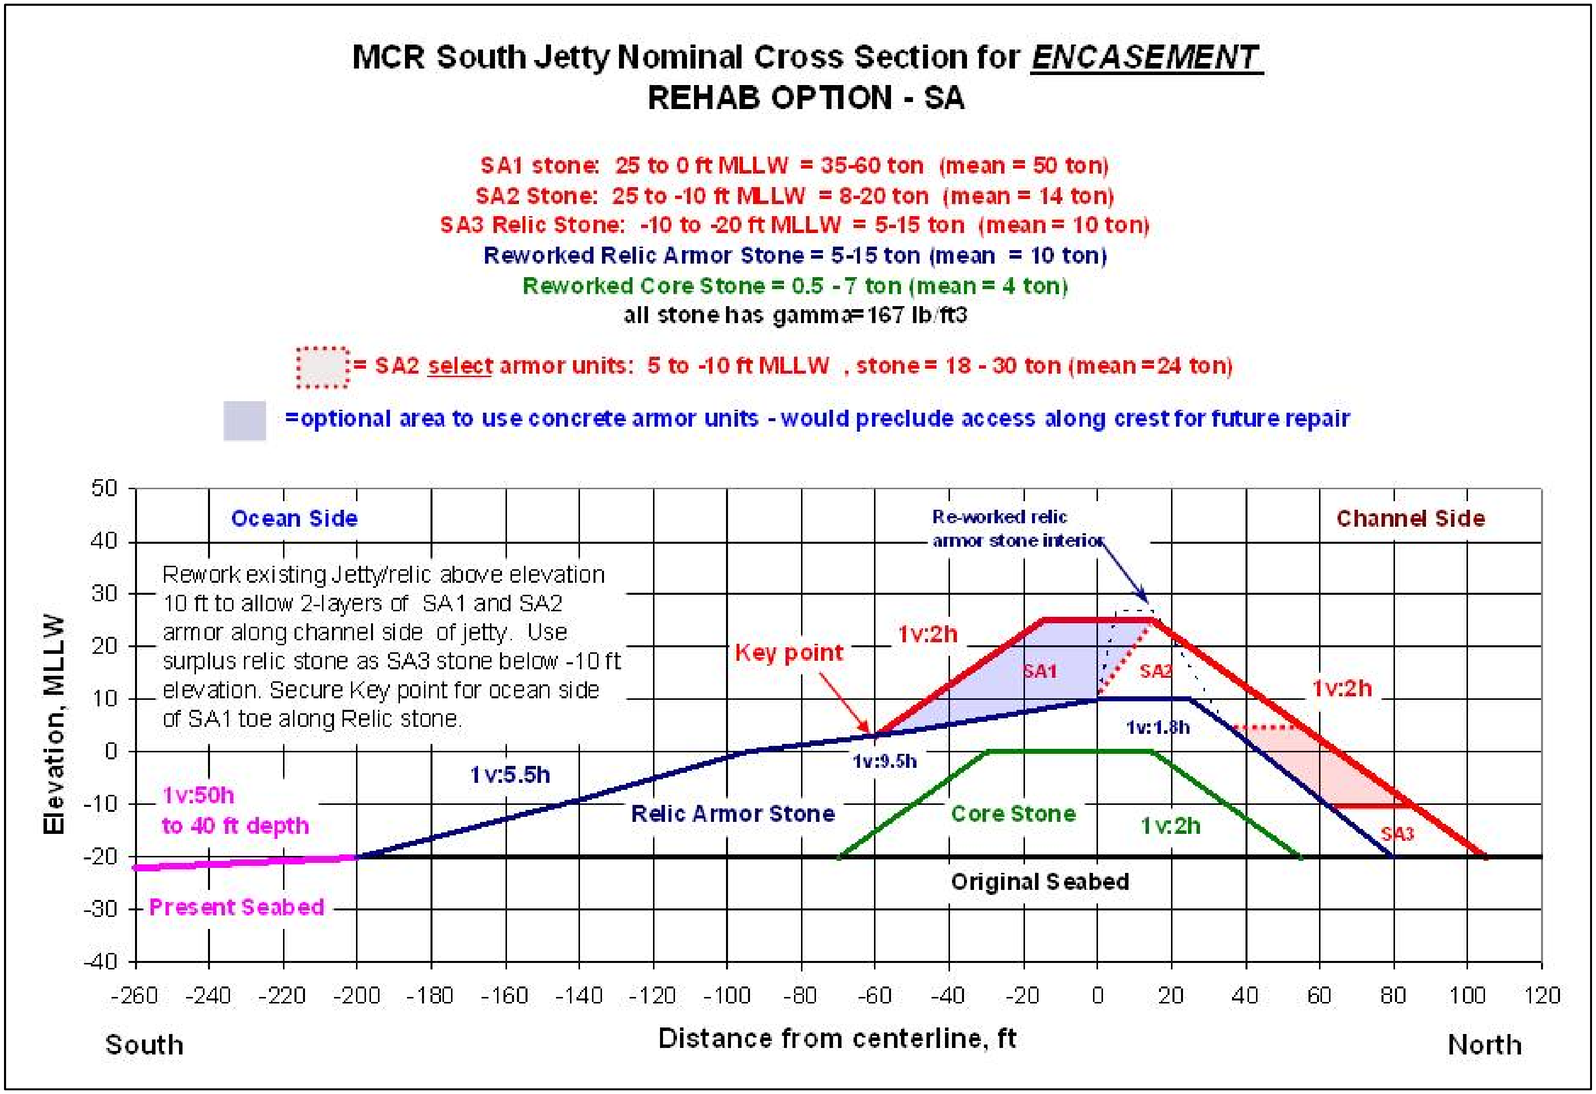

Figure A1- 193. South Jetty Encasement Section - SA

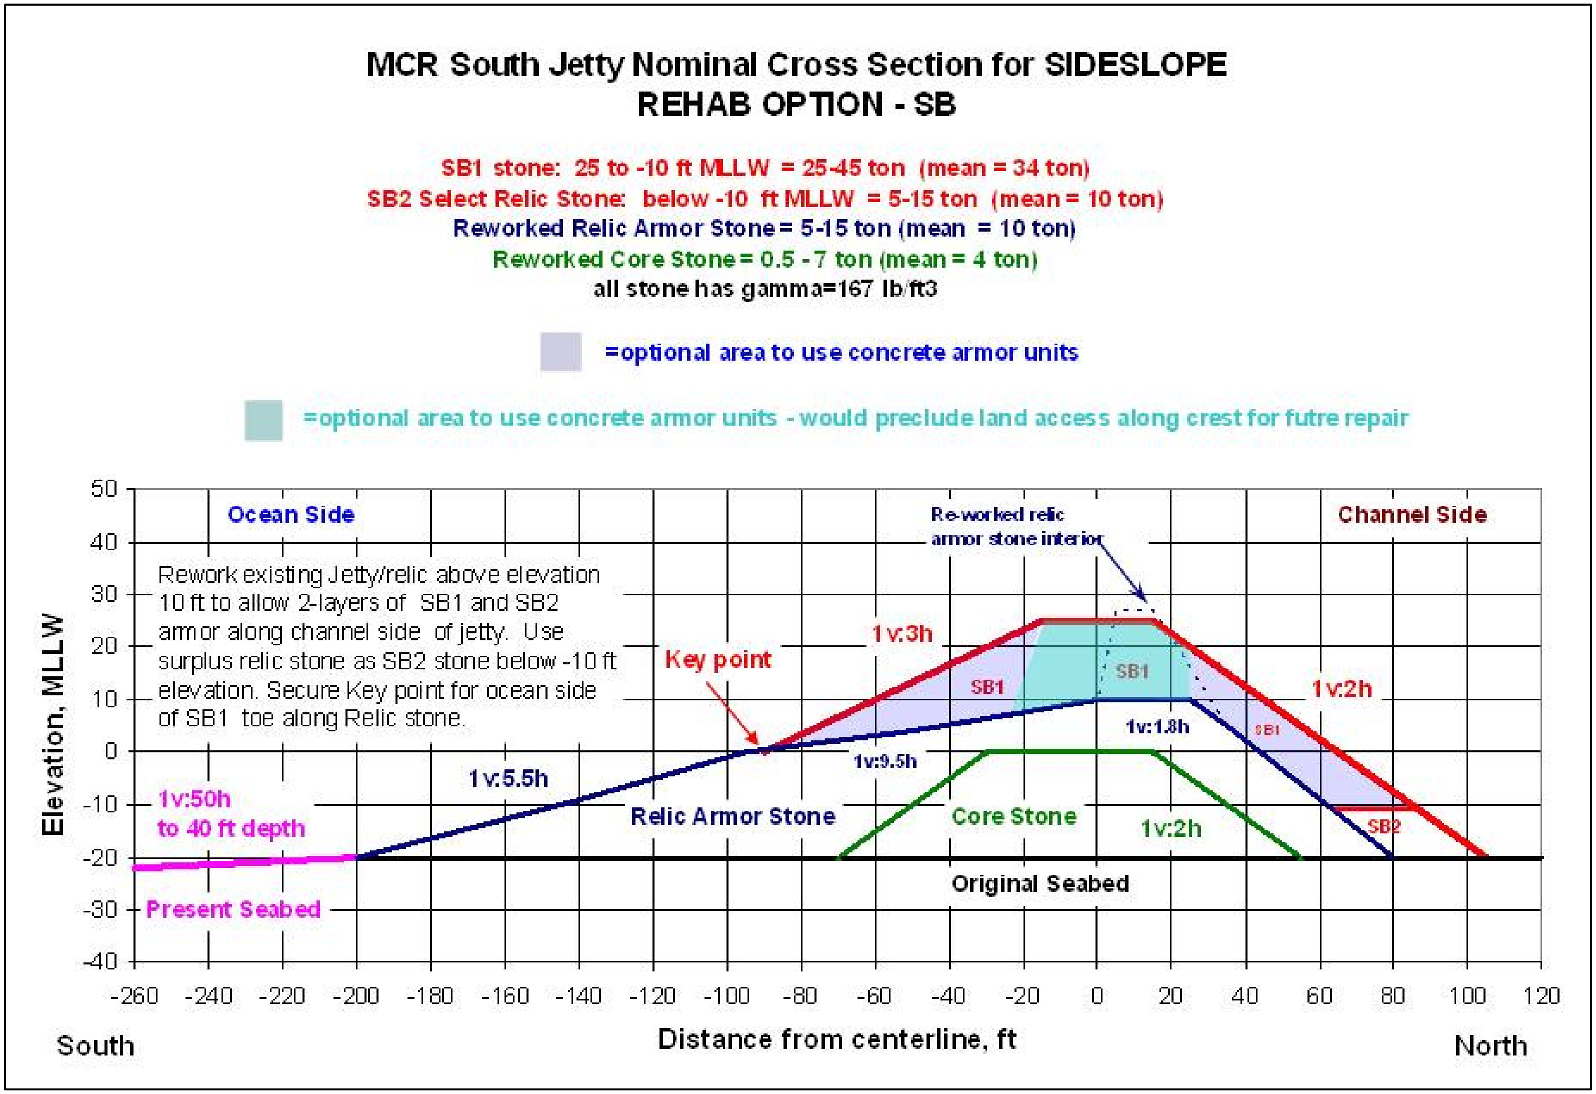

Figure A1- 194. South Jetty Sideslope Section - SB

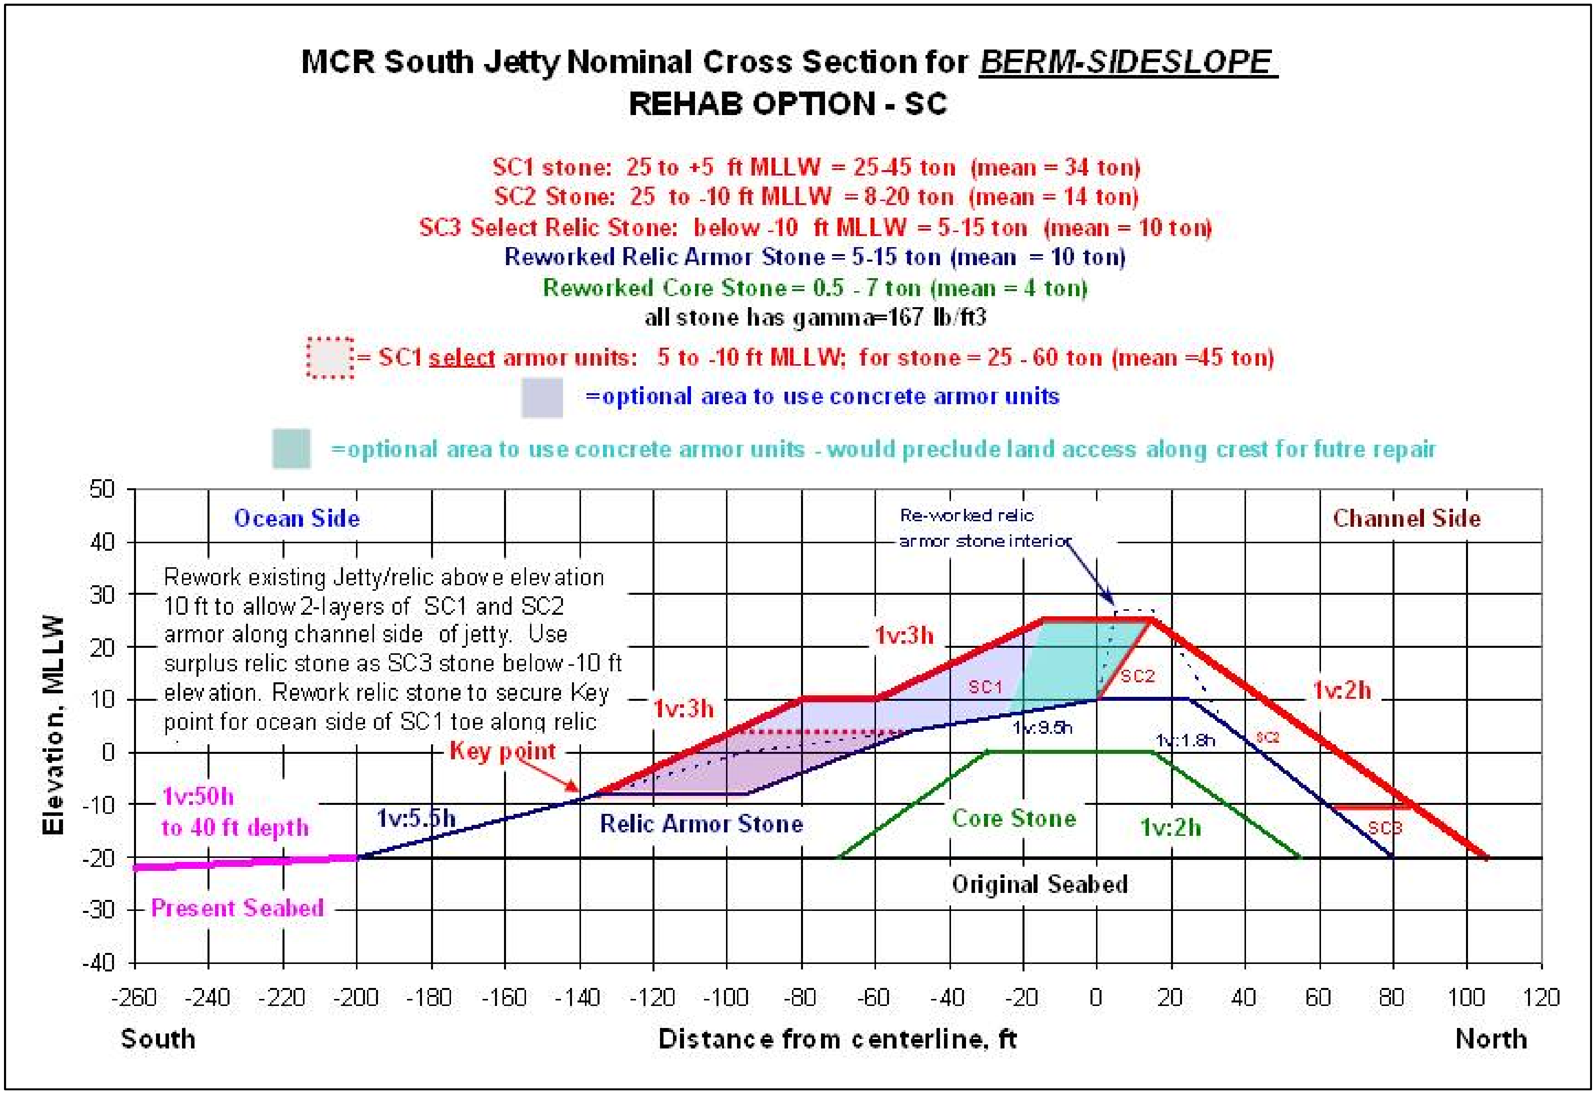

Figure A1- 195. South Jetty Berm Sideslope Section - SC

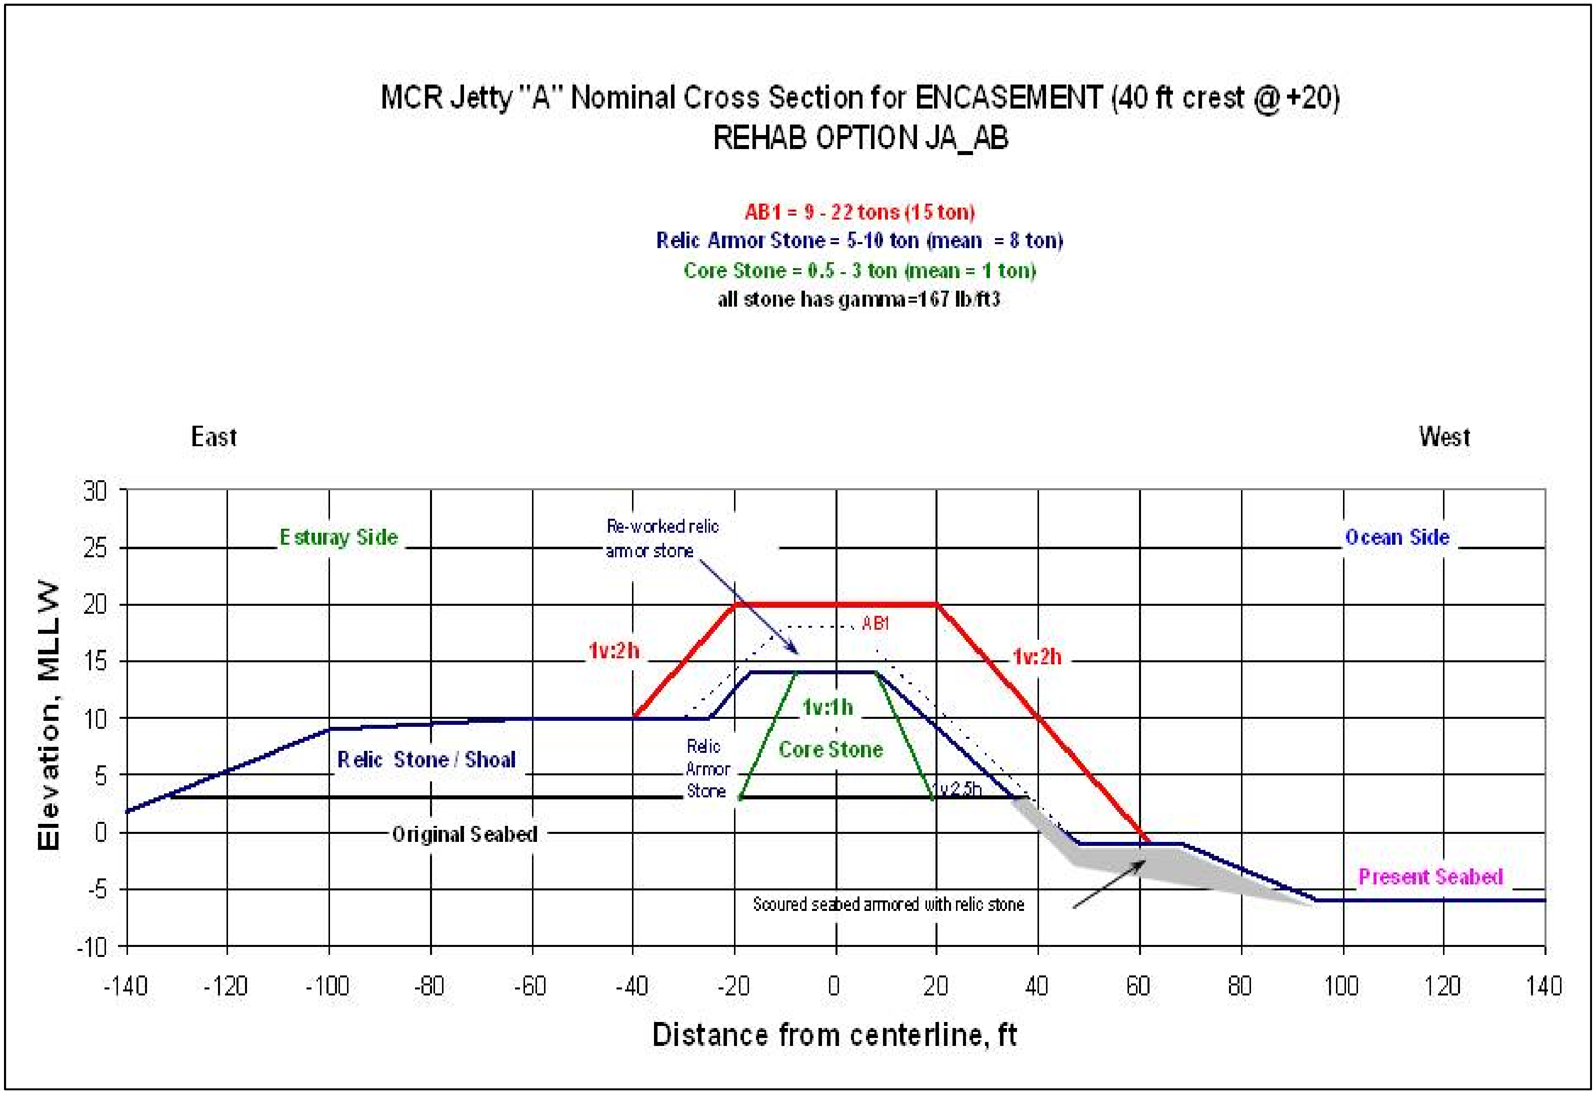

Figure A1- 196. Jetty A Encasement Section – AB

North 1A. Base slope of 1:3 channel side assumed to reduce wave action before attacking upper cross-section with 1:2 slope. 1:3 slope allows smaller armor stone size and forms stable base for some premitigated foundation scour protection. 25 ft crest elevation used to reduce stone quantity. Stone size increased from 10-30 tons to 20-40 tons based on initial model study results that indicated that 10-30 ton armor stone was too small. The effect of using 1:3 slope may be acting to 'ramp' waves onto the cross-section producing more severe wave damage. If true, this result is counter-intuitive to the hypothesis that a flatter slope makes more stable slope.

North 1B. Base slope of 1:1.5 channel side used to reduce stone volume along lower part of cross section, while providing a minimal bench to allow a key point for supporting a less steep upper cross section with 1:2 slope. NB1 select stone provides resistance to wave action near SWL where wave action is assumed to be worst. 25 ft crest elevation used to reduce stone quantity.

North 1C. Basal berm with bench used to serve as advance mitigation for toe scour to defer destabilization of lower and upper slope of jetty for 50 years. Berm to be constructed of small stone with slope of 1:1.5 to minimize volume. 1:3 mid-slope allows use of lower armor stone size and was assumed to dissipate wave action. Upper slope on channel side 1:2 to reduce stone volume. NC1 Select stone provides resistance to wave action near SWL, where wave action is assumed to be worst. Application of CAUs (concrete armor units) proposed as an option along upper slope. Berm and bench on beach side to premitigate toe scour. 25 ft crest elevation used to reduce stone quantity.

North 1D (improvement on 1B). 35 ft crest elevation used to eliminate wave overtopping and related instability on lee side. Stone size increased along entire upper cross section to reduce wave damage. Composite upper slope (1:1.5 to 1:2 variation) used to reduce stone volume. Assumed that above 20 ft MLLW, wave action is reduced such that 1:1.5 slope can be used. Improvement made in response to initial model study results that suggested wave overtopping crest of jetty was destabilizing crest and back slope.

North 1E (improvement on 1A). Concrete armor units used instead of stone to increase slope resistance to wave action. Improvement made in response to initial model study results that suggested wave overtopping crest of jetty was destabilizing crest and back slope due to undersized armor stone. Front slope of 1:3 may also be acting to 'ramp' waves making wave action more severe.

f. Results of Alternative Models Tested

Physical modeling results showed that the primary failure modes for the North/South jetties were high water level wave attack and overtopping. Individual results are summarized below.

1. Armor Unit Assessment:

- Majority of North Jetty can be reliably designed using attainable rock; seaward head of jetty may require advanced design.

- On the channel-side front face, 22-ton stone is too small (option A), 28-ton stone is marginal (option F) for a 1:2 slope.
- Channel-side toe of 16-ton stone between -10 ft and -20 ft MLLW and 8-ton stone down to -40 ft MLLW works very well at least when tested at high water (options A, D, F).
- Channel-side toe of 16-ton stone between -10 ft and -20 ft MLLW and 8-ton stone down to -40 ft MLLW works very well at least when tested at high water (options A, D, F).
- Ocean side toe: 16-ton stone from -10 ft to -20 ft MLLW worked well.
- Inner half of South Jetty can utilize rock; outer half may require combination approach.
- Dolos did not hold up well in the tests; very flat slopes needed.
- C-roc appeared to hold up well during the preliminary testing (concerns regarding C-roc application include question of reliability of one-layer system, never field-tested, elaborate construction control requirements, and uncertainty about interlocking with relic base).

2. Cross Section Element Assessment (preliminary):

- Heavy overtopping may require special crest and leeside design in some areas.
- Large toe berm not needed on South Jetty due to existing relic base.
- Sideslopes of 2 to 3 provide reliable section designs.

3. Damage Relationship Information Used in Reliability Analysis and Design:

- Existing and interim damage relationships define base condition.
- Various alternative damage relationships define alternative reliability.
- Alternative information interpolated for design based on position on jetty.

11. Engineering Features that Address System Degradation

a. General

Since original jetty construction, several large physical process changes have altered the current and projected future reliability of the system. It has been shown that as increased channel depths have been secured within the MCR inlet, larger waves are able to enter the channel and attack the jetties in addition to undermining the sandy foundation upon which they rest. These increased depths primarily affect the interior underwater shoals and the channelside of the jetties, and in particular the North Jetty, which is closer to the navigation channel.

Along the landward half of the North Jetty, another de-stabilizing flow path has developed through the structure as tidal flow moves through the structure to the accreted part of Peacock Spit, along the north side of the structure. In addition increased storm activity and intensity over recent decades has accelerated adjacent shoreline erosion exposing the deteriorated jetty root structure on both the North and South jetties.

The jetties continue to recede back from their original length. The South, North, and Jetty A head positions are currently shorter than authorized lengths by 6,200 ft, 2,200 ft, and 900 ft, respectively. Due to the interaction of wave patterns and currents with jetty configuration, the shorter jetty lengths can increase underwater shoal erosion and motivate increased recession of shoreline position adjacent to the jetties. Loss of jetty length also exposes the remaining structure to increased forces. Engineering features evaluated are summarized below.

South Jetty Existing Spur Groins. Historical records indicate that six spur groins were constructed along the channelside of the South Jetty. A 115-ft long spur was built landward of the jetty for shore protection. A 510-ft long sand-catch, consisting of heavy beach drift and loose brush, was built on the south side of the landward end of the jetty to continue filling the old outlet of a lagoon at the extreme end of Point Adams. Four of the groins are buried by accreted shoreline or sand shoal. The two visible seawardmost spur groins at approximately Stations 309+33 and 333+46 clearly show an influence on the surrounding underwater contours. The 100-ft spur groins push channelward the location of the more extreme tidal velocities so that the shoal material at the base of the jetty is stabilized. Figure A1- 57 illustrates the important effect these small features have on the surrounding contours. Even with the larger spacing of approximately 2500 ft between the groins, each one has a positive impact on stabilizing the underwater shoal and protecting the South Jetty. Processes important to long-term structural stability of the jetties that these small structural features help with include (1) offsetting the loss of jetty length and ebb tidal shoal extent and (2) offsetting the shoreline erosion occurring at the root of the jetty.

The basic purpose of jetties is to control and focus tidal velocities to a constricted area in an ocean inlet so that a navigation channel can be reliably maintained. An unintended consequence of that action is that the increased tidal velocities have the tendency to scour the foundation of the very structures that are channeling their flow. The majority of the spur groins proposed and analyzed in this study are intended to perform similar functions to the existing spurs on the channelside of the South Jetty. Those functions are to reduce the scour along the foundation of the jetty by reducing the velocity of the localized current that can develop along the length of the jetty along certain times in the tidal cycle. The intent is to reduce the bottom velocity only in a localized area along the base of the jetty. Since there is such a long distance between the jetties (about 2 miles), any application of spur groins at this inlet has a very localized hydrodynamic effect. Experience along the South Jetty has shown that spur groins work effectively at maintaining the critical shoal foundation supporting the jetty structure. One additional purpose for spur groins was evaluated and that was to slow down the adjacent shoreline erosion occurring on the oceanside at the jetty root. Both the North and South Jetties have experienced increased erosion at those locations.

Jetty Length Rebuild and Stabilization. All three jetties have receded significantly from their original authorized length and the protective jetty head construction has been lost. Continued jetty head recession is expected to occur at a rate of 5 to 50 feet per year, depending on the jetty. Due to the interaction of wave patterns and currents with the jetty configuration, the shorter jetty lengths can increase underwater shoal erosion as well as influence shoreline position adjacent to the jetties. Due to its increased exposure to wave attack from all directions as well as its critical protective function for the rest of the structure, the jetty head design is much more substantial than a typical jetty trunk section. Determining how much of the original jetty structure should be rebuilt and where the actual jetty head should be constructed was an important element of study. Parameters evaluated in assessing recommended jetty length included possible impacts on tidal velocities and salinity, protecting the navigation entrance from waves, impacts on adjacent shoreline and ebb tidal shoal erosion, and impacts on dredged material disposal activities. The extent and distribution of the relic stone base left over from past construction efforts played a role in determining a cost-effective location for jetty head construction (Figure A1- 197 illustrates a similar jetty capping application at Yaquina North Jetty).

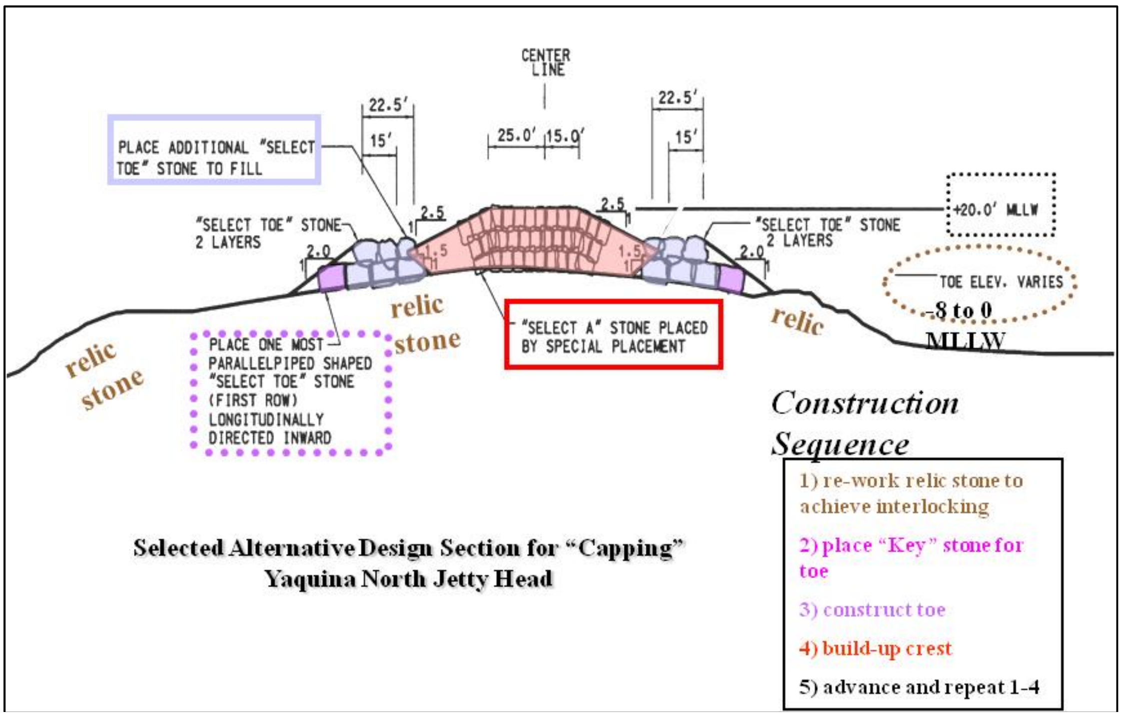

Figure A1- 197. Yaquina North Jetty Head Cappign Section

Erosion Areas at Jetty Root. An apparent increasing wave climate, erosion of the large ebb tidal shoal, and continued recession of the jetty lengths have all contributed to erosion of the shoreline adjacent to the jetty root for the North and South jetties. In addition, along the landward half of the North Jetty, another de-stabilizing flow path has developed through the structure as tidal flow moves through the structure to the eroded lagoon behind the structure.

b. Spur Groins

The present environment affecting the MCR jetties requires the application of spurs along each jetty to prevent the continual undermining of each jetty's foundation. This type of application has been used effectively both at MCR as well as other Pacific Northwest navigation entrances. A jetty spur or spur groin is a relatively short structure (in comparison to jetty length) extending outward from the main axis of a jetty. Spur groins are constructed for a range of reasons dealing with the need to effect currents and sediment transport along the jetty. Two prominent reasons why spurs are implemented are:

1. On the ocean or beach side of jetty, to deflect the longshore (rip) current and related littoral sediment away from the jetty and prevent littoral sediment from entering the navigation channel (Figure A1- 198); Figure A1- 199 illustrates how jetty length recession can also impact shore tie-in erosion conditions.
2. On the channel side of a jetty, to divert the tidal or river current away from the channel side toe of the jetty. In this application, spur(s) act to reduce the scour at the affecting the jetty's foundation while increasing the current in the navigation channel thus reducing the deposition in the channel.

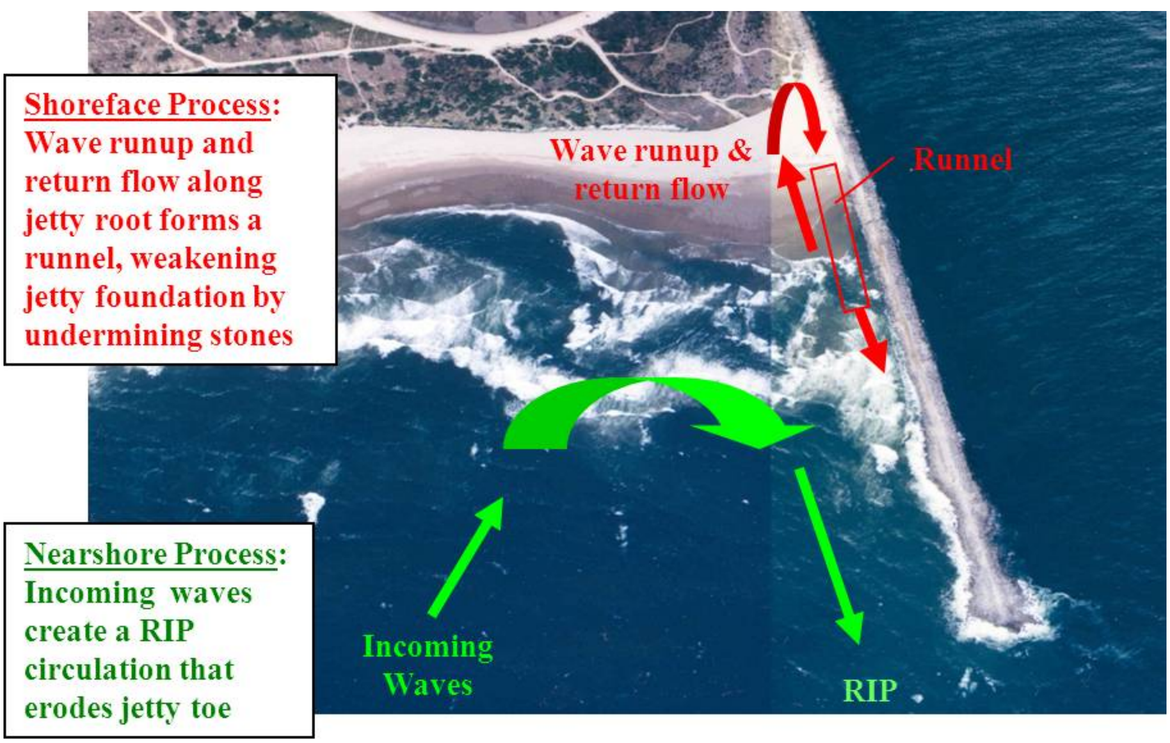

Figure A1- 198. Wave Run-up and Return Flow along Root of Jetty

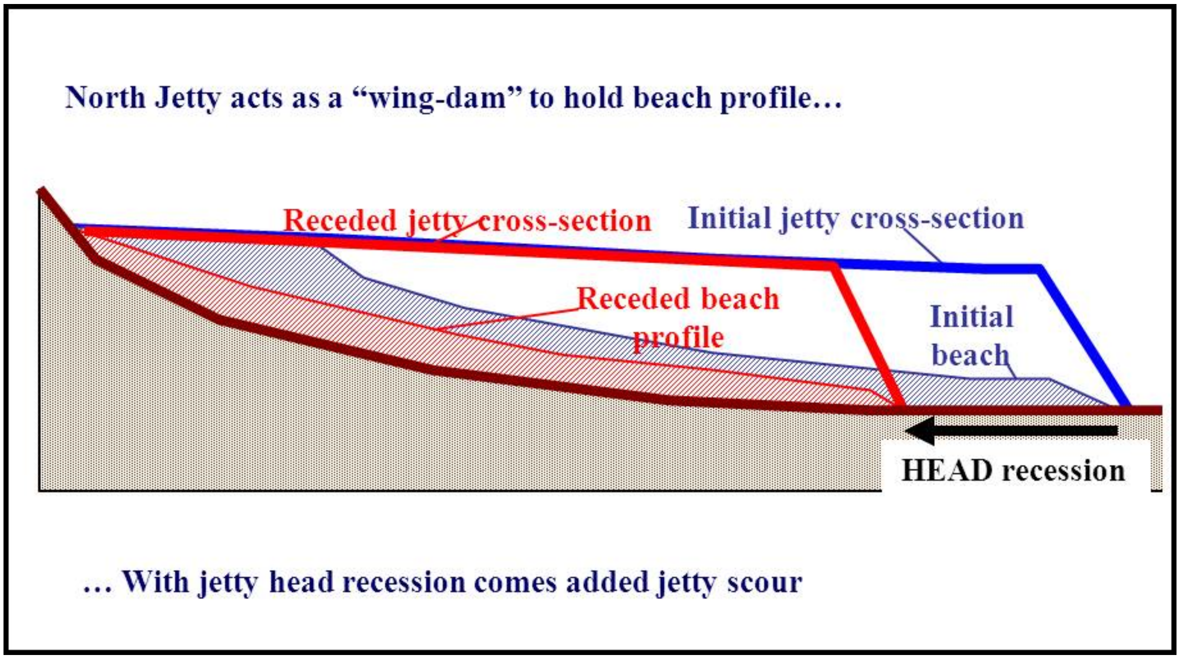

Figure A1- 199. Illustration of Jetty Length Operating as a Wing-dam

Spur application at a coastal inlet can be complex due to reversing tidal flow in the channel, possibly different primary flood and ebb flow channels, wave forcing, and wave-current interaction. Spurs are needed along each MCR jetty (on each side) to reduce the bottom current affecting the toe of the structure. See Figure A1- 200 for an illustration of existing spur groin influence along the channelside of the South Jetty at MCR.

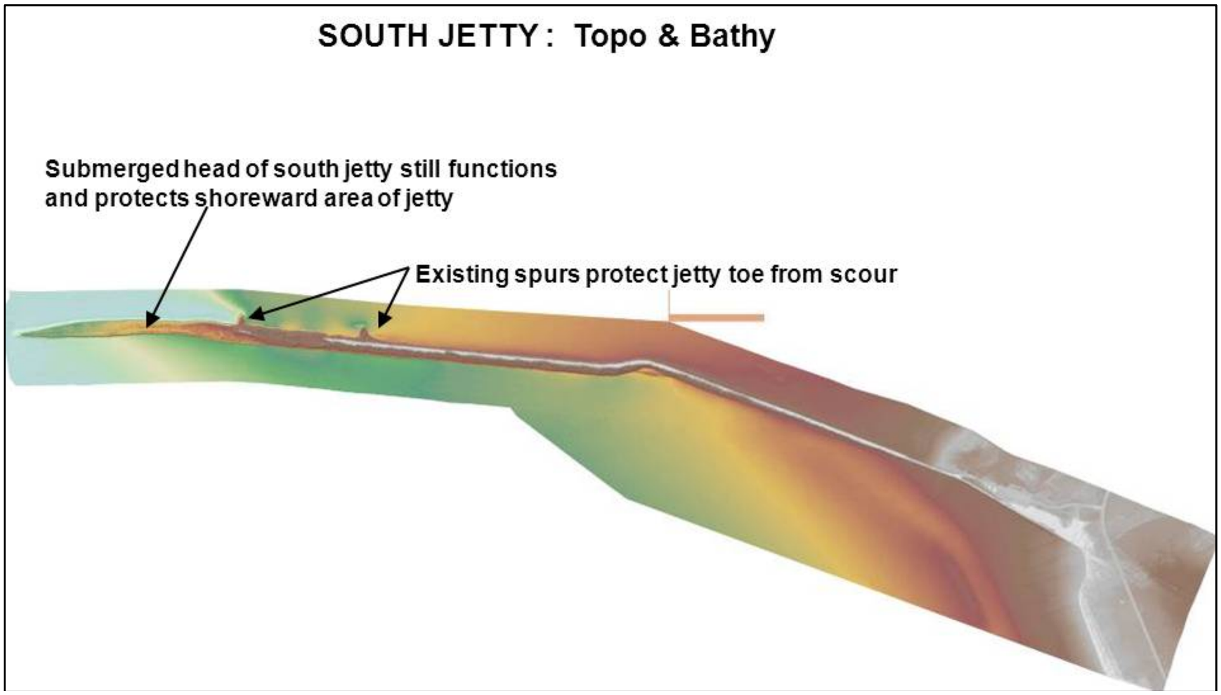

Figure A1- 200. Groins and Bathymetry around South Jetty

A range of information was utilized in developing recommended spur groin applications along the three jetties at MCR. The recommended plan was determined within the framework of trying to specify the lowest impact spur groin layouts (size and number of spurs) suitable to achieving the intended long term stability of the structures. Information utilized included knowledge of problem erosion areas along the three primary jetties, experience of spur groin application at MCR South Jetty and Yaquina South Jetty, observation of jetty relic stone wing impacts on shoreward sedimentation, other spur groin studies, and numerical hydrodynamic modeling. Figure A1- 201 and Figure A1- 202 illustrate a similar spur groin application at Yaquina Bay entrance.

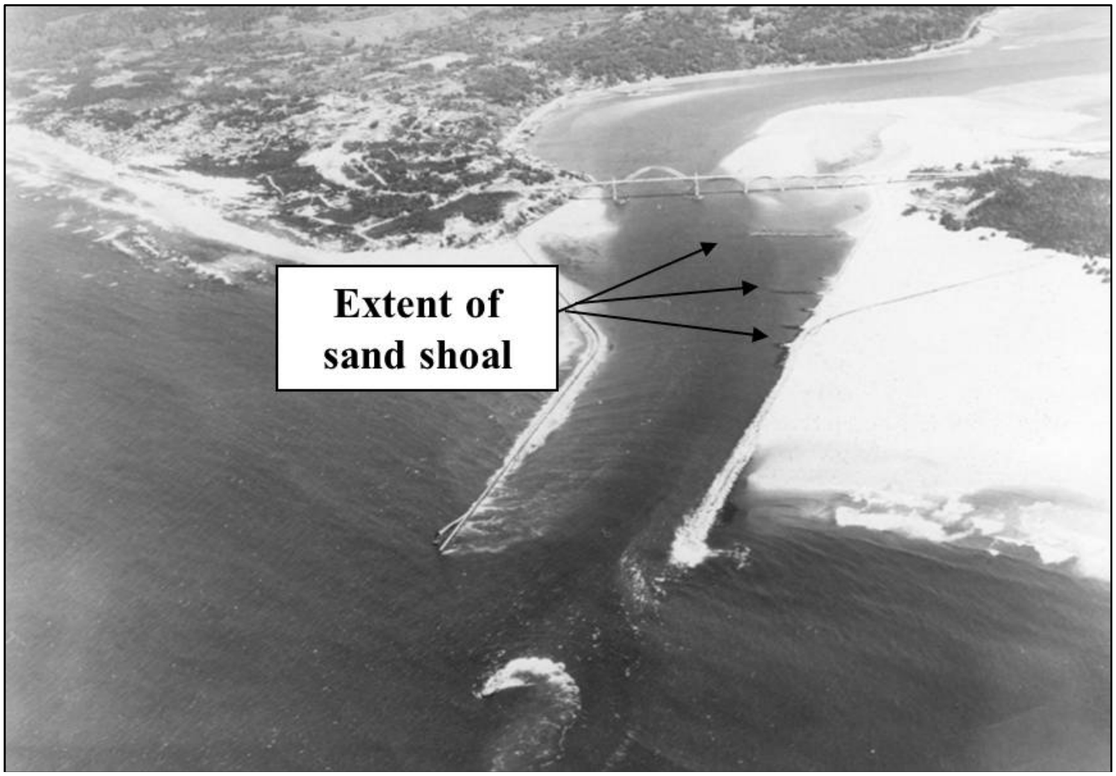

Figure A1- 201. Spur Groins and Shoaling at Yaquina Bay

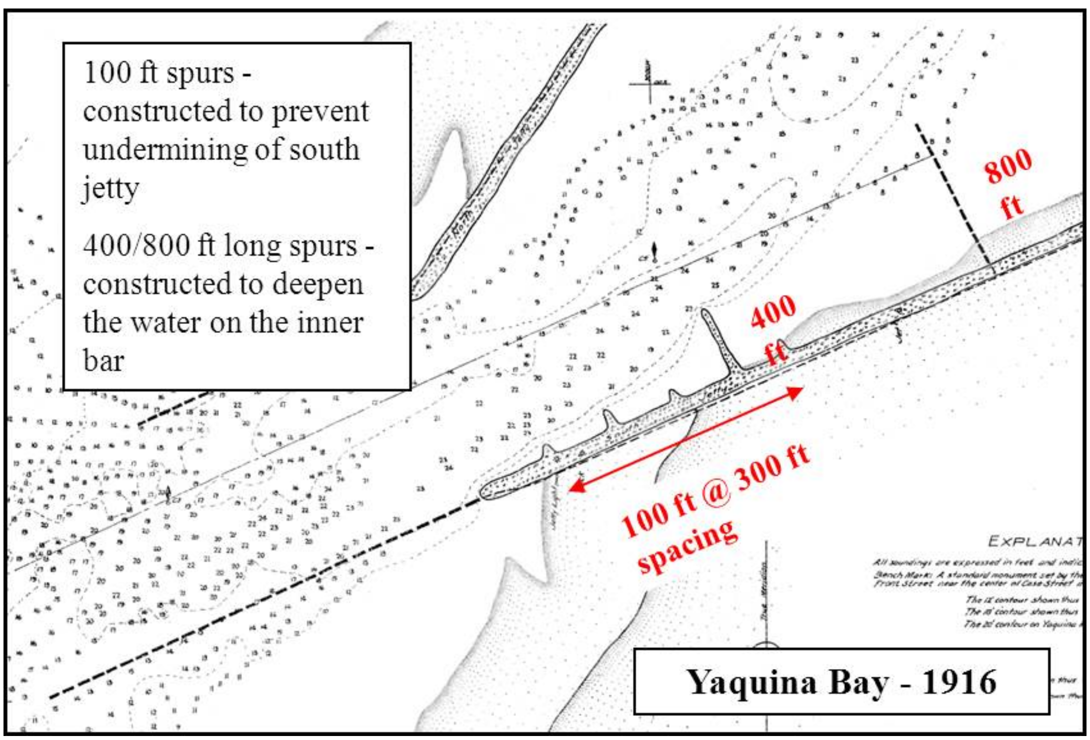

Figure A1- 202. Spur Groins along Yaquina South Jetty

The Corps' Engineering Research and Development Center in Vicksburg, Mississippi analyzed the hydrodynamics and circulation patterns in the MCR entrance as well as the potential impacts and effectiveness of placing spur groins on the jetties. This analysis was conducted with the coastal modeling system (CMS) and other models that operate within the surface water modeling system (SMS). A regional circulation model (ADCIRC) provided the tidal and wind forcing for the boundaries of project-and local-scale wave, current, sediment transport, and morphology change calculated by the CMS. The half-plane version of the wave transformation model, STWAVE, was coupled with two-dimensional and three-dimensional versions of the CMS, which calculates current, sediment transport, and morphology change. Figure A1- 203 illustrates typical spur groin configurations used in numerical modeling. Figure A1- 204 shows typical cross sections of spur groins along the channelside of the South Jetty.

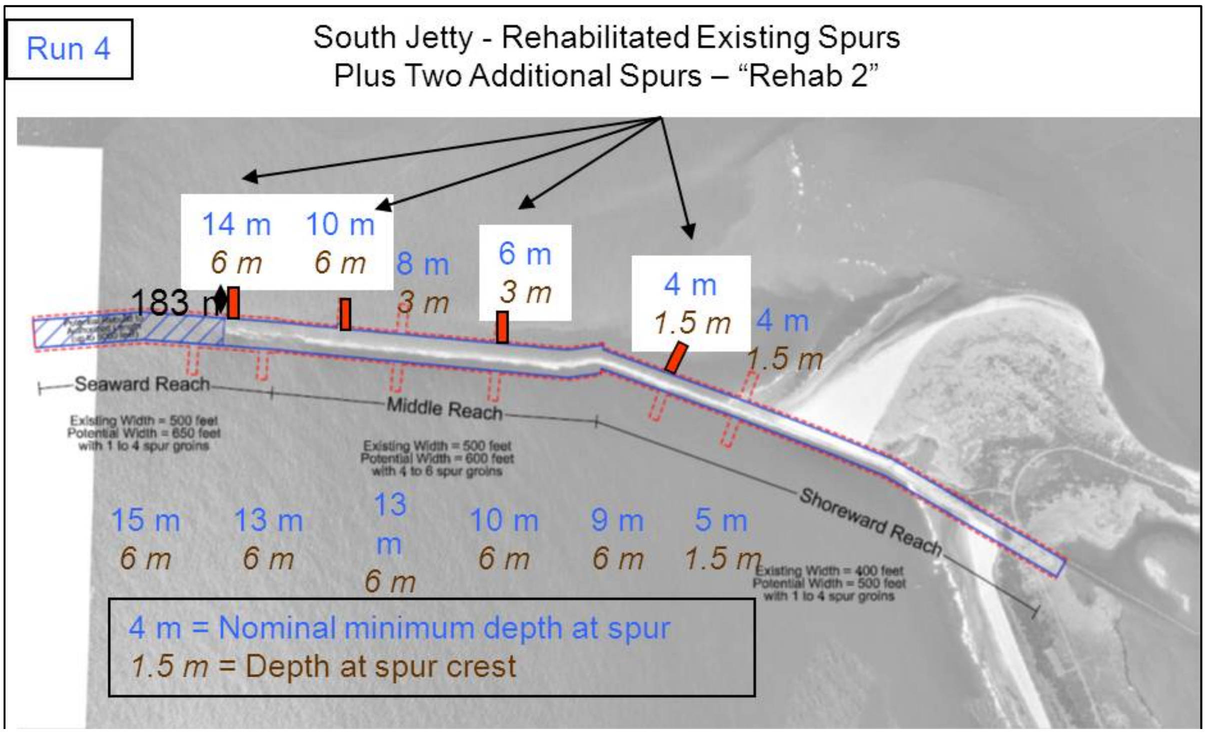

Figure A1- 203.   Spur Configuration used in Numerical Modeling

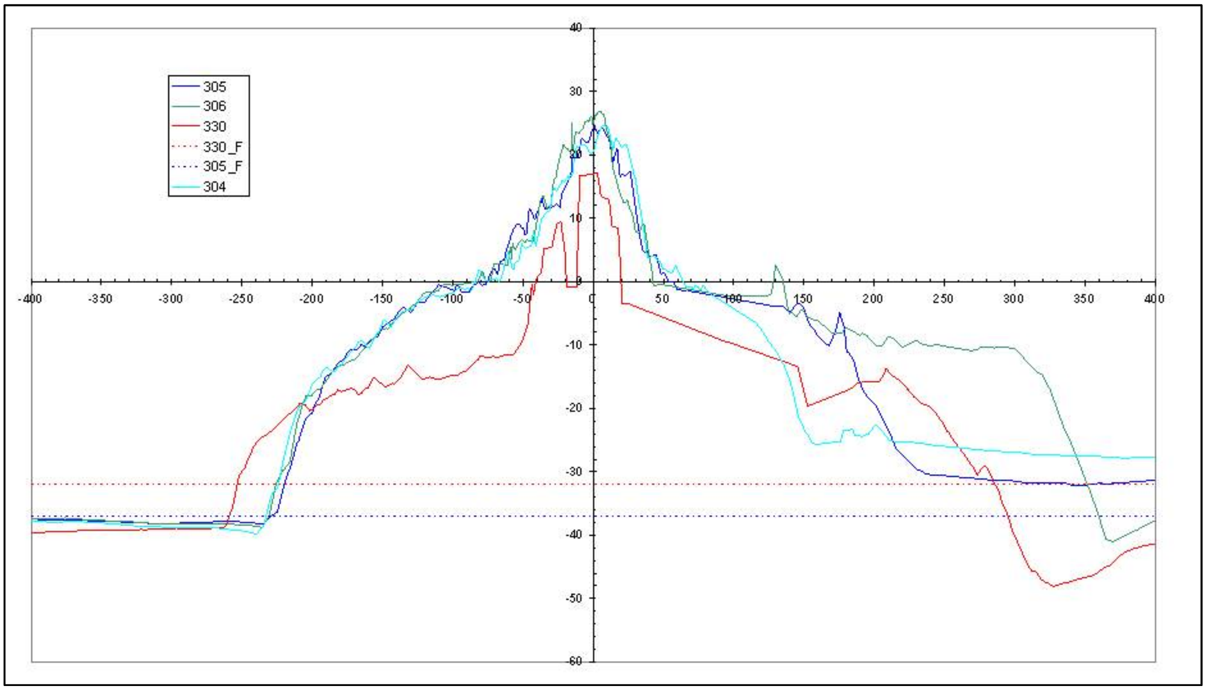

Figure A1- 204. South Jetty - Existing Spur at 306 and 330 - Channelside

The investigation was conducted by defining the largest possible plan and gradually reducing the number and size of spur groins necessary to achieve the intended purpose. The original and largest possible layout investigated of spur groins along each of the jetties is shown in Figure A1- 89 and Figure A1- 90. Studies began with 12 spur groins along the South Jetty, six along each side. Nine spur groins were proposed for study on the North Jetty, three on the north side and six on the channelside. Eight spur groins were proposed for Jetty A, four on each side. Spur groin length was originally specified as a maximum of 600 ft long. Along the South Jetty at least six spurs were originally authorized and constructed (1890-1913) with lengths of 90 ft to 1000 ft to stabilize the jetty foundation. These ‘original’ South Jetty spurs have degraded to such an extent that only two small spurs are presently discernable on the South Jetty, 60 to 80 ft widths, spaced approximately 2400 ft apart, extending 100 to 200 ft away from the side of the jetty (along the outer 1/3 of the jetty’s channel side).

Potential locations for jetty spurs were evaluated based on calculated peak ebb and flood currents as simulated with the regional-scale 2-D CMS. Locations of peak flood and ebb currents that exceeded 1 m/sec were identified. Currents that exceed 1 m/sec were identified at the tip of Jetty A, the channel side of the North Jetty, and the seaward third of the South Jetty, including the area of the existing spurs. Peak flood flow had the highest speed at the submerged tip of the South Jetty. Currents exceeding 1 m/sec for peak flood appear at the west side of Jetty A, the north side of the tip of the North Jetty, and the tip and both landward and seaward of the “knuckle” on the South Jetty. All spur groins modeled were found to decrease current to their lee by approximately 0.2 m/sec, and were found to potentially increase the current slightly off the toe of each spur by approximately 0.2 m/sec.

Based on the spur groin analysis, total spur groins along the South Jetty were reduced from the original six on each side to two spur groins on the seaside and three spur groins on the channelside (elimination of seven spur groins). In addition, the length of each of the spur groins was optimized based on the water depth at its proposed location (i.e., a shallower depth requires a shorter spur groin to have a positive impact). Proposed spur groin length along the South Jetty ranges from 60 to 180 ft with an average length of 94 ft. Figure A1- 205 illustrates the spur length estimated based on the depth of application. Total spur groins along the North Jetty were reduced from the original nine spur groins to a total of four, one on the seaside and three on the channelside (elimination of five spur groins). Proposed spur groin length along the North Jetty ranges from 60 to 250 ft with an average length of 145 ft. Total spur groins along Jetty A were reduced from the original four on each side to one on each side (elimination of six spur groins). Proposed spur groin length along Jetty A ranges from 125 ft to 135 ft, with an average of 130 ft. In summary, the proposed spur groin layout was reduced from a total of 29 spur groins to a total of 11 spur groins, a 62% reduction in number. In addition, the average length of the proposed spur groins is 120 ft compared to an original potential length of 600 ft. The final proposed approximate location of the spur groins can be seen on Figure A1- 206. Figure A1- 207 displays typical spur cross section changes with depth of application. Approximate dimensions and cross sections for the proposed spur groins can be found in Figure A1- 208 through Figure A1- 218.

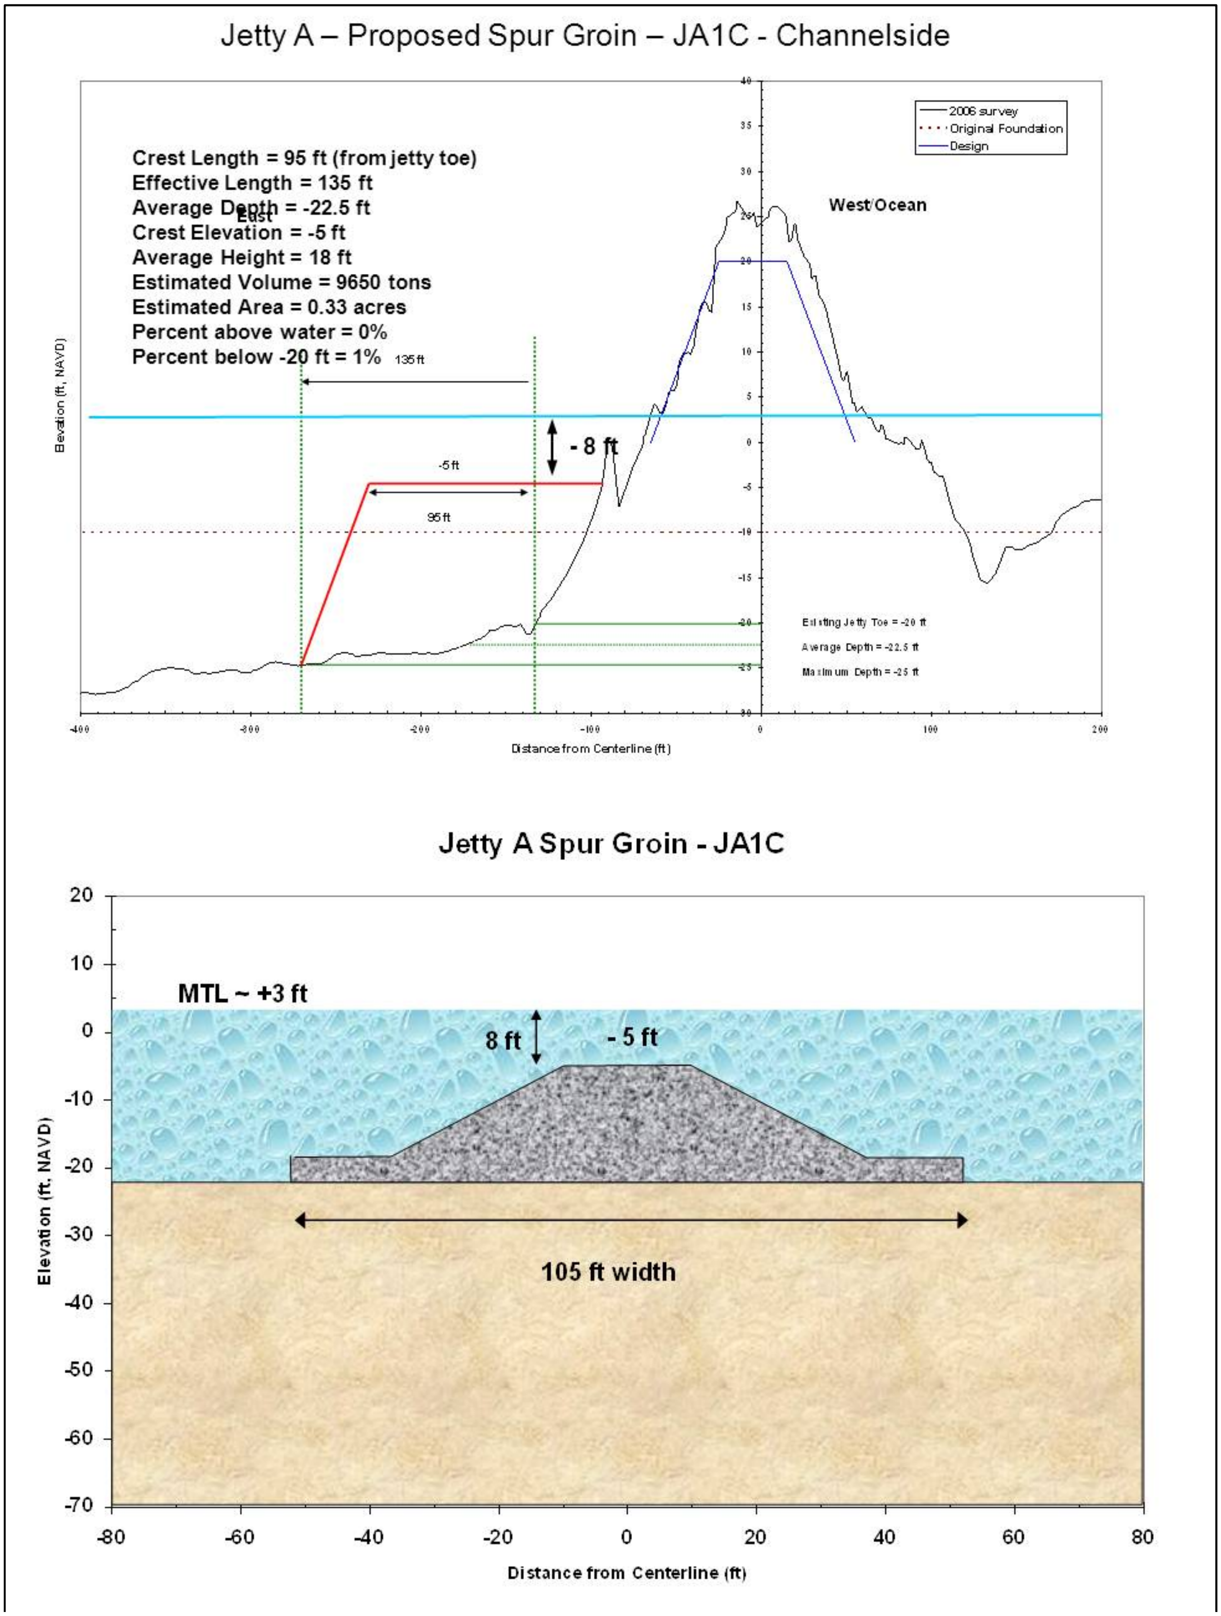

Figure A1- 217. Jetty A Proposed Spur Groin - JA1C

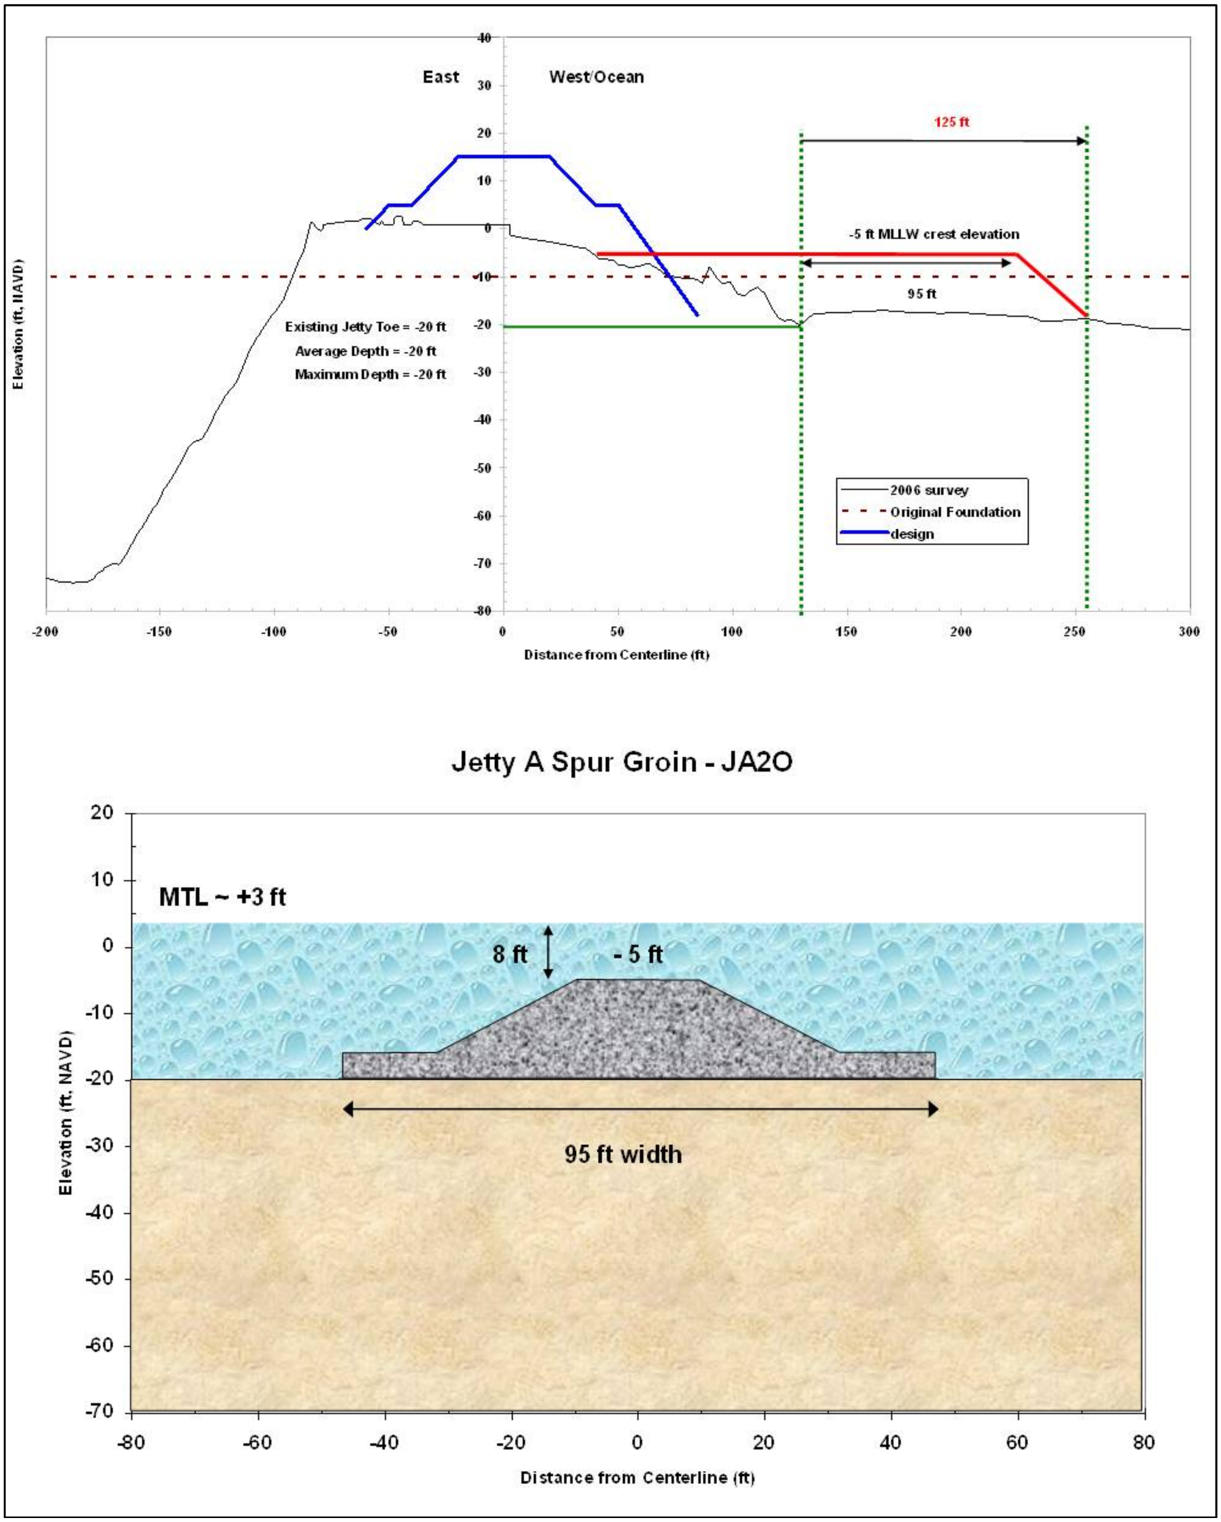

Figure A1- 218. Jetty A Proposed Spur Groin – JA2O

In areas where foundation scour threatens the overall stability of a jetty, spur groins will be constructed perpendicular to the jetty to facilitate stabilization via accumulation of sediment along the jetty foundation. Historical experience and numerical modeling were used to select the type, depth, and length of spur groin necessary to impact the processes causing increased scour at each jetty (e.g., rip currents, eddies). Each spur groin will have a 1V:2H side slope and crest width of approximately 20 feet and will be constructed using a 3- to 5-foot deep bedding layer composed of a mixture of gravel and rock that will then be covered with large stone sized for the location and exposure.

Two potential construction methods could be used for spur groin construction, either land-based or marine-based depending on location. Barges or similar equipment could be used to dump the bedding layer rock into place and a clamshell would be used to place larger stone on top of the bedding rock layer in locations with sufficient water depth. Or material could be placed using land-based equipment from on top of the jetty. Land-based construction might require a wide turnout crane placement with over-excavation down to grade as the crane walks back onto the main jetty axis. In addition, the emergent spur groins may be used as turnouts for construction equipment. The land-based construction method could be used for all but the deepest spur groin construction.

Figure A1- 219 shows percentage of time that the crests of spurs at 0 MLLW, +5 MLLW, and +8 MLLW would be exceeded (i.e. overtopped by water). Both spur groins with elevation +8 MLLW are not relevant to outmigration of fish because they are on the ocean side of the jetties. Spurs SJ2C and SJ3C on the South Jetty at an elevation of +5 MLLW would be above water 60% of the time for August-September and 55% for October-November. Spur SJ4C would be above water 5% of the time. It is expected that at some point on most ebb tides that spurs SJ2C and SJ3C would be above water, and that fish outmigrating within 70 feet of the South Jetty during that part of the ebb tide when the tops of these spur groins are exposed would have to swim around them. As noted earlier, sub-yearling Chinook tend to use nearshore areas, at least by the North Jetty, more than older juvenile salmonids and they typically go out of the MCR area over a period of more than one ebb tide. Table A1-8summarizes proposed spur groin characteristics for each jetty.

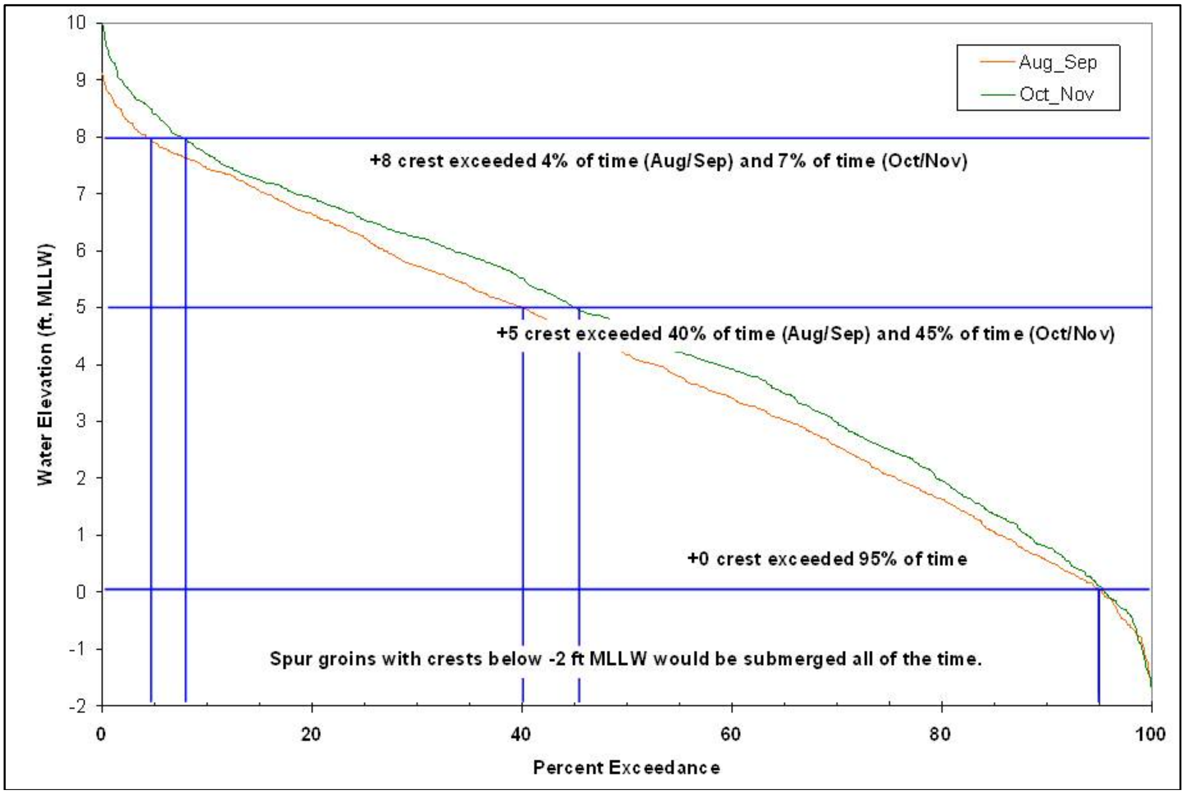

Figure A1- 219. Tidal Elevations at the MCR with Respect to Spur Groins

Table A1- 8. Proposed Spur Groin Characteristics

Spur Groin Feature	North Jetty	Jetty A	South Jetty

c. Jetty Length Rebuild and Stabilization

Authorized lengths and original construction for the North, South, and Jetty A were 6200 ft, 2200 ft, and 900 ft longer than the existing 2010 jetty head positions. For most of those receded lengths, submerged relic stone features exist extending approximately up to the lower level of wave impact, approximately -15 ft to 0 ft MLLW. A typical submerged head feature can be seen on Figure A1- 93. Jetty recession history and rates for the three jetties are plotted in Figure A1- 220 through Figure A1- 222. Current recession rates are expected to range around 20 to 40 ft/yr, 5 to 20 ft/yr, and 5 to 20 ft/yr for the North, South, and Jetty A, respectively.

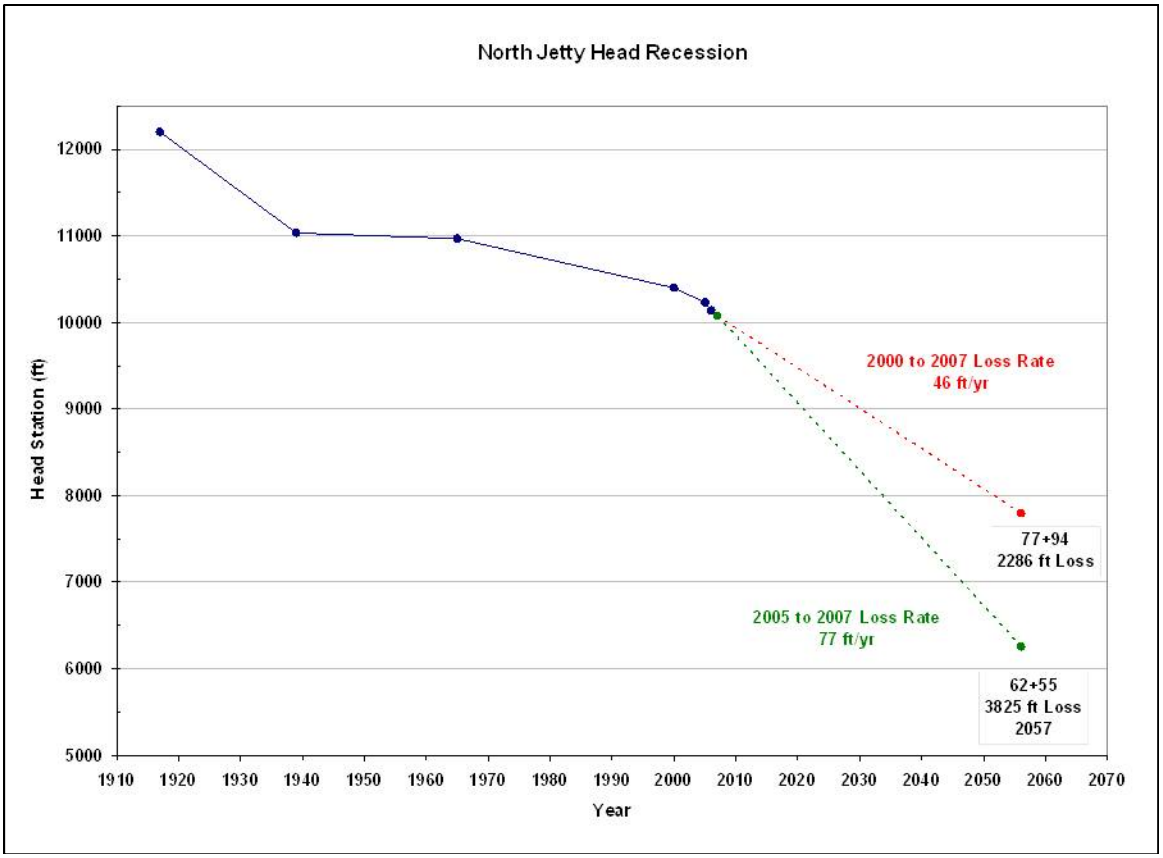

Figure A1- 220. North Jetty Head Recession

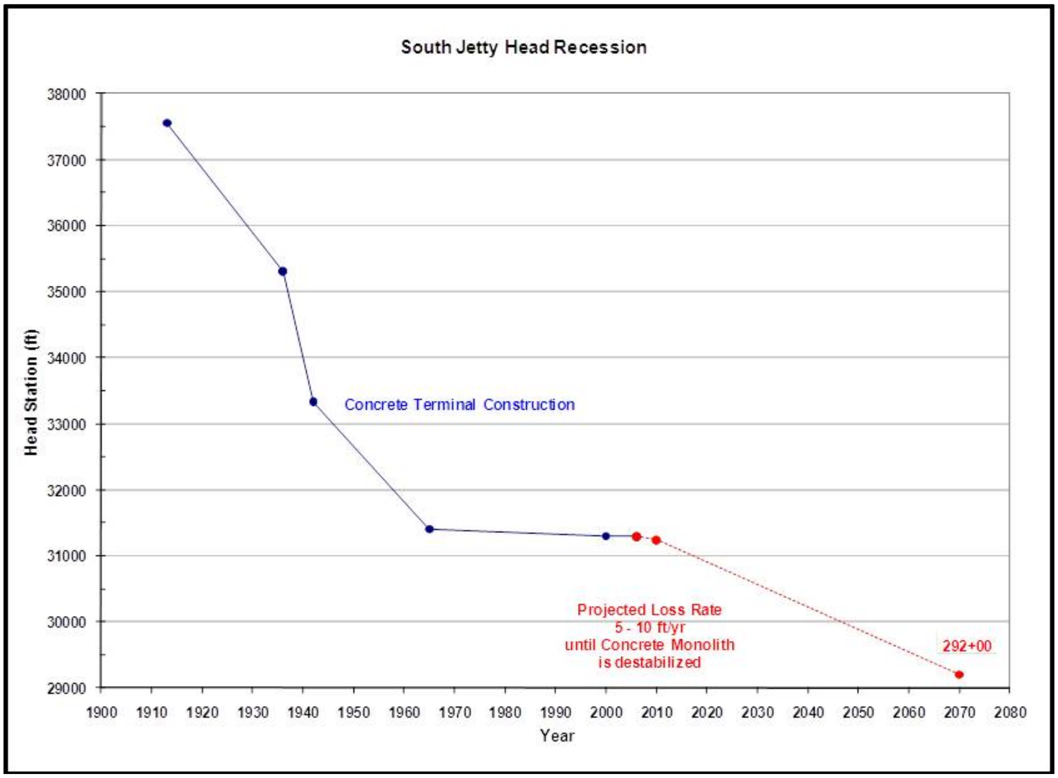

Figure A1- 221. South Jetty Head Recession

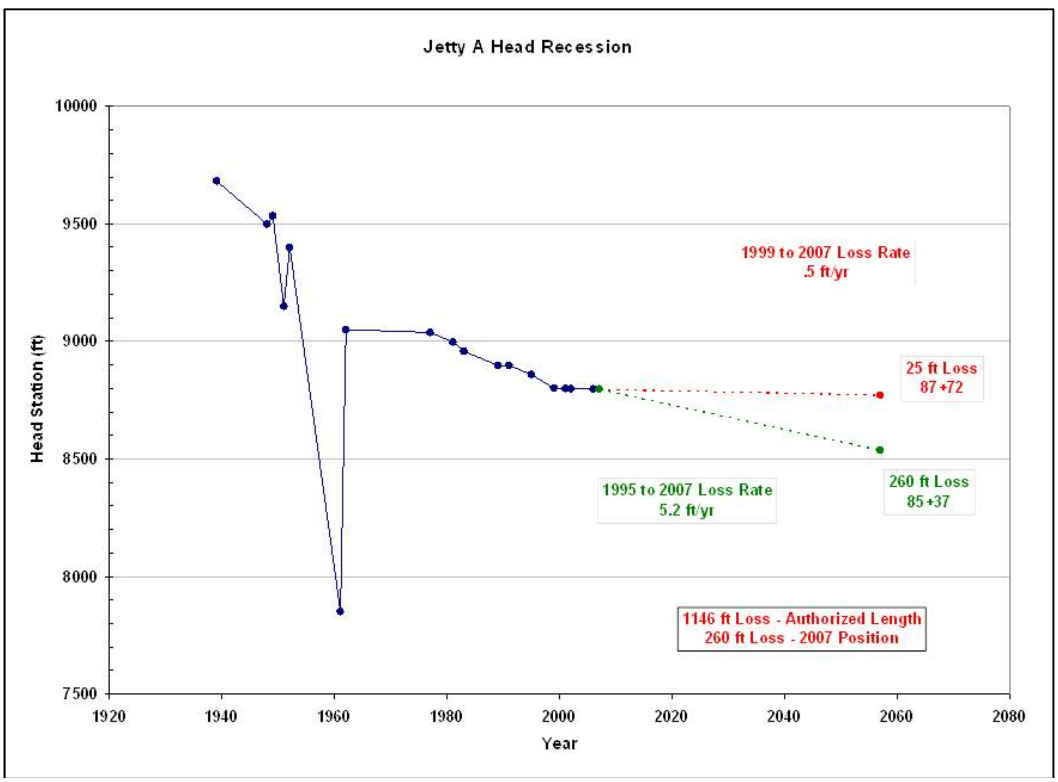

Figure A1- 222. Jetty A Head Recession

As stated earlier, jetty length recession has various consequences to the stability of the structures and the project including:

- Exposure of the weaker trunk of the jetty to wave action.
- Increased erosion of the ebb tidal and adjacent underwater shoals.
- Increased erosion of the adjacent shorelines.
- Increased depths along both sides of the jetties due to more effective wave penetration.
- Exposure of jetty foundation to greater forces.
- Greater sediment infill around the ends of the jetties into the navigation channel.

The circulation and stability of the present MCR inlet is tied to the condition of the inlet's morphology. This has been the case since jetty construction. In other words, the inlet's morphology is a function of the MCR jetties now in place. If the jetties change significantly over time (recession of jetty head or breach within jetty trunk), the inlet's morphology will respond accordingly. For example, if the head of the North Jetty recedes landward by 100 ft, the morphology adjacent to the North Jetty will adjust accordingly, with much of the mobilized sediment entering the MCR navigation channel. The offshore extent of the North Jetty acts to retain Peacock Spit and prevent its southward re-entry into the MCR inlet. The North Jetty acts to constrain current flow through the entrance to maintain a stable inlet.

The offshore extent of the South Jetty protects the MCR inlet from severe wave action and constrains destabilizing currents. The present condition of the South Jetty also acts to stabilize Clatsop Spit, and the shoreland south of the South Jetty. The South Jetty, in addition, serves to anchor the outer extent of portions of the ebb tidal shoal.

The offshore extent of Jetty A helps to reduce severe ebb tide circulation affecting the North Jetty, thereby protecting the North Jetty. Jetty A also protects Sand Island and Ilwaco channel from severe flood tide currents and storm wave action entering the inlet from the ocean. By effectively constraining currents within the inlet, Jetty A also reduces the likelihood of Clatsop Spit migrating northward into the inlet which would have a secondary effect of deepening channelside depths along the North Jetty. Continued head recession of any of the three jetties would increase the dredging requirement for the MCR channel.

Investigations examining the reconstruction of jetty length focused primarily on maintaining the underwater and adjacent shoals which have proven to be so critical to controlling the impinging wave climate and maintaining the current length to provide effective control of sediment movement into the navigation channel. Increased lengths were investigated to determine if those might provide a more sustainable project over the long term. South Jetty length rebuild was investigated out to Station 353+00, 4,000 ft seaward of the present location. North Jetty length rebuild was investigated out to Station 115+00, 1500 ft seaward of present location. Jetty A length rebuild was investigated out to Station 97+00, 900 ft seaward of the present location and equivalent to the original constructed length. Those lengths were still 2,200 ft and 700 ft short of the authorized lengths for the South Jetty and North Jetty, respectively, and are shown in Figure A1- 223 through Figure A1- 225.

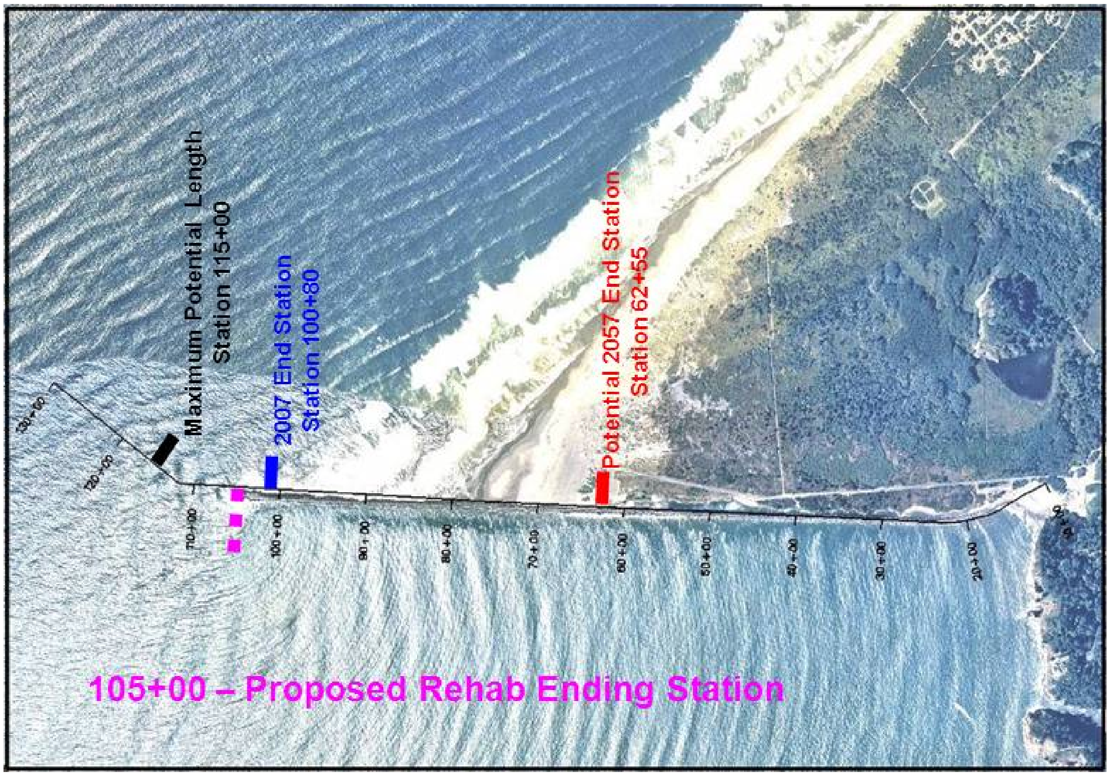

Figure A1- 223. ***North Jetty Proposed Rehab Ending Station***

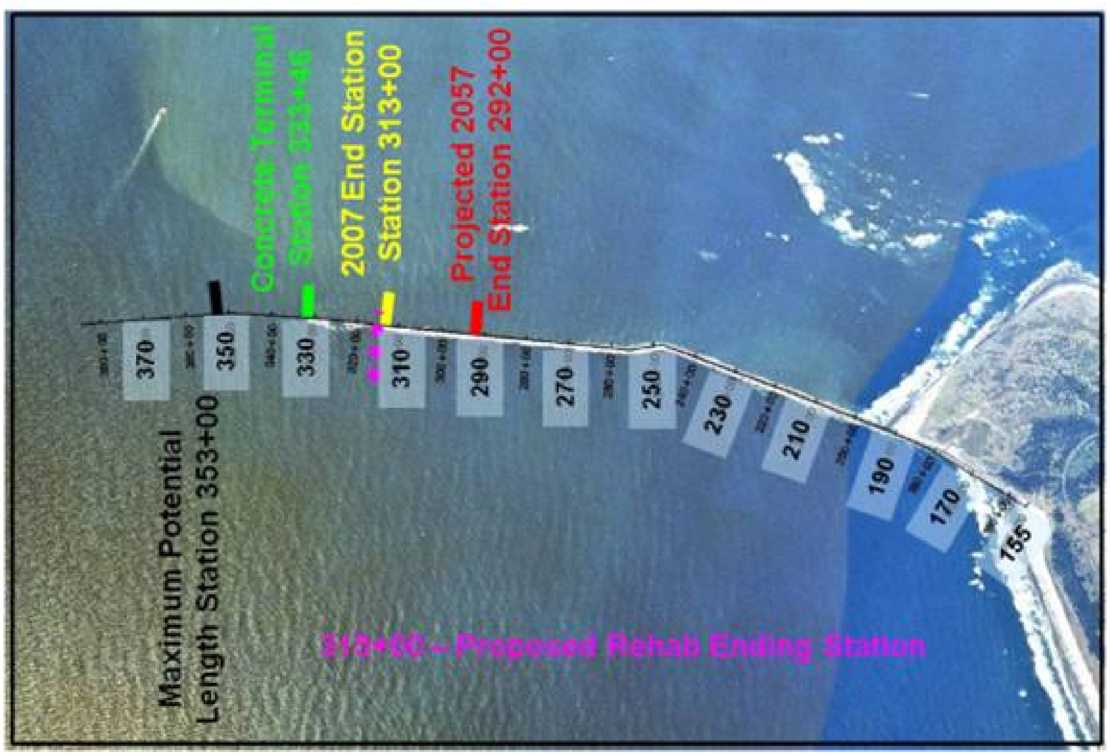

Figure A1- 224. ***South Jetty Proposed Rehab Ending Station***

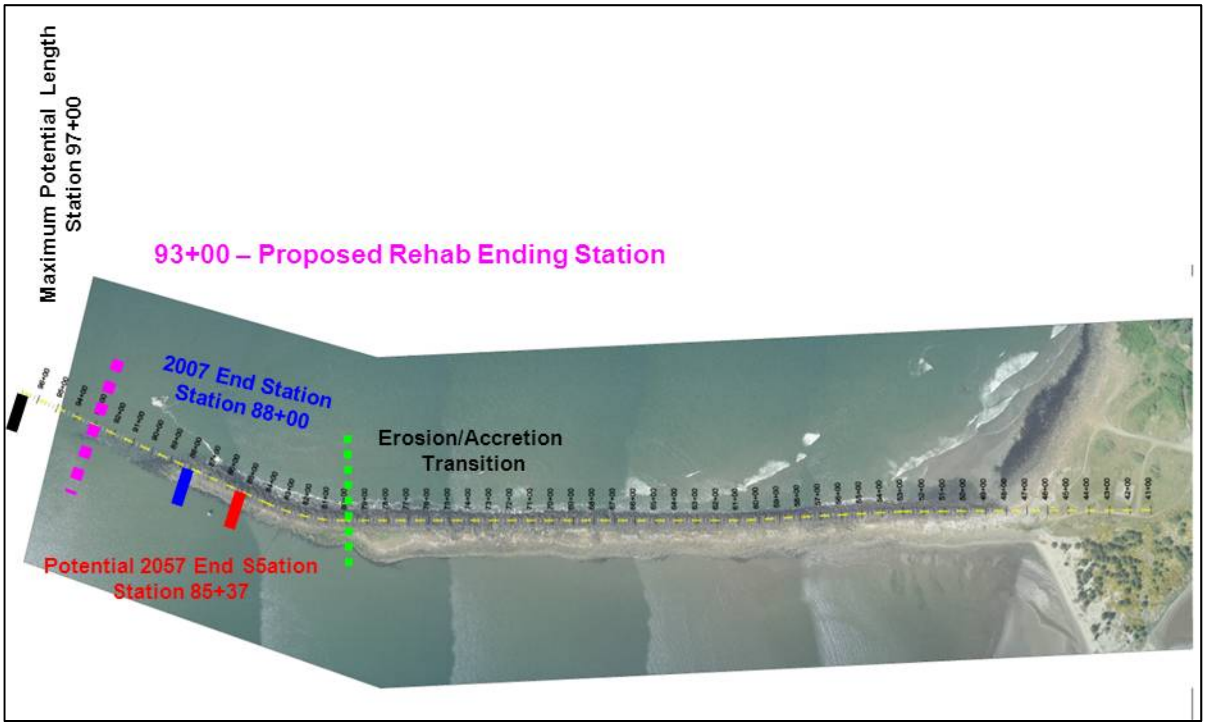

Figure A1- 225. Jetty A Proposed Rehab Ending Station

The USGS-Menlo Park assisted USACE with evaluating potential improvements and impacts of proposed jetty head rebuild for MCR. The USGS efforts focused on using the Delft-3D model to identify potential changes in circulation, salinity and sediment transport that could result from the offshore re-build of the three jetties. The Delft 3D model for MCR is the result of continual development supported through several regional initiatives, as sponsored by federal and state agencies. The model fully accounts for added circulation effects induced by waves and the baroclinic effect of the estuary (saltwater intrusion and related density driven circulation) and has been calibrated using the Mega-transect and CORIE data sets. The "baseline" model condition (no jetty re-extension) was based on 2006 bathymetry and attendant jetty configuration. The Delft 3D model was used to simulate the continuous circulation at the MCR during Aug-Sep 2005 and Oct-Dec 2001, for both the baseline condition and the condition featuring proposed re-extension of the jetties.

The October-November run was established for engineering purposes as this time period represents extreme conditions at the MCR. The model results (including all three jetty head rebuilds summarized above) show a limited response on the overall patterns of salinity flow, waves, and sediment transport on the MCR scale. For all jetty rehabilitation cases changes in residual salinity, velocity or sediment transport are small and mostly local at the rebuild location. Instantaneous velocities and salinities in the MCR show variations mainly due to small temporal shifts or spatial shifts rather than changes in e.g. maximum and minimum velocities or salinities. Outside the MCR, differences, small variations and fluctuations in position of the plume are observed. Most of these changes are generated at the jetty heads and advected seaward by the plume. Only the combined impact of rebuilding all the jetties shows a clear impact on sediment transport rates and morphology inside the entire MCR, with seaward transport and northward bypassing being enhanced (this plan was not carried forward).

In cases where the jetties have receded landward from their fully authorized offshore extent, evaluating the merits of jetty head rebuild is an important consideration for jetty rehabilitation. Due to the severe forcing environment of MCR, tremendous costs may be required to rebuild the jetties and re-establish a resilient jetty head section. An initial assessment of options for jetty rebuild, limited the considerations to partial jetty rebuild rather than considering rebuild to full authorized length. Added critical review determined that proposed options for rebuild of the head of a given jetty should be limited to conditions where the rebuilt jetty head could be placed within the relic stone footprint. These constraints were based on the need to balance the purpose of jetty rehabilitation with implementation cost.

Based on the above constraints, the rebuild of the South Jetty head (presently located 1,500 ft inshore of the concrete monolith) was not considered a viable rehab option. The head of the South Jetty was proposed to be stabilized at approximately its current location, Station 313 to 315. Maximum viable rebuild of the North Jetty head was determined to be Station 105, which would result in a re-established head position 1,700 ft inshore of the fully authorized length. Maximum viable re-extension of the head for Jetty A was determined to be Station 93, which is 500 ft seaward of its current position and 400 ft landward of its full authorized length. Jetty A length is important to controlling erosion along the North Jetty foundation; however, the substantial scour hole south of the Jetty A head limits a cost-effective head rebuild.

Figure A1- 223 through Figure A1- 225 illustrate the original length modeled as well as lengths and head positions of the proposed plan. Stabilizing the jetty heads can stop the loss of littoral sediment. Because the recommended project jetty lengths are approximately the same as existing jetty head locations (and significantly shorter than those modeled), it is not expected that the proposed project will have negative impacts on the hydrodynamics or sedimentation processes of the MCR inlet. It should be noted that a project plan which does not stabilize the jetty heads will more than likely have a significant negative impact on Clatsop and Peacock spits as well as the shoreline areas adjacent to both the North and South jetties.

d. Root Erosion Area Stabilization

There are two categories of erosion at the North and South Jetty roots. The erosion that is occurring on the adjacent shoreline on the oceanside is wave-driven and to some extent connected to the recession of the jetty head positions. Those erosion areas are being addressed through the jetty head stabilization as well as the spur groins proposed for those locations on the landward oceanside of both the North and South jetties. The second category of jetty root erosion occurs along approximately 50% of the North Jetty length. A depressed area behind the jetty root has been created over time due to a combination of factors including overland flow channeled toward the jetty root, erosion on the channelside of the North Jetty root, and tidal flow combined with wave transmission and overtopping into the lagoon area.

The continual hydraulic flow through the jetty root/trunk cross section undermines the foundation of the structure. An added concern is the shoreward retreat of Benson Beach toward the lagoon area generating the possibility that an ocean/lagoon connection may be eventually created, increasing exposure of the North Jetty and decreasing its long-term stability. The engineering feature which is proposed to stabilize the North Jetty root is a combination of re-directing the overland flow away from the lagoon area and placement of gravel and sand on the landward side of the jetty in order to eliminate the tidal flow through the jetty which is destabilizing the foundation. Table A1- 9 provides summary information on the proposed lagoon fill characteristics.

Table A1- 9. Lagoon Fill Characteristics

Lagoon Fill Features	North Jetty
Timing of construction	2012
Material used for fill	Sand, gravel, quarry stone
Short-term and long-term use	Stockpile area, long-term stabilization of root
De-watering	Culvert feeding into area will be re-directed
Impact on wetlands	1.78 acres
Impact on Section 404 waters	4.71 acres

12. Hydrodynamic Modeling of MCR Entrance

The USGS was contracted to apply the existing Delft3D model of the Columbia River estuary and adjacent coast to examine the effects of rebuilding the MCR jetties length on the circulation, sediment transport, and salinity field near the entrance. The modeling objective was to evaluate the functional performance of the proposed jetty rebuild extensions and potential effects which could impact out-migrating juvenile Salmon. To achieve this objective, the following questions were addressed:

1. What is the normal variation of circulation at MCR (without jetty modification) for each model time period?
2. How do the proposed jetty modifications affect the variation of circulation at MCR?
3. How far do changes in the above parameters extend away from the reconstructed jetty alternatives (i.e., will salinity or sedimentation be affected nearby the jetties, within the MCR, or within the estuary)?

The results of the jetty rehabilitation runs are based on model simulations using the refined model described in this section. Simulations have been made for both the summer (Base Case and Case E, all jetties rebuild), and winter conditions (Base Case and all jetty cases, A to F). Separate analyses for the effects of filling in the South Jetty low-crested section and rebuilding the jetty lengths were presented. For waves, salinity, flow, sediment transport and morphology overview maps are presented showing the reference simulation and the difference between the various alternatives compared to the reference simulation. In this section Case B, low-crested section rebuild but with existing jetty lengths, is used as a reference to minimize the change of instabilities during the model simulations. Figure A1- 226 shows the model bathymetry used for the modeling. Figure A1- 227 shows the model schematizations for the South, North, and Jetty A modeling. Various results from the model are illustrated in Figure A1- 228 through Figure A1- 248.

Analysis of the results shows limited influence of the jetty alternatives on flow, salinity and sediment transport outside the sea model domain. Therefore, the overview maps presented in this report are mainly focused on the MCR part of the sea domain.

a. Analysis of Rebuilding South Jetty Low-crested Section Seaward of Head

Local effects of filling in the South Jetty low-crested section seaward of the existing head were observed in the salinity, waves, flow and sediment transports. Rebuilding the height of the South Jetty induces differences in mean salinity for both the bed and surface layer but the differences are minor (less then 1ppt) and focused at the low-crested section location. Wave heights show a minor increase at the south side of the low-crested section and small decrease in the MCR (variations < 0.15 m). Changes in the residual surface flow patterns focus around the low-crested section and jetty head. Local velocities in and directly adjacent to the low-crested section reduce strongly as the closed off low-crested section eliminates flow. The residual velocity around the jetty head shows a small increase resulting in larger net sediment transports. The changes in residual velocity fields are focused mainly at the jetty head, but small deviations in the residual velocity magnitude and direction are observed in the entire MCR entrance. An interesting feature is the reduced return flows along the northern side of South Jetty. The slightly changed flow distributions are reflected in the relative sedimentation-erosion patterns and rates. With the low-crested section filled, less sediments are eroded at the location of the low-crested section but more sediments are eroded at the jetty head. Effects on sediment transport outside the sphere of low-crested section influence are minor.

b. Analysis of Restoring Jetty Lengths

Effects on Salinity. The effect of jetty rebuilds on salinity are visualized by plotting the maximum salinity range (defined as = maximum observed – minimum observed salinity) during the simulation, mean salinities, and time series of salinity in the mega transect. Inside the MCR, the change in salinity range is limited. In the surface layer, the central part of the MCR and along North Jetty shows up to a 1 ppt decrease in salinity range. Along the South Jetty an increase of 1 to 2 ppt is observed. In the bed layer changes have a wider spatial variation. Extension of Jetty A (to 97+00) tends to increase the salinity range by 1-2 ppt along the jetties, while the central part slightly (1 ppt) decreases. Extension of South Jetty shows an opposite behavior with an up to 1 ppt increase in the channel. North Jetty extension has limited effect.

Most pronounced changes are observed outside the MCR. Relative large fluctuations in maximum range (over 5 ppt) are observed along the South Jetty and along the edges of the plume. These relative large changes are due to small changes in the plume that affect areas that are normally completely saline. Since the maximum that is recorded is tracked, it becomes visible in the plot. Averaged over the month the effect of the jetty rebuilds shows only local changes near the rebuild jetty heads with the largest impact on mean salinities in the surface layer due to the South Jetty rebuild.

Detailed analysis of the salinity time series for mega transect Stations 3 and 5 illustrate only limited changes in salinity values. In the main channel (Station 3) over 10 ppt differences are observed sporadically due to small temporal shifts of the signal. Larger variations occur at Station 5, closer to the South Jetty. The overall maximum and minimum values do not change distinctively.

Effects on Waves. The 2001 October-December winter simulation is governed by a sequence of storm events. Wave heights over 8.5 m are observed on the open sea. Wave heights decrease significantly towards the coast due to refraction and bottom friction, with the majority of the energy dissipation occurring along the coastlines due to depth-induced breaking in the surf zone, and on the northwestern part of the ebb-delta facing the North Jetty. Inside the MCR a dissipation hotspot occurs on the shoals along the South Jetty.

The effect of jetty length rebuilds on the wave heights at MCR is visualized by plotting the mean wave height and mean wave dissipation over the October-December runs. The North and South Jetty rebuilds further reduce wave-heights inside the MCR to mean values below 1.0 m towards the estuary. The South Jetty extension is most effective in reducing the maximum and mean wave heights in the MCR. At the location of the mega transect the mean wave height reduces up to 15%.

Detailed analysis of the wave time series at the mega-transect stations show that the largest reductions occur during the major storm events when waves significantly exceed 2 meters. Only minor change is observed for lower wave cases. Rebuilding North Jetty and Jetty A only induces limited local effects in the MCR. However, the longer North Jetty might have a positive effect on the stability of Peacock Spit, between North Jetty and North Head, due to increased seaward energy dissipation rates around the new jetty head.

Effects on Flow. Analysis of the effects of jetty rehabilitation on flow velocities is based on animations of the velocity vectors and magnitude (differences), and residual flow plots. As a result of rebuilding the jetties, changes in the flow vectors (magnitude and direction) can be observed in the MCR and in the ebb-jet area; largest differences occur during peak ebb and flood (see snapshots of the flow at maximum flood and maximum ebb). The differences in the flow magnitudes mainly result from a slight spatial or temporal shift of the flow vectors rather than a strong increase (or decrease) of the overall velocities. In the central part of MCR at the location of mega transect locations differences between maximum and minimum observed velocities of the different alternatives are mostly small (<10%) compared to the original signal. At the boundary Stations (1 and 5) for some alternatives, differences from the base case are larger due to the direct influence of the jetty alteration (B72-73).

The changes in residual flow field are a good indicator for the longer-term (month-averaged) effects of the Jetty Rehabilitation alternatives on the flow at MCR. The residual flow field is obtained by summation of the Eulerian velocities over the simulation period (20 October – 9 December 2001). Figure A1- 246 and Figure A1- 247 illustrate the residual vectors for surface and bed layer respectively. The colors indicate the magnitude of the change in residual flow vector compared to case A (no distinction in increase or decrease is made).

Comparable residual flow patterns can be observed for the different alternatives. Residual flow in the MCR exceeds the flow along the adjacent coastal sections and is ebb-dominant due to the fresh-water influx. The various jetty rebuilds mostly induce local changes along the jetties. Rebuilding the North Jetty mainly impacts the velocities north of the jetty. In this area two opposite rotating eddies are observed in the surface layer. At the jetty head a residual clockwise rotating eddy forms. Landward a secondary anticlockwise rotating eddy determines the residual velocities along the jetty foot and coast. The changes in this secondary eddy might influence the sediment transports and morphology along the jetty and coast. South of the jetty, inside MCR, effects are negligible. Extension of Jetty A has a larger effect on the overall flow patterns inside the MCR as this jetty extends into the main channel. Changes in the residual eddy forming along the sheltered, downstream side of the jetty dominate the overall picture. In general the residual velocities towards the Peacock Spit coast tend to decrease and are more landward directed. Locally, at the jetty head, velocities increase due to contraction of flow and increased residual velocities extend seaward. Rebuilding the South Jetty reduces the residual return flow along the jetty. Main differences occur around the jetty head due to the different location of flow acceleration. Along the North Jetty and Jetty A, a minor increase in residual velocities is observed. Rebuilding all jetty heads results in a summation of all above mentioned effects, with the largest changes occurring inside the MCR and along the North and South jetties. Changes in the far-field area, outside the sphere of direct ebb-jet influence, along the adjacent coasts are minor.

Effects on Bed Layer. Residual velocities in the bed layer show a more complex spatial distribution compared to the reasonable uniform seaward flow in the surface layer. Nevertheless the effects of the jetty rehabilitations are limited to the jetties, with largest changes at the jetty heads. Rebuilding the North Jetty mainly impacts the velocities north of the jetty. Similar to the surface layer two opposite rotating eddies are observed, with augmented residual flow towards the coast due to the North Jetty extension. The increased length of Jetty A mainly increases the near-bed residual velocities between the coast and jetty. The South Jetty rebuild modifies the net inflow into the MCR. Minor changes in flow magnitude and direction can be observed in the entire MCR area. The largest alterations occur directly at the jetty tip. Along the jetty the residual seaward transport is reduced, while landward transports towards the channel increase.

Effects on Sediment Transport. Sediment transport along the coast is largest in the surf zone area due to wave-breaking induced currents. Residual transport rates are small compared to the large changes in the direct vicinity of the MCR. Wave breaking on the ebb-delta front contributes to the sediment transports directly by wave-driven currents, while wave stirring increases the amount of sediments available for transport by the ambient (tidal) flow. Inside the MCR, both waves and tides play a key role for sediment transport. Residual sediment transports peak at spring tide when velocity asymmetry is largest.

The reasonable small, local alterations of the tide, wave and salinity fields result in alterations of the sediment transport patterns and magnitudes in the direct vicinity of MCR. No clear change in sediment transports can be observed along the Oregon coast south of the inlet and along Long Beach north of North Head.

The bed-load and total-load show comparable differences in sediment transport rates due to the jetty rebuilds. In the entrance channel sediment transports are generally seaward directed. Extension of Jetty A slightly modifies and increases the flow in the central part of the main channel, increasing seaward sediment transport, while along Clatsop spit flow and transports are slightly reduced. Effects of the North Jetty rebuild are local with largest changes at the tip of the jetty and a reduction of sediment transport between North Jetty and North Head. Near the North Jetty, transports are more shoreward directed. Rebuilding the South Jetty mainly decreases the residual sediment transports at MCR. On the shoals along the South Jetty (where wave energy dissipation is large) a landward sediment flux prevails. The extension of the South Jetty reduces the residual seaward transports over the shoal due to a dominant decrease of the flood transports. The jetty rebuilds have minor effect on the seaward extension of the transports onto the ebb-delta.

Effects on Morphology. Morphologic change shows patches of alternating sedimentation and erosion. Changes in the MCR and near-field ebb delta are relative large. On the ebb-delta we observe a seaward (north-westward) migration of the delta frond. The MCR is governed by local re-deposition of sediments; erosion between Jetty A and the seaward tips of North and South Jetty, and accretion seaward.

The jetty rebuilds slightly alter the sedimentation erosion patterns. Jetty A predominantly induces changes in the central part of MCR. Rebuilding the North Jetty reduces the accretion at its southern margin while increasing accretion (less erosion) north of the jetty. The South Jetty rebuild reduces the sediment redistribution between the North and South jetties.

Limited changes occur in the overall transport rates due to the single jetty rebuilds. North Jetty locally increases Northward bypassing rates at the Jetty head, but no significant change in the longshore and cross-shore transports along the Washington coast is observed. Jetty A mainly impacts the transport rates in the channel. Increasing seaward transports show the potential of this alternative for reducing channel dredging volumes. The South Jetty rebuild causes the largest change in transport rates in the MCR. Seaward transport in the mouth is reduced. An interesting feature is the change in sediment direction bypassing the tip of the South Jetty from northward to southward (although magnitudes are very small).

Despite limited effects of the separate jetty rebuilds, the cumulative effect of all jetty rebuilds does show a clear initial signal. Seaward transport in the MCR and northward bypassing on the ebb-delta is enhanced. Along the adjacent coasts however no clear changes occur. Note that this analysis is based on short-term runs. For morphology it is necessary to do longer simulations to distinguish between initial effects and long term trends.

c. Hydrodynamic Modeling Conclusions

The state of the art Delft 3D online morphology model has been used to calculate flow, sediment transport and bathymetric change at the MCR. Simulations were made for two time frames. The August-September summer computation (25 July - 9 October 2005) is based on the time frame when the mega transect experiment was performed and is representative of typical mild summer conditions. Hydrodynamic validation of the model results with the mega transect observations showed that the model is able to simulate the dominant features in the tidal flow, salinity and wave field. Absence of sediment transport data did not allow for morphodynamic validations. Sensitivity analysis shows the strong influence by tides, waves and density differences for sediment transports at MCR. A near-balance between the tidal and non-tidal (density-driven) contributions exists; tides only, in the absence of salinity gradients, induces a large sediment export in the entrance as both the tidal residual and tidal asymmetry driven component are ebb-dominant. Including salinity has shown to affect the (near-bed) residual flow considerably, and as a result of the changes in vertical flow distribution with reversed residual bed velocities, sediment export at the entrance reduces to near zero. Loss of momentum and dissipation of wave energy due to wave-breaking generates wave driven currents and sediment transports outside the MCR.

Using the model settings of the mega transect experiment, a second period of winter (storm) conditions was modeled (20 October - 9 December 2001) that illustrates the large sediment transports and morphological change associated with waves. Sediment transport rates along the coast are still small compared to the large changes in and around the MCR. The winter campaign has been used to evaluate the functional performance of different jetty rehabilitation schemes on circulation changes in salinity, flow and sediment transport. The model results show a limited response on the overall patterns of salinity flow, waves, and sediment transport on MCR scale. For all jetty rehabilitation cases changes in residual salinity, velocity or sediment transport are small and mostly local at the rebuild location. Instantaneous velocities and salinities in the MCR show variations mainly due to small temporal shifts or spatial shifts rather than changes in e.g. maximum and minimum velocities or salinities. Outside the MCR, small variations and fluctuations in position of the plume are observed. Most of these changes are generated at the jetty heads and advected seaward by the plume.

Only the combined impact of rebuilding all jetties to the full rebuild position (South Jetty at Station 353, North Jetty at Station 115, Jetty A at Station 97) shows a clear impact on sediment transport rates and morphology inside the entire MCR, with seaward transport and northward bypassing being enhanced.

Even though the single jetty rebuilds only show limited change in the hydrodynamic and morphodynamic regime of MCR, there is a potential for locally affecting flow and sediment transport. In general the North Jetty rebuild has minor effect on MCR processes. Changes in flow and sediment transport are observed at the jetty head and on the north side of the jetty that could benefit the Peacock Spit shoreline due to wave-energy reduction. Jetty A impacts the flow in the central part of the MCR enlarging velocities, possibly decreasing channel sedimentation and reducing dredging, while reduced residual flow might favor the Peacock spit shoreline between North Head and Jetty A. South Jetty shows most widespread effects in the MCR, probably due to reduction of the wave climate during extreme wave conditions. Only little effects are visible south of the jetty.

The model results described are based on the re-extension of the Jetty A (900 ft) to its fully authorized length and North Jetty partial re-extension to 115+00. After the USGS modeling was completed, and in consideration of the model results and added evaluation based on functional assessments, the USACE determined that the candidate re-extension options for each jetty be revised. The present consideration for maximum seaward North Jetty rebuild has the reconstructed jetty head terminating at Station 105 (300 ft from the 2006 position). The present consideration for maximum seaward South Jetty re-build is Station 315+00. The present consideration for maximum seaward Jetty A re-build is Station 93+00. It should be noted that the Delft 3D model results described above are based on longer jetty rebuilds than those currently proposed.

Modeling the proposed post-construction condition predicted a negligible increase in velocity in waters in the vicinity of Jetty A; differences were less than 0.1 meter/second (0.33 feet/second). Surface current direction was predicted to change slightly toward the north as water flows around Jetty A, forming a more pronounced clockwise eddying effect west of Jetty A and tending to force water more directly toward the North Jetty. Residual velocities toward the North Jetty are predicted to decrease, however, and this effect will act to protect the North Jetty. Changes to current direction and velocities were found to be negligible in the vicinity of the South Jetty.

Salinity. Salinity distribution is determined by the circulation patterns and the mixing process driven by tidal currents. In surface waters near the North Jetty salinity naturally varies with tides to about 20 parts per thousand (ppt) during October-November. Modeling the post-construction condition predicted minor local changes to mean salinity. Changes to bed layer salinity are predicted in waters between Jetty A and the North Jetty. An increase in mean salinity of about 0 to 4 ppt (from 26-28 ppt to 28-30 ppt) was predicted to occur over some of this area. A similar but less extensive salinity pattern was predicted for the near surface layer in waters between Jetty A and the North Jetty. A decrease in mean salinity of 0 to 4 ppt (from about 12-14 ppt to 14-16 ppt) was predicted to occur over a relatively small area south of West Sand Island, which is located just east of Jetty A.

For the bed layer, a small-scale extrusion of higher salinity water was predicted for the main channel and along the South Jetty. For the existing condition, salinity in the range of 28-30 ppt occurs just upstream of Jetty A, whereas for the post-construction condition, this zone of salinity ends directly south of Jetty A. Only small changes were predicted in the bed layer near the North Jetty.

For the surface layer, a small-scale extrusion of higher salinity water was predicted for waters near the South Jetty. For the existing condition, salinity in the range of 24-26 ppt was predicted along the seaward one-third of the South Jetty, whereas for the post-construction condition, this area was predicted to support salinity in the range of 22-24 ppt. A minor reduction of lower salinity waters in the range of 18-20 ppt was predicted for along the landward half of the North Jetty.

Plume Conditions. Modeling the post-construction condition predicted that there would be only small changes to residual velocity and current directions for both bed layer and near surface layer in the plume. A decrease in bed layer salinity of 0 to 4 ppt (from 28-30 ppt to 26-28 ppt) was predicted in the plume west of the terminus of the North Jetty. Also, it was predicted that there would be only small changes to residual bed load transport and residual total load transport within the plume.

Bed Morphology. Modeling the post-construction condition predicted that a decrease in bed level would result in deeper water habitat than currently exists along the channel side of the seaward half of the North Jetty, with differences in bed elevation from 1.25 to 1.50 meters (4.1 to 4.9 feet). This change is relatively small, considering that water depth here is 12 to 24 meters (39.4 to 78.7 feet). Also, a decrease to bed level are predicted for a broad area in deep waters of the navigation channel off of Jetty A, deep waters around the seaward portion of Jetty A, and for locations north of the North Jetty, which includes shallow nearshore waters. Areas predicted to have an increase in bed level occur upstream and downstream of Jetty A, downstream of the above-mentioned broad area in the navigation channel, on the ocean side of the North Jetty, and downstream of Clatsop Spit.

From the modeling results for the spur groin structures, it was predicted that an increase in bed level due to sedimentation would occur upstream of the spurs, but that a decrease in bed level due to erosion would occur immediately downstream of the spurs.

The potential for jetty rehab to affect the circulation at existing MCR nearshore disposal sites (SWS and NJS) was considered using results from the Delft 3D model. The potential changes on these disposal sites would not inhibit the existing use of the sites. The likely effect of North Jetty rehab will be to slightly increase currents within the eastern 1/3 of the SWS, during part of the tidal cycle. This effect could enhance the already high dispersion rate within the SWS. Effects on the NJS associated with North Jetty rehab would be minimal. Use of the NJS was intended to reduce current scour effects on the North Jetty. If use of the NJS is no longer advantageous to stability of the MCR inlet and continued NJS use adds increased burdens to the MCR project, its use for dredged material placement could be reduced accordingly. In this case, the material destined for the NJS would be placed within the deepwater site or other available nearshore site. Several ongoing initiatives, brokered by the Lower Columbia Solutions group and sponsored by MCR regional stakeholders, are focusing on obtaining additional nearshore sites for MCR dredged material disposal.

13. Potential Consequences of Jetty Failure

a. Systematic Jetty Performance and Impacts

In an aerial sense, a jetty consists of three parts (see Figure A1- 163). The <u>head</u> is the seaward terminus and is exposed to the most severe wave action. The <u>trunk</u> forms the connection from jetty head to subareal beach, retains sub-tidal shoals, and confines circulation within the inlet. The <u>root</u> forms the connection from the jetty trunk to shore and prevents accreted landforms from migrating into the inlet. Deterioration of a jetty's head, trunk, or root will have different impacts on the functionality of the structure and inlet. Effective maintenance of the jetty and, reliability of navigation through an estuary entrance, depends on determining which of these weaknesses is most detrimental to a structure's stability and function.

Stabilization of the head of the jetty is critical to long-term project function and maintenance. A jetty head performs as a type of anchor for all of the components of the navigation entrance, serving to protect the landward portion of the jetty structure, the configuration of the underwater shoals and the adjacent shoreline position, the location and configuration of the seaward-most part of the navigation channel, and finally the overall ebb tidal shoal. Omission of stabilization of the jetty head in any long-term jetty maintenance or rehabilitation plan would introduce a higher level of uncertainty regarding maintenance funds required (jetty repair and dredging) as well as projected performance of the navigation entrance.

The most critical parts of a jetty in the short-term are the root and trunk. The jetty root (trunk) retains the subareal (sub tidal) part of a shoal that would otherwise encroach upon the navigation channel. A breach at the root or trunk would release the tidal shoal and result in rapid in-filling of the navigation channel. Additional complications resulting from a breached jetty root (or trunk) include reduced hydraulic efficiency of the inlet, destabilization of the remaining jetty foundation, and severe shoreline erosion within or outside of the inlet.

In some instances, a jetty segment may be damaged at such a high rate as to fail before timely repair can be implemented. A given jetty segment is assumed to lose function when the upper cross-section area has been reduced to less than 15 ±5% of the original standard upper cross-section. If a jetty segment fails within the body of the jetty, the segment is considered breached. If the breached segment was acting to retain the inlet's morphology, the failed segment may release a large volume of sand into the inlet which has the potential to impact MCR navigation. Figure A1- 249 and Figure A1- 250 show a breached jetty example at a smaller navigation entrance and the resulting adjacent shoreline sediment loss that resulted.

Figure A1- 249. Breached Jetty at Smaller Navigation Entrance

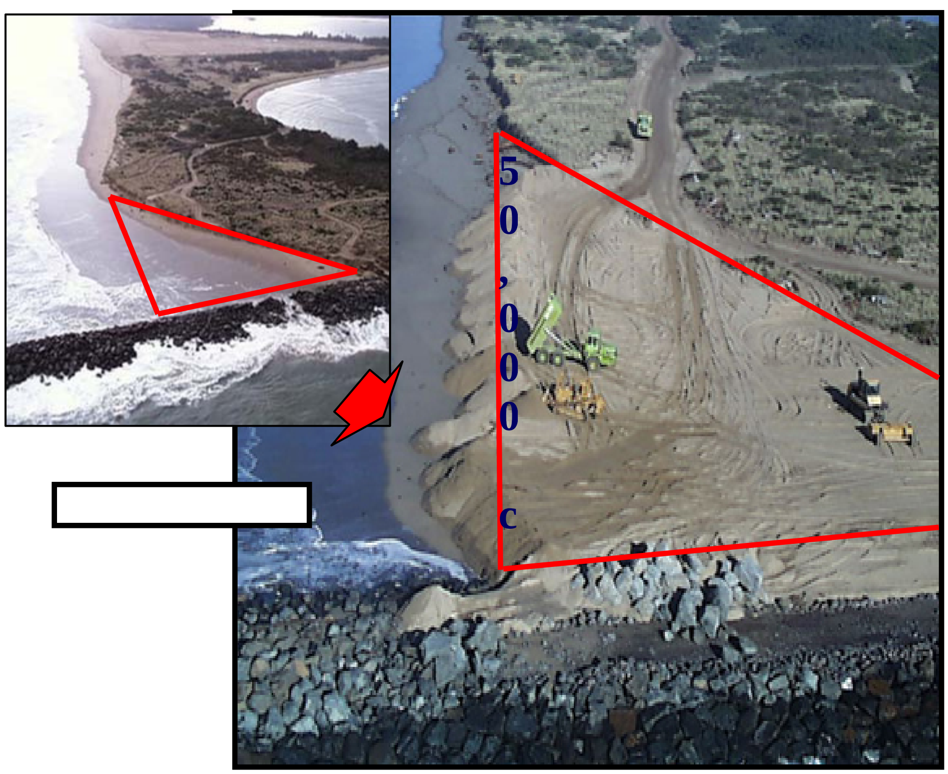

Figure A1- 250. Adjacent Shoreline Sediment Loss after Jetty Breach

Jetty head recession leads to progressive loss of jetty function which can impact inlet dredging requirements and stability of other jetty areas. Cumulative jetty trunk damage can result in a trunk breach which can have functional consequences on the inlet. Cumulative jetty root damage can result in a root breach which can have serious functional consequences on the inlet. Figure A1- 251 through Figure A1- 253, shown below, illustrates modifications to inlet with various jetty failures.

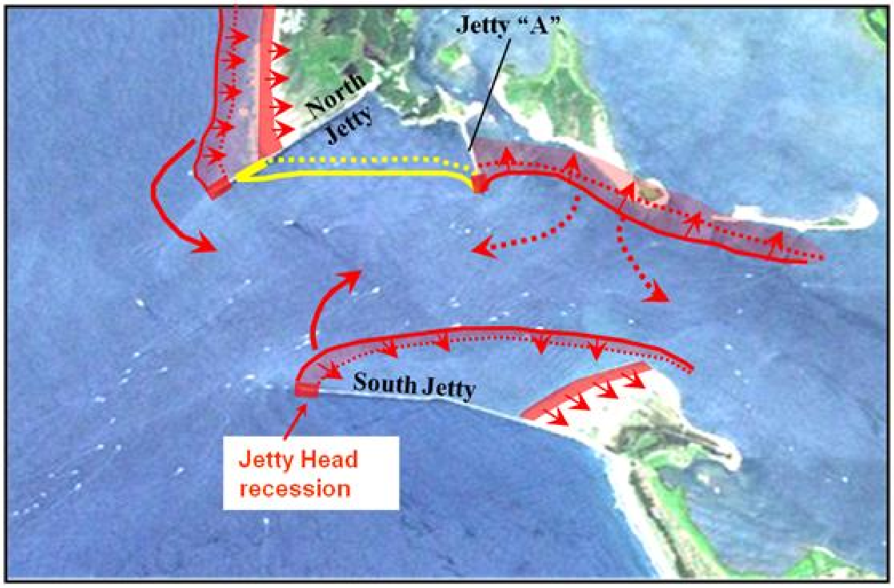

Figure A1- 251. Inlet Response to Jetty Length Loss

As a jetty head recedes landward, sand from the retained morphology is released and transported past the receding jetty and deposits within the MCR channel. The bathymetry deepens adjacent to the jetty and the morphology recedes, exposing the jetty to increased wave action. Head recession at Jetty A, exposes the North Jetty to increased scour.

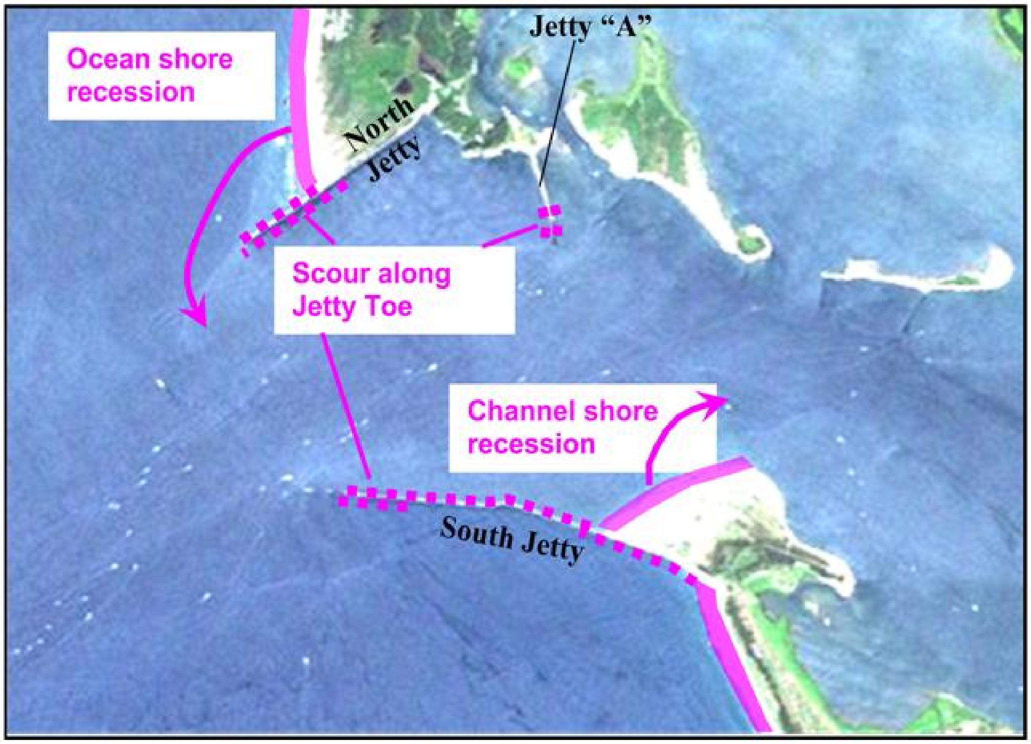

Figure A1- 252. Rip Currents along Jetty Length

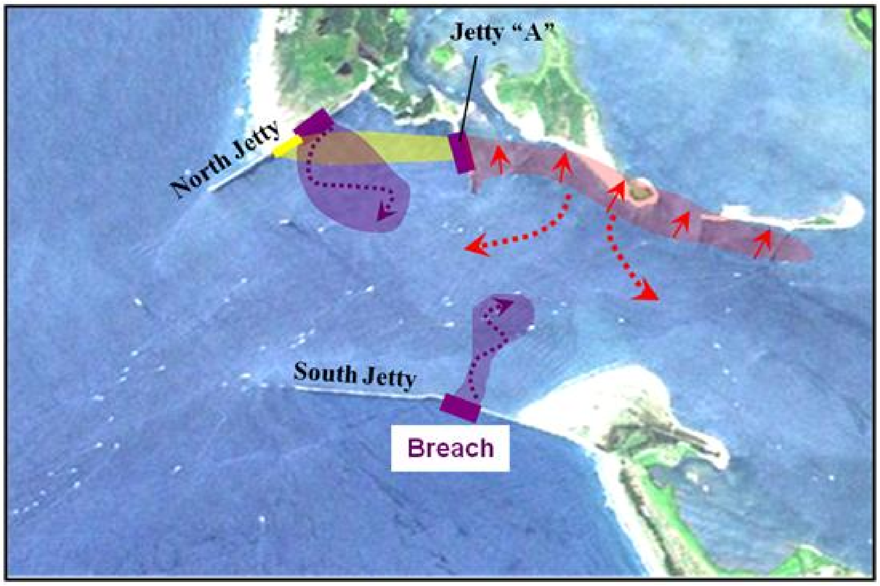

Figure A1- 253. Inlet Response to Jetty Breach

A jetty breach at MCR would establish flow through the jetty and destabilize adjacent morphology. Elevated shoaling within the MCR would occur. Aggressive dredging may be required to maintain the MCR channel, and the jetty may require emergency repair.

Enhanced rip currents form along the jetties acting to erode the jetty foundation (dotted line) and motivate continual loss of morphology adjacent to roots of the jetties, exposing the jetty foundation of each jetty to increased wave action and scour. Much of the eroded sediment is tranported into the MCR inlet

The longer a damaged jetty segment goes without repair, the higher the rate of cross-section degradation due to wave action, and the more likely that the jetty segment could breach before repairs are made. In rare instances, a jetty segment may be damaged at such a high rate as to fail (lose function) before timely repair can be implemented. A given jetty segment has the potential to lose function when the upper cross-section area has been reduced to less than 20% of the standard upper cross-section.

The distinction should be made between jetty damage and jetty failure and MCR project function failure. The primary function of the MCR project is to maintain the navigation channel for deep draft shipping. The secondary function evaluated in the structure rehabilitation effort is to significantly extend the life and reliability of the jetties in order to reliably maintain the primary function. Sub-categories addressed in order to accomplish the primary purpose included prevention of a significant breach to the jetties, minimizing dredging of the channel, minimizing the frequency and magnitude of the required jetty repairs, and reducing the degradation rate of the jetties over time.

If a jetty breach occurs, because of the higher wave heights it is likely to occur during the timeframe of November through March. Due to the typically severe weather conditions at the Mouth of the Columbia River during winter months, emergency jetty repairs (to fill the breach) and/or emergency dredging activities (to maintain the navigation channel) may not be possible or may only be possible at a reduced rate with the end result potentially being impacts to navigation until the actions can be completed. Jetty repairs are expensive and due to the sheer size of the structures usually include high costs of mobilization. Because these jetties are typically repaired from the top of the structure (especially during winter months), construction of a haul road is required for each jetty repair effort. In addition, there are some areas along the seaward half of the North Jetty and the seaward half of the South Jetty for which emergency jetty repairs during the winter months could not be conducted due to the exposure of the construction site to overtopping wave conditions.

The degree of navigation impact motivated by a breached segment is dictated by how many neighboring segments breach, the volume of shoaling that could be mobilized into the inlet, and the proximity of the breached segment(s) to the navigation channel. In the analysis of the MCR project, a breach of the North Jetty is expected to be a more serious threat to the primary function of the project. This is due to its proximity to the navigation channel as well as its current function of holding back Peacock Spit from encroachment into the channel.

b. Responding to a Breached Jetty at MCR

Attempting to perform emergency dredging at MCR in winter can be problematic, yet the activity may be required if deep draft navigation becomes threatened by a breached jetty. The cost of performing such dredging will be significant. The cost of repairing a breached jetty segment can be significantly higher under emergency conditions as compared to normal repair conditions. Although the likelihood of jetty breach is low, the consequences of jetty breaching can be high. The successive steps and consequences of jetty failure are explored and explained in more detail in the life cycle analysis in Appendix A2.

In a historical context, the South Jetty had breached extensively during the late 1920s affecting navigation and motivating a significant rehabilitation campaign of the south and north jetties during the 1930s. During the mid-2000s, reaches of the north and South Jetty become partially breached, motivating recent interim repairs to both the North and South jetties.

If a jetty segment fails at the seaward terminus, the subareal jetty head will recede landward as shown in Figure A1- 198. In most cases, some relic jetty head remains as a submerged structure extending vertically to somewhere between -20 ft and 0 ft MLLW. In most Pacific Northwest prototype cases, in the short term, jetty heads are allowed to recede landward without repair due to the difficulty and high cost associated with jetty head repair. Resilient jetty head repair alternatives are generally not considered to be within the "normal" maintenance budget. However, recession of the jetty head can result in larger process changes to the inlet and the navigation structures. In many cases, head recession will cause added shoreline recession along the jetty root, which can expose the jetty to increased wave action and increase the requirement for maintenance dredging. Long-term effects from jetty head recession can take the form of less reliable structures, higher degree of wave exposure in the navigation entrance for vessels, and increased shoreline and underwater shoal erosion.

If a breach along the North or South Jetty occurred, it would likely happen during winter (Oct-Mar) in response to a storm wave event. Wave action at MCR throughout winter can be intense. Initiating jetty repairs and performing channel dredging during winter would be difficult, especially if land access to the jetty breach is not available. If 100 to 500 ft of jetty were affected by the breach, approximately 10,000 to 50,000 tons of armor stone would be needed to affect an emergency repair. The cost of such an activity would be \$5 to \$15 million, which is 2-5 times more than a preventative (pre-breach) repair scenario. Procuring this amount of armor stone (5-25 ton size) in a 2-month period would be problematic.

If the breach promoted sand in-fill within the MCR channel, then dredging would be required to remove the shoal material. If the channel shoaling were severe enough to impede/restrict deep draft navigation through MCR, then emergency dredging of the material would have to be performed concurrent with emergency jetty repairs. Assuming that dredging of the MCR channel during winter is possible, the efficiency of dredging operations during winter would be reduced due to wave action. Dredging production during winter is estimated to be 1/2 to 1/3 of normal operations (or 15,000-25,000 cy/day). If the channel experienced 2 mcy of in-fill due to a jetty breach, removal by dredging would take 3 months (or about \$7 million).

After dealing with the short-term effects of a breached jetty at MCR, many of the breach-related effects (modified tidal shoal morphology) would be profound and long lasting. The reliability of the affected jetty and deep-draft navigation through the MCR would be challenged in a post-breached condition. This would be reflected in a higher O&M

expenditure over the long-term (10 years), and is estimated to be $1-2 million per year (associated with increased dredging at MCR).

14. Graduated Levels of Jetty Cross-Section Repair Design

In the jetty cross section template figures (Figure A1- 254 through Figure A1- 256), the light brown represents sand foundation or land, the dark brown represents existing relic stone (existing rock structure from earlier construction efforts), and the light blue represents proposed new cross section and new rock. The border around each cross section is also color coded (pink, yellow, blue, black) to help describe the composite cross section.

Jetty Head Cross Section. The jetty head cross section stays constant regardless of the cross section applied along the trunk of a jetty. All jetty caps are very substantial features designed to withstand wave attack from three sides and significant overtopping forces. Note that primarily to control costs, all of the jetty head templates are designed to be constructed on top of the existing relic stone base.

Minimum Template and Scheduled Repair Cross Section. This cross section rehabilitates both jetties along their current length using a minimum cross section that extends above the waterline and lies essentially within the existing jetty footprint.

Small Template Cross Section. This cross section was only considered for the South Jetty and Jetty A because the minimum and small cross-sections were essentially the same for the North Jetty. This cross section rehabilitates the South Jetty along its current length using a small cross section that only extends above the waterline; however, it is not constrained to fit within the existing footprint of the jetty.

Moderate Template Cross Section. This cross section was considered for the North and South jetties and rehabilitates both jetties along their current lengths using a moderate cross section that encases the existing jetty both above and below the waterline and extends beyond the existing footprint.

Large Template Cross Section. This cross section was considered for the North and South jetties and rehabilitates both jetties along their current length using a large cross section that encases the existing jetties both above and below the waterline, and also places a stabilizing toe berm along key reaches of each structure. The cross section would extend outside of the existing jetty footprint.

Composite Cross Section. This could entail any combination of the above cross-section types tailored to address structure concerns along specific jetty reach sections. Up to four cross sections could be used together over the length of a jetty to make a composite plan.

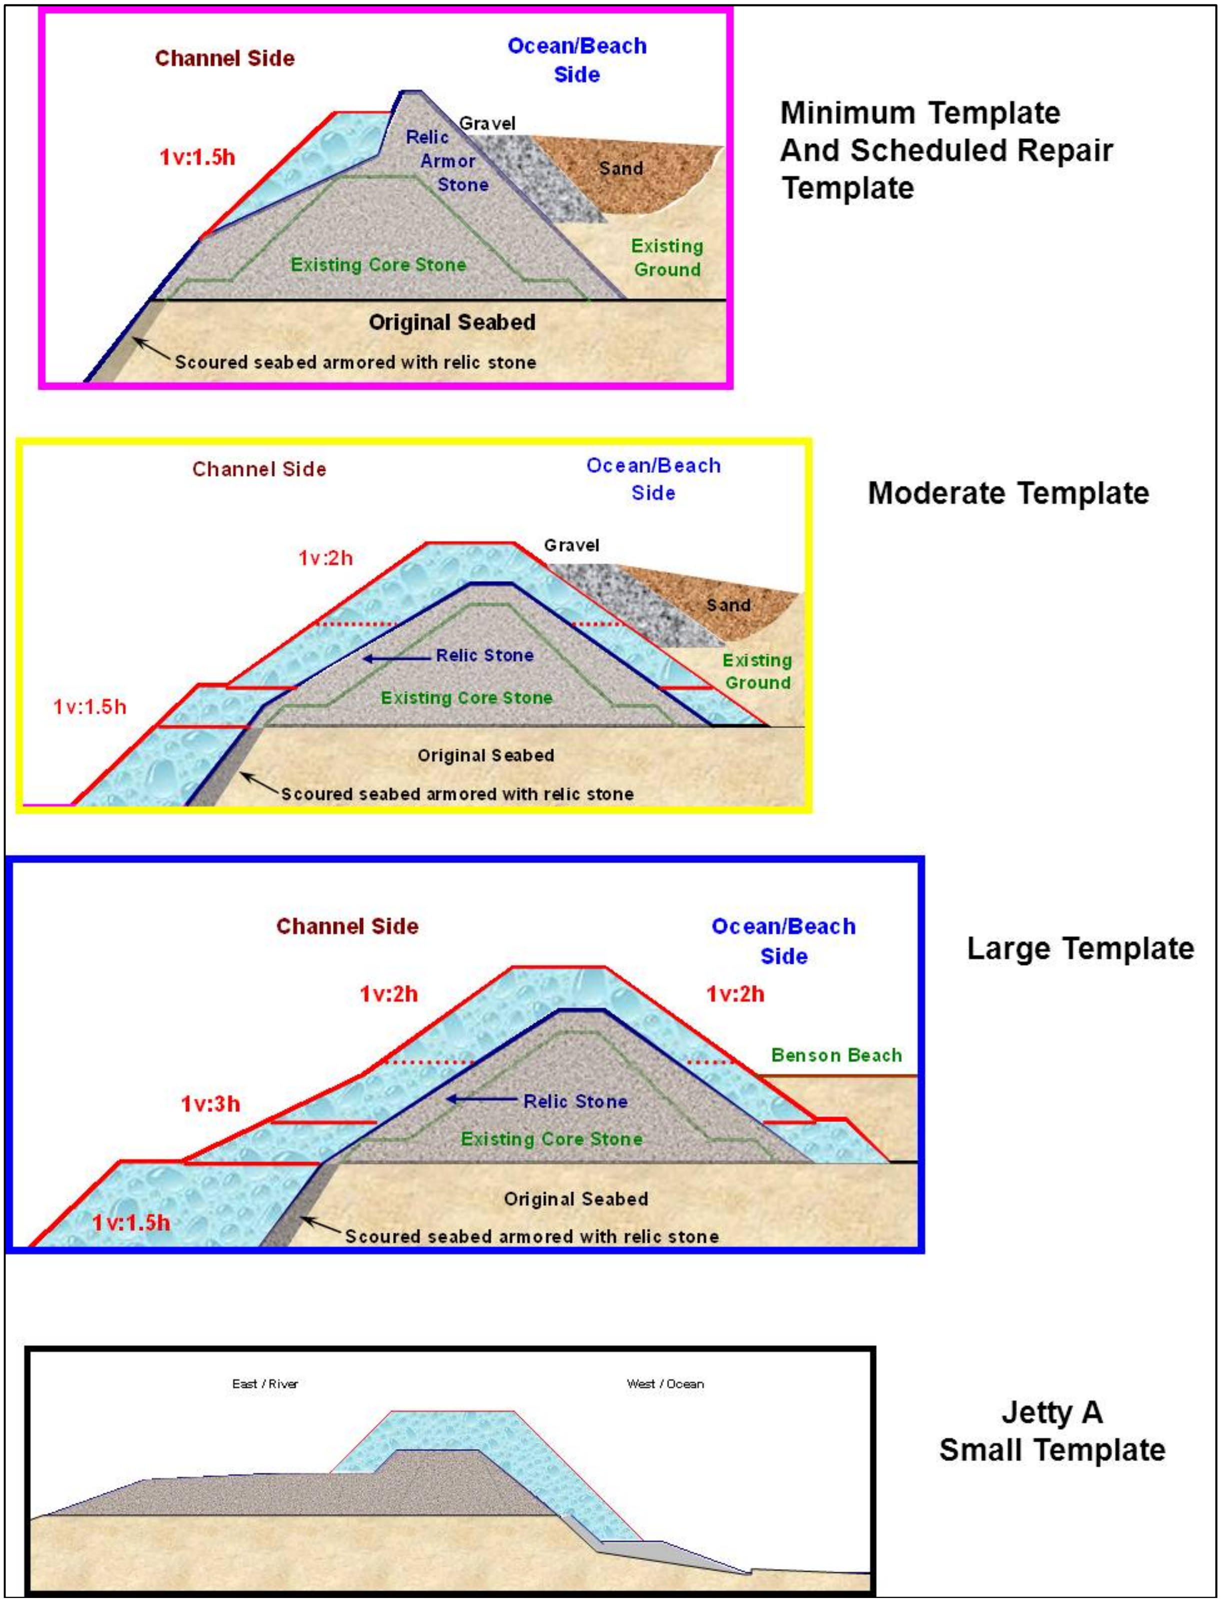

Figure A1- 254. North Jetty and Jetty A Conceptual Cross Section Templates

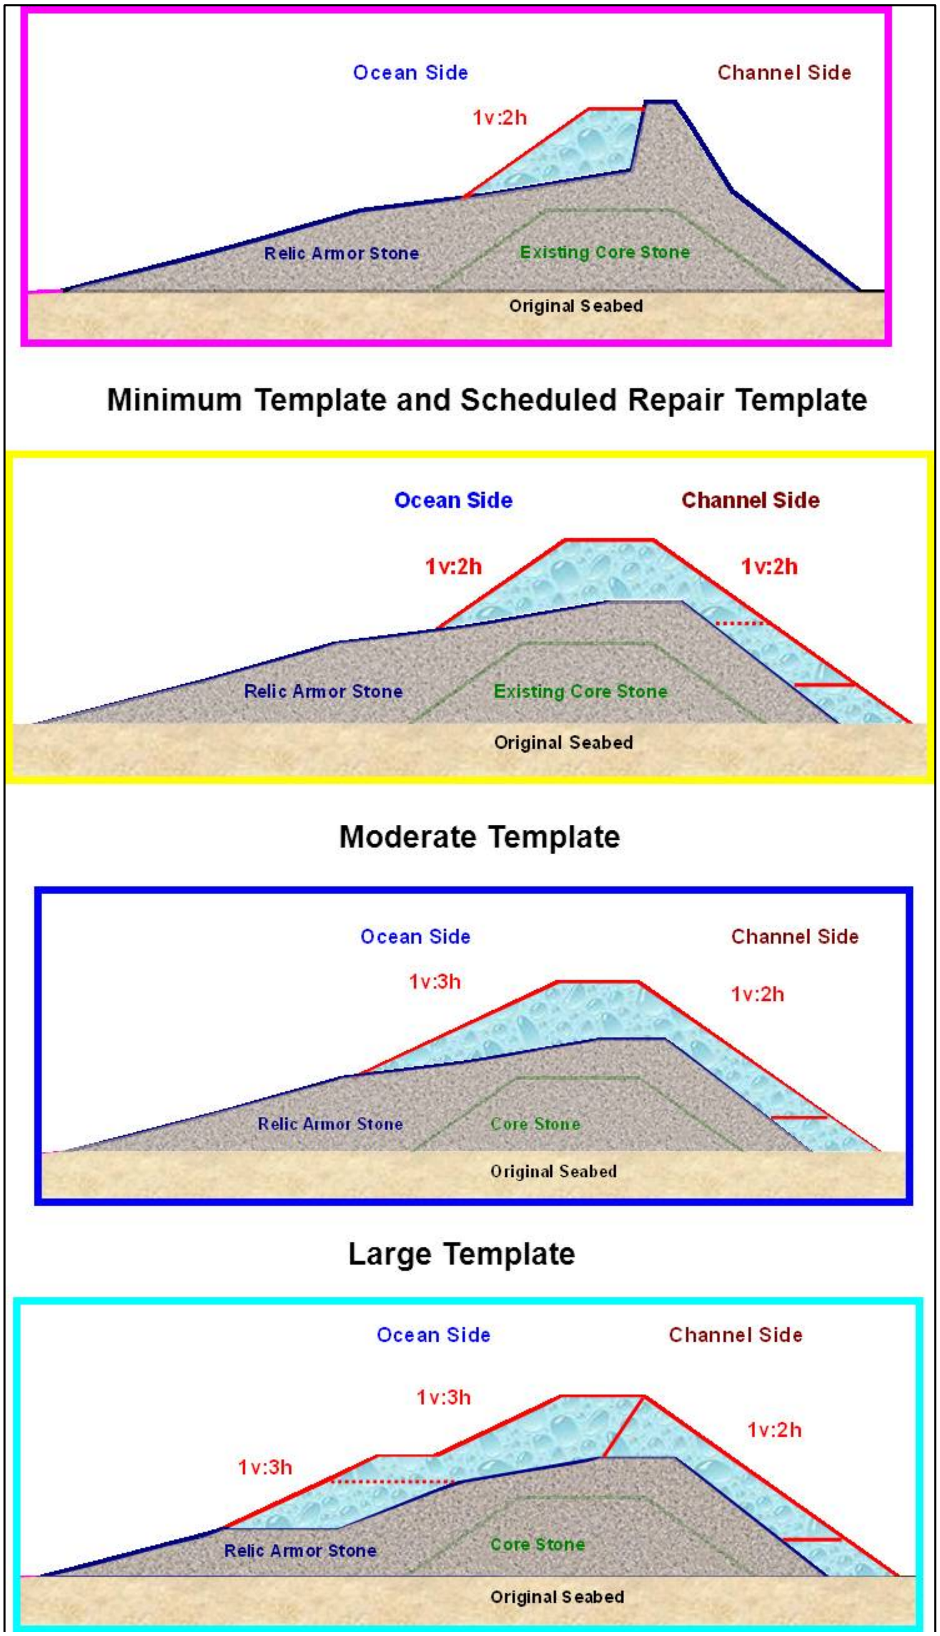

Figure A1- 255. South Jetty Conceptual Cross Section Templates

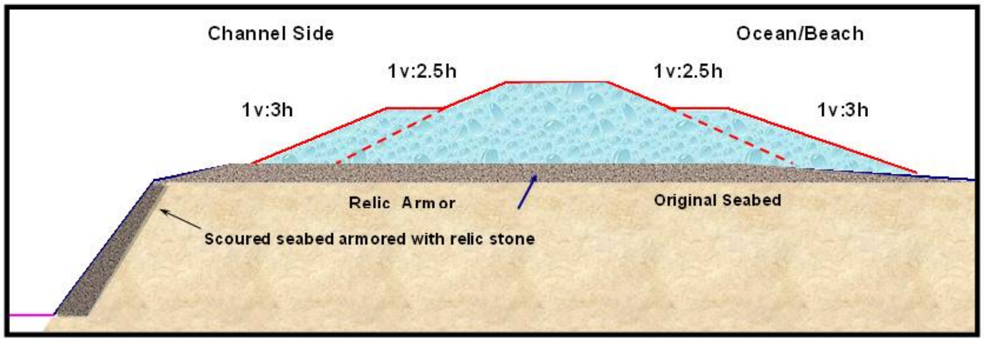
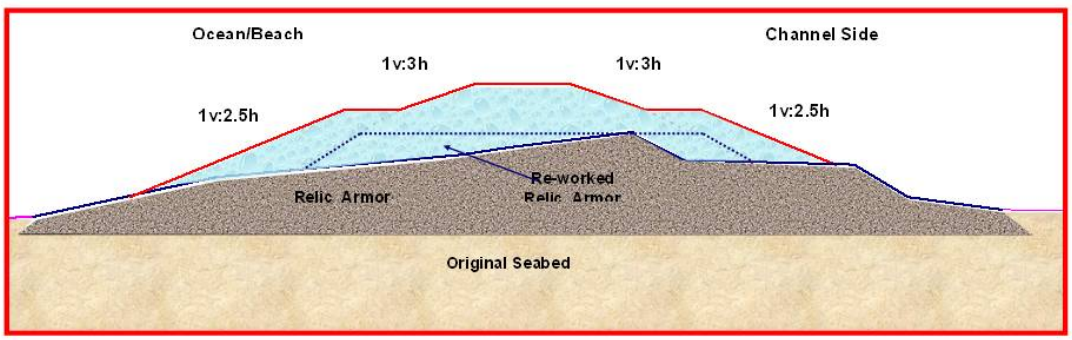
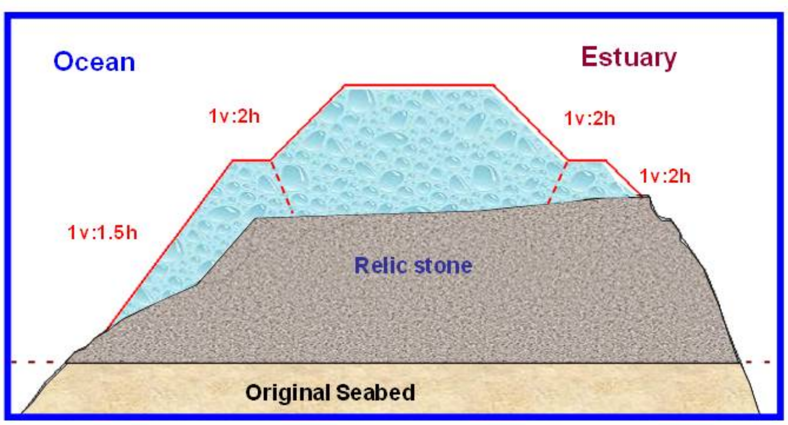


North Jetty Head Template



South Jetty Head Template



Jetty A Head Template

Figure A1- 256. Jetty Head Cross Section Templates

Figure A1- 254 through Figure A1- 256 are intended to be generic examples of the template types. It is important to realize that the particular template/cross section shown (as well as the relic stone base it is constructed on) will vary along the full length of each structure.

The top sketch in figures Figure A1- 254 and Figure A1- 255 show the minimum template or scheduled repair approach to the rehabilitation which does not require as much rework of the relic stone as the larger more substantial designs. The figure showing the minimum template is trying to convey that the repairs conducted will just build off of the existing relic configuration as much as possible. No attempt will be made to modify the backslope for additional stability in that area. The moderate and large templates are more substantial and comprehensive design templates requiring more re-work, more stone, and a larger area of placement.

The large template for the North Jetty does not show the gravel and sand area on the backside because, in general, for most of the alternative where this template is used, it is seaward of the lagoon fill area that requires the sand and gravel backfill. The horizontal red lines in the cross sections indicate transitions to different stone sizes within the cross section.

15. Categories and Features of Alternatives

a. Considerations

The following considerations were taken into account during the plan development and selection process. At a minimum, structure rehabilitation should restore project resilience to a prescribed baseline condition, such that future structure risk can be managed at a sustainable level. Structure risk is a function of repair timing, frequency, and maintenance costs. Metrics for jetty maintenance focused on repair timing (when do repairs occur) and repair frequency (how often). Minimum rehabilitation is appropriate in cases where the forcing-loading environment is stationary and not severe, and the structure can be adequately maintained in the future. In cases where the present loading environment is moderate to severe (or is non-stationary, increasing over time), more robust rehabilitation alternatives were required to increase project resilience and address increased structure loading. This approach may also be needed to address certain areas of a structure that cannot be easily maintained. Applying engineering features along a given jetty can reduce foundation scour and other jetty-specific degradation issues.

Repair and rehabilitation options comprise the general categories of alternatives considered and evaluated for the MCR jetty system, as described below.

b. Repair Alternatives

Repair alternatives involved adding limited amounts of stone to trunk and root features. Under repair options, stone placement is generally limited to above-water sections and remains within the existing jetty and relic stone structures. Repair alternatives also considered differing degrees of repair. Repair alternatives include dune augmentation at Trestle Bay, if needed. Repair alternatives were considered to occur either on the basis of a scheduled, predetermined time and place, or on a interim basis for which a stochastic model predicted both jetty repair and/or breach scenarios. The damage threshold for which the jetty repairs are implemented was also varied to some degree. With a lower damage threshold, the likelihood of a jetty breach is increased along with risk to navigational channel impacts. The implementation of the damage threshold in the stochastic model is discussed further in Appendix A2. Although a single damage threshold was used in the current analysis, there is the possibility of testing various thresholds to optimize the risk of failure against the possibility of deferring repair costs. For the North and South jetties, the repair alternative included repair combined with and without engineering features.

c. Engineering Features

Additional engineering features are potential options to address the larger system-based degradation processes that impact the project as a whole and over the long term. Engineering features included jetty head stabilization through a robust head construction, construction of spur groins at key locations along each jetty to promote foundation stabilization, and lagoon fill behind the North Jetty root. These features were evaluated individually and incrementally in the life-cycle model.

d. Rehabilitation Alternatives

Rehabilitation alternatives generally incorporate engineering components which may extend beyond the current footprint of jetty and relic stone structures and could entail both above and below-water fill. Certain engineering features were incorporated as common components present in all of the rehabilitation alternatives considered. These engineering features included capping the jetty heads, constructing additional spur groins, filling of the North Jetty lagoon area, and augmenting the Trestle Bay dune, if needed. Rehabilitation strategies were evaluated both immediate and scheduled. The scheduled rehabilitation alternative constructs at specific locations along the jetty at specific time periods in order to maximize the effectiveness of the federal investment.

16. Proposed Rehabilitation Plans

a. General

The rubblemound jetties have experienced significant deterioration since construction, mainly due to extreme wave attack and foundation instability associated with the erosion of tidal shoals on which the jetties were built. The purpose of the proposed action is to perform modifications to the North and South Jetties and Jetty A at the MCR to improve the reliability of the jetty structures (i.e., reduce the risk of failure), extend the jetties' functional life, and maintain deep-draft navigation.

A secondary purpose which is supportive of the above purpose is directed at slowing down the larger degradation processes that are impacting the long-term project reliability. These processes include ebb tidal and adjacent shoal erosion, jetty length loss, and shoreline erosion.

A reliability and life cycle analysis was used to examine the performance of the jetties (past and future) and develop structural alternatives to increase the reliability of the jetty system. Appendix A2 defines the coastal processes affecting jetty reliability and summarizes the event tree and life cycle analysis. Finally, a holistic approach is used to propose a phased strategy for jetty rehabilitation.

Despite intermittent repair and rehabilitation efforts over their lifetimes, all of the jetties are currently in a significantly deteriorated condition. The last partial rehabilitation on the North Jetty was conducted in 1964 and addressed 17% of its length. The last partial rehabilitation on the South Jetty was conducted in 1982 and addressed 25% of its length. The last partial rehabilitation on Jetty A was conducted in 1961 and addressed 56% of its length. The lengths of the north and south jetties which have never been repaired since original construction are 55% and 36%, respectively. The jetties continue to recede back from their original length. The South, North, and Jetty A head positions are currently shorter than authorized lengths by 6200 ft, 2200 ft, and 900 ft, respectively. Due to the interaction of wave patterns and currents with the jetty configuration, the shorter jetty lengths can increase underwater shoal erosion, influence shoreline position adjacent to the jetties, and alter the forcing climate at the project.

Progressive damages to one of the primary jetties could result in a significant breach which can trigger an emergency repair to the jetty, rapid infill into the navigation channel, and emergency dredging activities. The major rehabilitation approach for the MCR jetty system focused on adequately defining the larger processes affecting the jetty system, and then describing the jetty system reliability over time. Consequences evaluated included frequency and consequences of future jetty repairs as well as potential impacts to dredging and navigation. Each alternative adds additional elements of either process stabilization or above or below water cross section stabilization as well as varying degrees of cross section reliability improvement.

b. Alternative Approach

Rehabilitation will be considered as an alternative when it can significantly extend the physical life of the feature and can be economically justified by least cost analysis. Reliability is a measure of a facility to perform its intended function under specified operating conditions for a given period of time, in this case 50 years. The alternatives change the life-cycle cost time path of the project. In the case of the MCR jetty system, an adverse event is described as a jetty breach which has the potential to impact navigation at the entrance. Consequences are evaluated in three general categories: jetty repairs, dredging, and potential navigation impacts. In the execution of this major rehabilitation study, the assumption was made that all attempts to avoid navigation impacts would be employed by the District. Navigation impacts, therefore, were not evaluated quantitatively.

This alternatives investigation was conducted in phases. The first phase involved a detailed analysis and summary of the base condition for the jetty system. This phase is essential and provided the standard to which all of the other plans would be compared. An extensive hindcast analysis was conducted to simulate past performance of each jetty so that future performance could be projected with a level of confidence.

The second phase investigated and proposed actions for the larger system-based degradation processes which impact the project as a whole and over the long term. Those actions have been discussed under "Engineering Features" above. These features were evaluated individually and incrementally in the life cycle analysis model using the minimum cross section repair plan. Engineering features included head stabilization through a robust jetty head construction, construction of spur groins at key locations along each jetty to promote foundation stabilization, and lagoon fill behind the North Jetty root.

The third phase evaluated graduated levels of cross section repair or improvements. The conceptual cross sections for the three jetties can be seen in Figure A1- 254 through Figure A1- 256. Each of these cross sections was applied along the full length of each jetty to identify resiliency and performance of general design concepts along the jetty's length. Variability of segment-by-segment cross section resiliency is typically driven by existing condition of the structure, degree of exposure to wave attack, directions of wave attack, and foundation condition. Each of these plans was also evaluated using the life cycle analysis model which is described in detail in Appendix A2.

The fourth and final phase evaluated the feasibility of phasing the jetty repair to minimize project failure and maximize construction efficiency. Through this phase a plan to conduct a scheduled rehabilitation effort was developed.

c. Key Selection Criteria

The focus of this rehabilitation study was to identify and recommend a course of action which optimizes the future life-cycle costs for the system of jetties at MCR. While this was a least cost analysis, various other elements of project reliability, constructability and access, and potential navigation risk were also considered in the plan comparisons and ranking. Since potential navigation impacts were not evaluated quantitatively, greater importance is placed on quantifying the risk associated with not maintaining the system and considering other relevant criteria. The complexities of major jetty repair in challenging conditions as well as the feasibility of emergency winter time dredging at the Mouth of the Columbia River were considered in the final evaluation. Only four U.S. contract dredges are capable of dredging at MCR during winter conditions and those four dredges are normally scheduled for work in milder climates during winter months. Key selection criteria considered included:

- Initial construction cost;
- Total repair costs over life;
- Average annual costs (AACs);
- Number of repairs and year of first repair;
- Number of expected jetty breach events;
- Reliability over project life and residual risk;
- Constructability and access;
- Potential to impact navigation entrance function; and
- Potential impacts to larger inlet system.

At a minimum, structure rehabilitation should restore project resilience to a prescribed baseline condition, such that future structure risk (maintenance costs) can be managed at a sustainable level. This approach is appropriate in cases where the forcing-loading environment is stationary and the structure can be adequately maintained in the future. In some cases (i.e., where a non-stationary loading environment is increasing over time or if questions remain regarding the ability to maintain), more robust rehabilitation alternatives are required to increase project resilience, to match increased structure loading. This approach may be needed to address certain areas of a structure that cannot be easily maintained, such as the outer half of the South Jetty. The recommended plan will identify the optimum investment both in terms of proposed actions and timing of proposed actions, given the risk and uncertainty identified during the study. That plan will offer the greatest benefit to the project with respect to the cost and reliability.

There are some basic and broad distinctions between the analyzed plans that should be considered as further reduction of plans is conducted:

- With the exception of the base condition which utilizes an interim repair strategy, all of the other plans utilize a programmed repair strategy which is initiated approximately 4 years prior to construction.
- The base condition and the scheduled repair plans were evaluated both with and without maintaining current jetty head positions. Without head stabilization, the jetties continue to lose length at a rate of 5 to 50 feet per year with any accompanying impacts to project resilience and performance. Significant changes to the navigation inlet and surrounding environment are expected under these scenarios.
- The base condition and the scheduled repair plans do not include the construction of spur groins or lagoon area infill to help stabilize jetty foundation.
- All of the scheduled repair plans and the minimum template plans address only the above water portion of the jetty cross section.
- Life cycle maintenance of the MCR navigation entrance can be handled in two different ways: (1) large initial cost, lower maintenance costs resulting in higher reliability and lower risk, or (2) low initial cost, higher maintenance costs resulting in lower reliability and higher risk. The full rehabilitation plans represent the former and the scheduled repair and minimum template plans represent the latter.
- Environmentally, the full rehabilitation plans are similar in that they all include engineering features (jetty head capping, spur groins, lagoon fill) and all address the full length of each structure in some manner. The plans that may have a different environmental impact would be those allowing significant physical alteration of the system (base condition, scheduled repair) and those requiring frequent and continual construction activities (base condition, scheduled repair, minimum template plans).

d. Alternative Comparison and Selection Process

Due to the complexity of the MCR system and the potential range of alternatives, alternative selection was an iterative process which involved several levels of technical and project analysis. Numerous plans were run using modified cross section layout and/or timing of repair. Each of the jetties was evaluated separately and had slightly different emphasis in the criteria for plan selection.

The North Jetty is distinctive in that it is closest to the navigation channel as well as serves to hold back a very large subaerial and subaqueous sediment feature in the form of Benson Beach and Peacock Spit. The existence of this large shoal has served as protection for the oceanside of the North Jetty for a good portion of its life. A major breach along this jetty has the potential to impact navigation if either (a) emergency repairs cannot be instituted quickly and/or (b) emergency dredging cannot be conducted of the resulting sediment infill in the channel. For this reason, a major breach along this jetty would result in emergency repairs being instituted immediately, regardless of the time of year or the cost of those repairs. Another significant difference for the North Jetty is the 60 to 80 ft depths on the channelside of the seaward half of the structure and the rapid loss of jetty length, two to three times the jetty length loss as for the South Jetty and Jetty A.

The South Jetty is very important to the MCR inlet serving as a type of anchor that aids in controlling the overall shape of the ebb tidal shoal which ultimately impacts sediment pathways as well as wave approach patterns. The South Jetty is also distinctive in that it extends for over 4 miles out into the ocean and is exposed to the greatest wave forces of any of the structures. The exposed nature of the South Jetty makes it difficult to repair quickly since fall through spring construction on the jetty is too hazardous. Access to the outer half of the South Jetty is particularly problematic and results in extreme exposure of any equipment being used. The South Jetty is located further from the navigation channel than the North Jetty and a major breach would not immediately impact the channel. Due to a slower potential impact to navigation response as well as the hazardous access, the South Jetty would not be repaired following a major breach until the following summer.

Jetty A is less exposed than either the North Jetty or the South Jetty and it is also oriented perpendicular to the navigation channel, making a breach in this structure less likely to have an immediate impact on the channel. This jetties evolution over time, however, has been impacted by the large, +100-foot deep scour hole which has developed off of the south end of the head. The rehabilitation/repair of this jetty is primarily to maintain a robust cross section and stable jetty length so that the forces along the length of the North Jetty are controlled and the alignment of the navigation channel remains centered in the inlet.

e. Environmental Considerations

Comparisons were made between the alternatives and results were evaluated regarding three categories predicted to have some degree of environmental impact. The categories included: (1) frequency of required repair and construction activities; (2) potential morphological changes at the inlet from continued jetty recession; and (3) shallow-water habitat loss due to placement of engineering features, specifically spur groins and lagoon fill. Category one was evaluated based on minimizing repeated impact to the same area after the area had re-established. Category two evaluated the changes to the jetty foundation, the inlet, and the adjacent beaches as a result of continued recession of jetty length. The current assumptions favored rigidity as a surrogate for resilience, and assumed fewer environmental impacts by maintaining current habitat locations. Category three reflected the loss of shallow-water habitat by the engineered structures and fill. These categories were rated high, medium, and low depending on the loss of habitat or frequency of repair or change in morphology of the inlet. Maximum effects were assumed to occur with the largest jetty cross section, maximum change in morphology from the largest reduction in jetty length or highest amount of breaching, and the highest amount of repairs. Other construction and staging elements also were evaluated to determine the best way to avoid and minimize environmental impacts. Additional common project elements across alternatives included location of stockpile storage, selection of staging areas, location of barge offloading sites, and construction access.

f. Definition of Base Condition

The base condition assumes that no action would be taken to slow down the large-scale physical processes that are negatively affecting the structural stability of the MCR jetty system. Those larger physical processes include landward recession of the jetty head, shrinking of the ebb tidal shoal, foundation erosion, and adjacent shoreline erosion. The heads of each jetty would continue to recede landward with the expected response of the surrounding morphology including continued shrinking of adjacent underwater shoals and the overall shrinking of the ebb tidal shoal. Much of the material eroded from the inlets shrinking shoals would be transported into the MCR inlet, thereby adding the requirement for maintenance dredging. The underwater sand shoals upon which the jetties are built would continue to erode, leaving deeper water depths along the jetties. The deeper water (over the eroded shoals) would allow larger waves to attack the jetties resulting in a greater rate of jetty deterioration and foundation erosion. Wave and current action within the MCR inlet would increase. The lagoon near the root of the North Jetty, where tidal flow and wave surge through the jetty is de-stabilizing the structure foundation, is assumed to be filled. This improvement was addressed in the 2011 Major Maintenance Report.

Due to the level of construction and the high mobilization costs, the base condition does not include any jetty head re-construction. Only the trunk and the root of the jetty are maintained, and the jetty head is allowed to recede landward. Maintenance of the trunk and root of the jetty is minimized by deferring repair activities into the future for as long as possible. Jetty repairs are initiated only when a failure of the upper portion of the jetty cross section seems to be progressing. A rubblemound structure can incur a certain level of damage before the whole cross section fails resulting in a functional impact; however, a complete breach through the above water portion of the structure can result in rapid deterioration. The base condition is identified as an interim repair approach because the upper portion of the cross section is allowed to be damaged to approximately 40% remaining prior to repair actions being taken. In this way, the jetty is maintained close to the margin of functional loss.

Depending on the percentage of lost cross section which results from the deferred action, maintenance actions may need to be conducted on an expedited basis. In all cases, the repair occurs before the complete failure of the upper part of the cross section

The interim repair approach carries an elevated risk for incurring added costs either through expediting repairs (to prevent functional loss of a jetty). Consequently, there is an elevated likelihood that jetty repairs may be more expensive (cost/ton of repair stone placed) when they do occur

g. North Jetty Base Condition

The North Jetty has receded approximately 2,100 feet in length since original construction in 1916. The jetty head will continue to deteriorate at a rate of about 20 to 50 feet per year. In 50 years, it is estimated to reach Stations 76-90 (or about 1,800 feet lost), in very close proximity to where the existing shoreline is today. Under the base condition, the jetty head is not repaired or rebuilt during the 50-year period. Peacock Spit and Benson Beach are expected to continue to erode shoreward at a similar rate to the jetty length deterioration. Much of the sediment loss associated with shoreline retreat will migrate into the federal navigation channel and routine maintenance dredging of the entrance will increase over time. The maintenance dredging volume could be greater than present by an amount of 0.5 to 1 mcy per year (or by a rate up to 25% greater). The resulting head loss would have moderate effect on wave climate and navigability. Erosion of the surrounding shoal would expose more vulnerable areas of the jetty to increased damages. Continued loss of jetty length (and Peacock Spit) could potentially expose the seaward half of the South Jetty to higher wave conditions.

The trunk of the jetty is expected to degrade by three distinct processes: direct wave impact, wave overtopping (affecting the above water level of the jetty) and scour at the base of the jetty (affecting the below water portion until it fails and destabilizes the above water portion of the jetty). During the 50-year project life, it is predicted that the North Jetty may breach, destabilizing more of the jetty and allowing significant amounts of sand to move through the jetty. Breaching typically occurs during severe winter storm attack. The model suggests that during the 50-year project life, breaching will occur approximately 10 times at multiple locations along the North Jetty resulting in emergency repairs. If a segment breaches, adjacent segments have a high probability of also breaching.

For significant breach events, approximately 2-3 mcy of material could move from Peacock Spit and Benson Beach into the navigation channel. A shoal within the navigation channel would begin to form. In the absence of emergency dredging, it is expected that the depth of the navigation channel could be reduced from -55 feet to -40 feet in about 2 to 4 months. In order to maintain navigability of the navigation channel, the USACE would perform emergency repairs on the breach and attempt to mobilize sufficient dredges to maintain the authorized channel depth. During the 50-year project life, approximately 2 to 5 planned repairs would be expected to occur along the North Jetty.

To perform emergency repairs to the breached area, a contractor would truck in readily available stone to the North Jetty, build a haul road on top of the jetty, and place jetty stone in the breached area with a tracked mounted excavator or similar piece of equipment to stop the volume of material migrating into the navigation channel. Not only will the breach allow for sand to move through the jetty opening, but also sea water may flood low-lying Benson Beach park areas complicating access to the repair. The contractor may need to pioneer a road into a jetty access point for breach repairs.

The Columbia River Bar can only be maintained with the use of a hopper dredge. These types of dredges have two drag arms that extend to the river bottom and hydraulically remove material. The material is temporarily stored within the ship in a hopper, and then transported to a disposal location. Once at the proper location, doors on the bottom of the ship open or the hull of the ship opens and the material falls from the hopper through the water column to the disposal site. To perform emergency dredging, one or two dredges would be mobilized. Production rates for the dredges would be approximately 20% to 25% of normal due to weather conditions and storm events. The dredges would rely on weather windows and favorable sea conditions to remove as much of the shoal as possible with a goal of maintaining navigation. Due to the physical limitation of the dredges, it is unlikely they could achieve the -55 feet of depth of the outbound lane with swells of 10 to 16 feet.

It should be noted that this course of action would present high risks to the dredges and their crew. Given the winter wave conditions that the dredges would be performing in, it is highly likely that damage would occur to the drag arm of the dredge while working. Environmental concerns regarding loss of hydraulic fluid or oil spills may result if the dredges are damaged. Dredged material will be disposed of at an approved in-water disposal site. Because it is predicted that 2 to 3 mcy of material will enter the navigation channel, the dredges are not expected to be able to remove all of the material that has migrated into the channel; therefore, the following dredging year could require up to three dredges to work the entrance to remove twice the amount of material of a normal maintenance year. During the last 23 years, there were about 7 years when the wave climate would have been too severe to do emergency dredging. Under those circumstances, there would be more risk of not being able to do emergency dredging with the potential impacts to navigation.

h. South Jetty Base Condition

The South Jetty has receded approximately 6,200 feet in length since original construction in 1885-1913. Under the base condition, the jetty head is not capped and no spur groins are constructed to control foundation scour. The jetty head continues to recede back at a rate of 5 to 20 feet per year until the concrete monolith collapses at which point the head recession is projected to be more rapid. In 50 years, it is expected to reach approximately Station 292 (or about 2,100 feet lost). The jetty head would not be repaired or rebuilt during the entire 50-year period. Continued loss of the jetty length (and Clatsop Spit) under the base condition would expose the seaward half of the South Jetty to higher wave conditions. Loss of jetty length would contribute to continued loss of the underwater shoal, exposing the jetty to increasing wave action and the shoreline at the root of the jetty to higher wave forces. The shoreline would continue to erode and recede, resulting in a shoreline breach into Trestle Bay in about 8-16 years. Based on the present condition of the concrete monolith, it is expected to slump into the ocean and basically be non-existent within 12-20 years adding additional deteriorating forces to the seaward half of the jetty. The remaining rubblemound portion of the South Jetty would then begin to deteriorate in an accelerated way.

The trunk of the jetty is expected to degrade by three distinct processes discussed above. During the 50-year project life, about 3 to 6 repairs would be expected to occur along the South Jetty. Unlike the North Jetty, emergency dredging would not occur because the material is not anticipated to affect the federal navigation channel in the short term. Increased dredging would occur during the summer maintenance months. The breach would not be repaired by emergency actions; rather repairs would be performed during the following summer.

i. Shore Area along South Jetty

The shore area along the South Jetty root has experienced profound changes since the time of jetty construction. Before construction, the nearshore area immediately south of the jetty was dominated by a broad shallow ebb tidal shoal, exhibiting relatively shallow water depth. Construction of the South Jetty dissipated this shoal, resulting in a rapid trend of increasing water depth through time. As the water depth along the south side of the jetty increased, wave action along the jetty root and adjacent shore area increased. The increased wave environment motivated rapid deterioration of the entire South Jetty and culminated with the significant breaching event along the jetty root in the late 1920s. During the 1930s, extensive efforts were undertaken to rebuild the South Jetty and re-establish the shore-land interface along the south side root of the jetty. The effort was successful; however, the result has been subjected to an increasingly harsh environment of wave action and related circulation since the 1930s.

Currently, the coastal shore interface along the South Jetty is in a condition of advanced degradation. The foredune separating the ocean from the backshore is almost breached. The backshore is a narrow strip of low elevation, accretionary area, separating Trestle Bay from the ocean by hundreds of yards. The offshore area along the South Jetty (and to the south) continues to erode, promoting larger wave action to affect the shoreline along the jetty root. The shoreline at the jetty root will continue to erode and recede, resulting in a possible shoreline breach into Trestle Bay in approximately 8-16 years. If this sand spit breach occurs, the resulting scenario would be catastrophic. The MCR inlet would establish a secondary flow way from the estuary to the ocean along this area (south of the South Jetty). This condition would profoundly disrupt navigation at the MCR and bring lasting changes to the physical nature of the inlet. Augmentation of the foredune along the South Jetty root is required to prevent the above realization.

Augmentation of the foredune would consist of placing 60,000 to 70,000 cy of cobble material to fortify the toe of the foredune and improve the foreshore fronting to resist wave induced erosion/recession. The augmentation material would be composed of a well graded mixture spanning the size range of large gravel (3-inch diameter) to large cobble (12-inch diameter.). The material would likely be delivered by truck and placed by earth moving equipment. There is the possibility that MCR sand or coarse-grained sand from the lower Columbia River could be hydraulically placed to enhance the foredune augmentation effort. However, use of sand-sized material would require a significantly large volume (200,000 to 400,000 cy) to produce the equivalent resilience as the proposed cobble material augmentation. The timing of this action is expected to be within first 8 years of proposed jetty rehabilitation. Note that the nearshore placement of MCR dredged material within the proposed South Jetty Site would mitigate the erosion of the South Jetty root area. The South Jetty Site is a potential nearshore dredged material placement site located in a water depth of 40-50 feet approximately 1 mile south of the South Jetty. This would complement the proposed foredune augmentation and help ensure balance of the sediment budget south of the South Jetty. However, this action should not be viewed as a replacement for foredune augmentation.

j. Concrete Monolith

During rehabilitation of the South Jetty in the 1930s, a significant effort was expended to stabilize the rapidly receding jetty head. The effort culminated with the construction of a 500-foot long concrete cap on the South Jetty to secure the jetty head at Station 330, approximately 4,500 feet inshore of the original seaward terminus of the jetty and approximately 3.3 miles offshore. The seaward most 200 feet of the concrete cap was composed of a solid core monolith. This cap has served well since 1940; however, the entire cap has been severely damaged due to the severe wave climate that exists 3 miles offshore and is progressively failing. The cap serves as an anchor to secure and protect the un-reinforced area of the South Jetty immediately inshore of the cap. When the cap fails completely (i.e., falls off the jetty crest), the land area adjacent to the cap will rapidly deteriorate because of severe wave action. Based on its current condition, the concrete monolith is expected to slump into the ocean and basically be non-existent within 12-20 years, adding additional deteriorating forces to the seaward half of the jetty. The remaining rubblemound portion of the jetty would then begin to deteriorate in an accelerated way.

k. Jetty A Base Condition

Jetty A has receded approximately 900 feet in length since original construction in 1939. The head of the jetty will continue to deteriorate at a rate of about 5 to 20 feet per year. In 50 years, it is estimated to reach Stations 78-86 (or about 1,500 feet lost). Under the base condition, the jetty head is not repaired or rebuilt during the 50 year period. There will be increases in dredging as Jetty A recedes. Clatsop Spit will prograde northward toward the navigation channel. The bathymetry in front of Sand Island will be cut back, mobilizing that additional material. The shallower area between Jetty A and the North Jetty will also be impacted allowing movement of that material toward the channel. The deepening which will be expected to happen in the vicinity of the North Jetty will further destabilize the foundation of that structure impacting its long-term reliability. The primary purpose of Jetty A is to direct river currents away from the North Jetty. It is expected that a one-time increase in dredging will occur on the order of 800,000 to 1.6 mcy followed by incremental increases in dredging that will depend on changes in channel shoaling patterns and spit movement.

The trunk of Jetty A is expected to degrade by three distinct processes: direct wave impact, wave overtopping (affecting the above water level of the jetty) and scour at the base of the jetty (affecting the below water portion until it fails and destabilizes the above water portion of the jetty). During the 50-year project life, it is predicted that Jetty A will breach, destabilizing more of the jetty and allowing significant amounts of sand to move through the jetty. Breaching typically occurs during severe winter storms. Modeling suggests that during the 50-year project life, breaching will occur between 5 and 8 times along Jetty A. If a segment breaches, adjacent segments have a high probability of also breaching. It is estimated that 2 to 4 repairs would occur along Jetty A. Unlike the North Jetty, emergency dredging would not be needed because the material is not expected to affect the navigation channel in the short term. Increased dredging would occur during the summer maintenance months. Also, repairs to the breach would occur the following summer.

I. Range of Alternatives Considered

The alternatives under consideration ranged from the interim repair approach of the base condition to increasingly higher levels of repair or rehabilitation action to prevent cumulative jetty damage and possibility of jetty failure and impacts to project function. Not all of the plans address the full range of structure and project degradation and each of the plans has varying levels of risk as well as need for repair and emergency action readiness associated with it. The alternatives considered included scheduled repairs, immediate rehabilitation, and scheduled rehabilitation.

Scheduled Repair
Scheduled repair without engineering features (North Jetty, South Jetty, Jetty A)
Scheduled repair with engineering features (North and South jetties)

Immediate Rehabilitation
Using minimum cross section
Using small cross section (South Jetty and Jetty A)
Using moderate cross section
Using large cross section
Using composite cross section

Scheduled Rehabilitation
Using minimum cross section (North and South Jetties)
Using composite cross section (North and South Jetties)

All of these alternatives were evaluated with and without an option to hold the jetty heads at their current location. When the jetty head was held at the specified location, the repair alternative being simulated was used to repair the jetty head when damage occurred.

The importance of engineering features (spur groins, jetty capping, lagoon fill) that target damaging long-term degradation processes at the inlet was discussed earlier in this appendix. These features have been incorporated in all of the above plans except for scheduled repair for the North Jetty and Jetty A. In the case of the South Jetty, scheduled repair with engineering features was evaluated. In addition, scheduled repair utilize a minimum cross-section repair template that addresses only above-water jetty structure degradation processes.

Two types of repair strategy were used to realistically assess the life cycle performance of each plan. A great deal of work went into defining the necessary damage threshold which would trigger a repair and/or a failure. More detail on this work is provided in Appendix A2. Two general categories were utilized: (1) interim repair scenario, and (2) programmed repair scenario. The interim repair strategy which is only used in the base condition, allows the jetty to degrade at each 100 ft segment until only 40% of the above water cross section remains for a given segment. Once that threshold is reached, a repair action is triggered. The repair action does not always repair the structure before a breach happens. The programmed repair strategy monitors each 100 ft segment for current cross section and degradation rate. When a threshold occurs (calculated separately for each 100 ft segment and for each repair plan) which represents approximately 4 years prior to a failure, a jetty repair action is triggered. This repair strategy is used for all of the alternative plans.

The intent of a full rehabilitation of the jetties is three-fold: (1) to improve the stability of the foundation (toe) of each jetty affected by scour; (2) to improve the side-slope stability (above and below water) of each jetty; and (3) to improve the stability of each jetty to withstand wave impact. Two different methods were used to apply the full rehabilitation alternatives: immediate and scheduled. Under the immediate rehabilitation, actions would begin at a given year and continue annually until the entire jetty is completed. Under a scheduled approach, the timing of the rehabilitation would be staged throughout time applying the rehabilitation to only the portion of the jetty when it was needed, postponing the federal outlay of funds throughout the 50-year project life. The sheer size of the MCR jetties along with the limited construction window available at the project would require that any rehabilitation effort would result in scheduling the construction over a number of years. Construction of the North and South jetties is projected to take between 5 and 20 years, depending on the alternative.

Full rehabilitation plans would all include the engineering features and would also address, in some manner, the full length of each structure. The intent of a full rehabilitation of the jetties is three-fold: (1) to improve the stability of the foundation (toe) of each jetty affected by scour; (2) to improve the side-slope stability (above and below water) of each jetty; and (3) to improve the stability of each jetty to withstand wave impact.

Two different methods were used to apply the full rehabilitation alternatives; immediate and scheduled. Under the immediate rehabilitation, actions would begin at a given year and continue annually until the entire jetty is completed. Under a scheduled approach, the timing of the rehabilitation would be staged throughout time applying the rehabilitation to only the portion of the jetty when it was needed, postponing the federal outlay of funds throughout the 50-year project life. The sheer size of the MCR jetties along with the limited construction window available at the project would require that any rehabilitation effort would result in scheduling the construction over a number of years. Construction of a full rehabilitation plan on the North and South jetties is projected to take a minimum of 5 and 8 years, respectively. Due to the length of time required to implement a full rehabilitation on the South Jetty and the extent of that jetty's exposure to extreme conditions, scheduling construction over a broader time window was not found to be effective. On the North Jetty, the scheduling of rehabilitation efforts was assessed due to vulnerability and was spaced out over about a 12-year time frame.

The modeling performed to assess the project alternatives assumes that Jetty A is in place and fully functioning. This is because Jetty A, as originally constructed, protects the North Jetty and helps to train the Columbia River mainstem. In addition, Jetty A is believed to play an important function for the Columbia River plume. The plume is an important food source for the 13 Columbia River salmonid evolutionarily significant units (ESUs) listed under the Endangered Species Act. Jetty A will be treated as the first added increment for the North Jetty, and because of this only one plan was developed and analyzed for each of the alternative categories. The three alternatives (scheduled repairs, immediate rehabilitation, and scheduled rehabilitation) for Jetty A will be evaluated against each other in the same manner as the North and South jetties.

m. Alternative Descriptions

The characteristics of the alternatives analyzed are summarized in the following paragraphs.

Scheduled Repair. This alternative consists of conducting scheduled repairs that only address above-waterline instability, performing emergency repairs as needed, and performing emergency/increased routine dredging. This alternative is slightly more proactive than the base condition, but like the base condition would not include any engineering features (there would be no lagoon fill, spur groins or capping performed on any jetty) but would include action to improve the South Jetty shore area near the root. This type of repair strategy would continue for the entire project life, with only slight increases to the reliability of the structures. Aggressive and ongoing monitoring of the structures is necessary to prevent loss of function to the project. This alternative was evaluated for the North and South jetties and Jetty A.

Scheduled Repair with Engineering Features (South and North Jetty only). This alternative consists of conducting scheduled repairs that only address above-waterline instability, performing emergency repairs as needed, and performing emergency/increased routine dredging. This alternative is slightly more proactive than the base condition and would include action to improve the South Jetty shore area near the root. This type of repair strategy would continue for the entire project life, with only slight increases to the reliability of the structures. Aggressive and ongoing monitoring of the structures would be necessary in order to prevent loss of function to the project. Construction efforts to implement these plans are estimated to extend from 2 to 5 years.

Immediate Rehabilitation using Minimum Cross Section. This plan would rehabilitate the jetties along their full length using the minimum cross section which basically repairs the cross section above the waterline and within the existing footprint, and includes spur groins, jetty capping, lagoon fill, and South Jetty shore area near the root. If the minimum cross section template does not fit within the existing jetty footprint, the crest elevation is lowered until the cross section does fit. It is envisioned that it would take approximately a minimum of 5 years to complete all three jetties, assuming that work could be conducted on all three jetties concurrently. In the event that concurrent construction does not occur, completion of the three jetties could take up to one-and-a-half to two times as long. This alternative was evaluated for the North Jetty and for the South Jetty.

Immediate Rehabilitation using Small Cross Section. This plan would rehabilitate the jetties along their full length using the small cross section which basically repairs the cross section above the waterline, and includes spur groins, jetty capping, lagoon fill, and South Jetty shore area near the root. Although this cross section template is relatively small, it is not constrained to fit within the footprint of the existing structure. It is envisioned that it would take approximately a minimum of 5 years to complete all three jetties, assuming that work could be conducted on all three jetties concurrently. In the event that concurrent construction does not occur, completion of the three jetties could take up to one-and-a-half to two times as long. This alternative was evaluated for the South Jetty and for Jetty A.

Immediate Rehabilitation using Moderate Cross Section. This plan would rehabilitate the jetties along their full length using a large cross section which encases the existing jetty cross section. It would repair the cross sections both above and below the waterline, and include spur groins, jetty capping, lagoon fill, and South Jetty shore area near the root. It is envisioned that it would take approximately a minimum of 9 years to complete all three jetties, assuming that work could be conducted on all three jetties concurrently. In the event that concurrent construction does not occur, completion of the three jetties could take up to one-and-a-half to two times as long. This alternative was evaluated for the North Jetty and the South Jetty.

Immediate Rehabilitation using Large Cross Section. This plan would rehabilitate the jetties along their full length using a large cross section which encases the existing jetty cross section and which also places a stabilizing toe berm along key reaches of each structure. It would repair the cross sections both above and below the waterline, and include spur groins, jetty capping, lagoon fill, and South Jetty shore area near the root. It is envisioned that it would take approximately a minimum of 9 years to complete all three jetties, assuming that work could be conducted on all three jetties concurrently. In the event that concurrent construction does not occur, completion of the three jetties could take up to one-and-a-half to two times as long. This alternative was evaluated for the North and South jetties.

Immediate Rehabilitation using Composite Cross Section. This plan would rehabilitate the jetties along their full length using a plan suited to deterioration processes by jetty station, repair the cross section above and below the waterline where needed, foundation instability issues addressed where needed, and include jetty capping, spur groins, lagoon fill, and South Jetty shore area near the root. It is envisioned that it would take about a minimum of 8 years to complete all three jetties, assuming that work could be conducted on all the jetties concurrently. In the event that concurrent construction does not occur, completion of the three jetties could take up to one-and-a-half to two times as long. Five separate immediate composite plans were evaluated for the South Jetty and one immediate composite plan for the North Jetty.

Scheduled Rehabilitation using Minimum or Composite Cross Section. In reality, due to the sheer size of the MCR jetties and the limited construction window, any rehabilitation work on the MCR structures will need to occur over a number of years. A scheduled rehabilitation plan takes the scheduling a step further to implement the rehabilitation of specific reaches of each jetty at designated times to address the most vulnerable reaches first; includes adding spur groins on the jetties to promote structure stability, capping the head of both the North and South jetties to stop deterioration, lagoon fill at the North Jetty to stop erosion at the jetty root, and South Jetty shore area near the root. Rehabilitation is not conducted until conditions indicate that there is a need for rehabilitation of specific portions of the jetty. The reliability and the cost of the scheduled alternatives were evaluated for the minimum and composite templates. Conducting the rehabilitation when needed instead of continuously, as in the immediate rehabilitation alternative increases the length of time construction occurs to 15 years but construction actually occurs only 11 years out of that total. This is expected because construction is not expected to occur on all jetties at the same time. These alternatives were evaluated for the North and South jetties.

The alternatives analyzed are:

1. Scheduled Repair without Engineering Features
2. Scheduled Repair with Engineering Features
3. Immediate Rehabilitation using Minimum Cross Section
4. Immediate Rehabilitation using Small Cross Section
5. Immediate Rehabilitation using Moderate Cross Section
6. Immediate Rehabilitation using Large Cross Section
7. Immediate Rehabilitation using Composite Cross Section
8. Scheduled Rehabilitation using Minimum or Composite Cross Section

A summary of the alternatives evaluated is provided in Table A1- 10 through Table A1- 12for the North Jetty, South Jetty, and Jetty A, respectively.

17. Engineering Evaluation and Life-Cycle Model Results for the Range of Alternatives

a. General

The SRB model uses a Monte Carlo method to increase the confidence of life cycle estimates and allow for the evaluation of variance. In general terms, the model can assist with managing the future life-cycle of each jetty at MCR. Due to their porosity and flexibility, rubblemound jetties are relatively resilient structures which can sustain a certain amount of damage before a structural failure can be considered to occur. The event tree cycles through each year of the project life and accumulates damages along each jetty segment until a specified threshold or percent damage above the water line occurs. Once that threshold occurs, one of two branches will be initiated. The first branch triggers an interim repair action intended to address an imminent failure before a breach occurs. If the interim repair action is not conducted, the jetty segment will continue to damage until an actual breach occurs.

Once a breach occurs, adjacent jetty segments are evaluated for level of damage and may be included in the overall breach length if damage is at a high enough level. A breach in one of the jetties results in a repair action, sediment movement through the gap in the jetty toward the navigation channel, and additional dredging activities. All of these additional costs are accumulated over the life cycle for each individual plan.

Model considerations include: (1) existing condition of structure, (2) previous repairs of structure, (3) foundation conditions, (4) structural failure modes, (5) function, and (6) exposure to waves. The life cycle model application was initiated by simulating the structures' previous life cycle history thus producing a calibrated model of structure performance in the project environment. After the calibration to historical performance, the life cycle analysis model was used to evaluate the effectiveness of the proposed engineering features; jetty head capping, spur groins, and North Jetty lagoon fill. The smallest proposed rehabilitation plan was run with and without the engineering features, each feature separately, to determine if significant benefits were accrued to the project performance. All of the engineering features were found to be justified through the life cycle model application.

The engineering features described above have been applied to all of the full rehabilitation plans. Those features address the larger system deterioration processes and include: (1) jetty head capping to reduce structure loss and morphological impacts, (2) spur groins to stabilize foundation shoals and adjacent shorelines, and (3) backfill of lagoon behind North Jetty root.

The SRB model allows one to review the simulated future life-cycle cost stream in current year value or net present value. Forecasted costs associated with increased dredging are incremental, above normal outlays. Metrics provided by the SRB model which can be used to evaluate life-cycle performance include: time-varying structural and functional reliability, jetty repair occurrence, jetty breach occurrence, components of life-cycle cost, cross-section evolution, and jetty end-state condition. The SRB model is used to formulate an optimal plan for rehabilitating each jetty, predicated on the need to minimize life-cycle costs or maximize reliability. A more detailed description of the SRB model and its application to the MCR jetties can be found in Appendix A2.

The paragraphs and tables below summarize the SRB model results for each alternative type and for each jetty, focusing on the following output parameters:

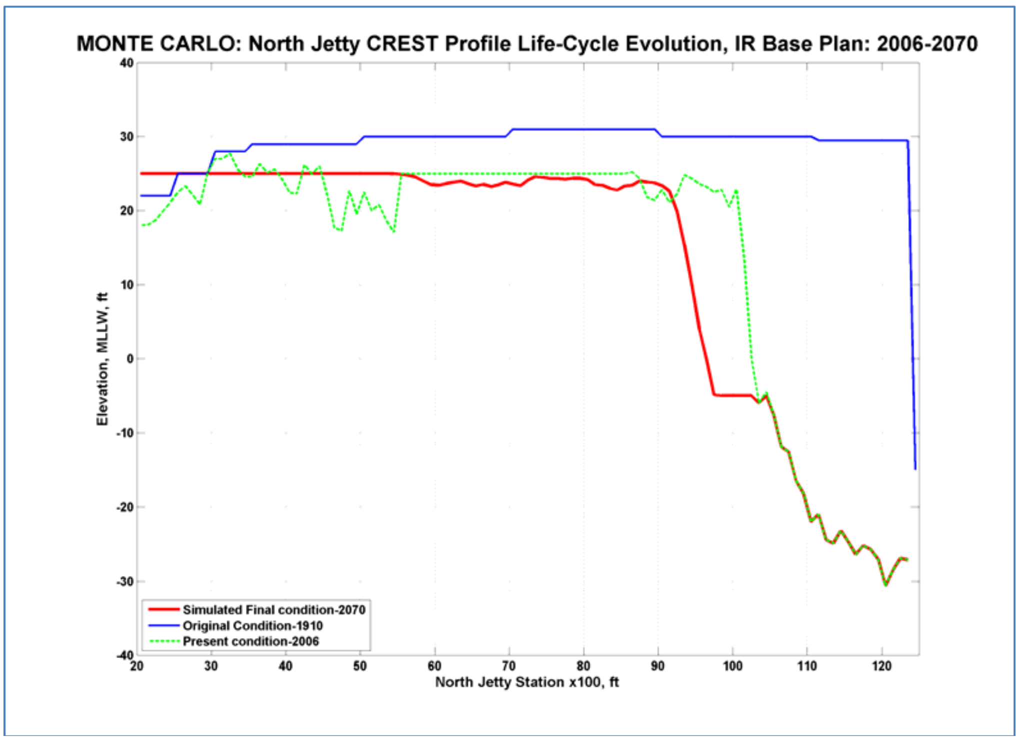
- Degree to which larger system degradation processes are addressed.
- Final projected position of the jetty head.
- Number of large scale repair efforts expected over the project life.
- Expected jetty repair costs over the project life.
- Initiation and frequency of jetty repairs expected.
- Expected increases in dredging costs over project life.
- Extent to which emergency dredging may be expected.
- Estimate the number of significant breach events with potential to impact navigation.
- Average projected structural and functional reliabilities.
- Additional comments on expected jetty maintenance program and potential environmental and inlet effects.

b. Base Condition

1. North Jetty Base Condition

The base condition takes no action to address the larger system degradation processes. The head of the North Jetty continues to recede back at a rate of 20-50 feet per year. The modified head position at the end of the life cycle analysis is estimated at Station 82+00 (about 1,900 feet shorter than the current head position). Potential repairs are expected to begin immediately and extend for the life of the project, as needed. The base condition is expected to result in significant changes to the navigation entrance.

Figure A1- 257, shown below, illustrates the simulated North Jetty crest profile evolution over the project life. In this figure, the blue line depicts the originally constructed North Jetty showing both the authorized length and crest elevation. The green line shows the 2006 condition of the jetty and the red line depicts the changes predicted to occur in the jetty over the next 50 years if the jetty is maintained as described in the base condition. The second graph illustrates the estimated repair and breach frequency per 100 ft segment along the jetty under the base condition. The abbreviation "IR" refers to the Interim repair scenario. The pink line refers to breach frequency and the blue line refers to repair frequency. The dotted black vertical line identifies the head position at the beginning of the simulation. The solid black line shows the head position at the end of the simulation. The third graph shows the functional and structural reliability over the project life.



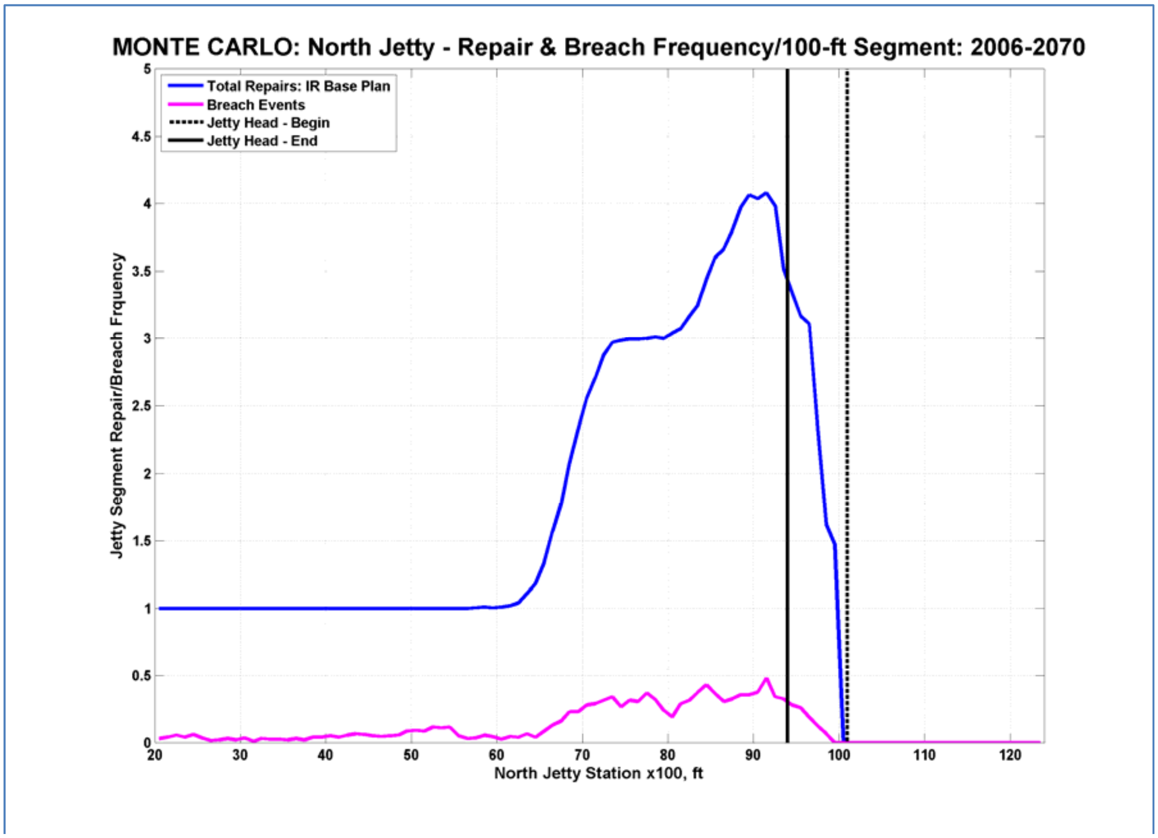


Figure A1- 257. North Jetty Base Condition

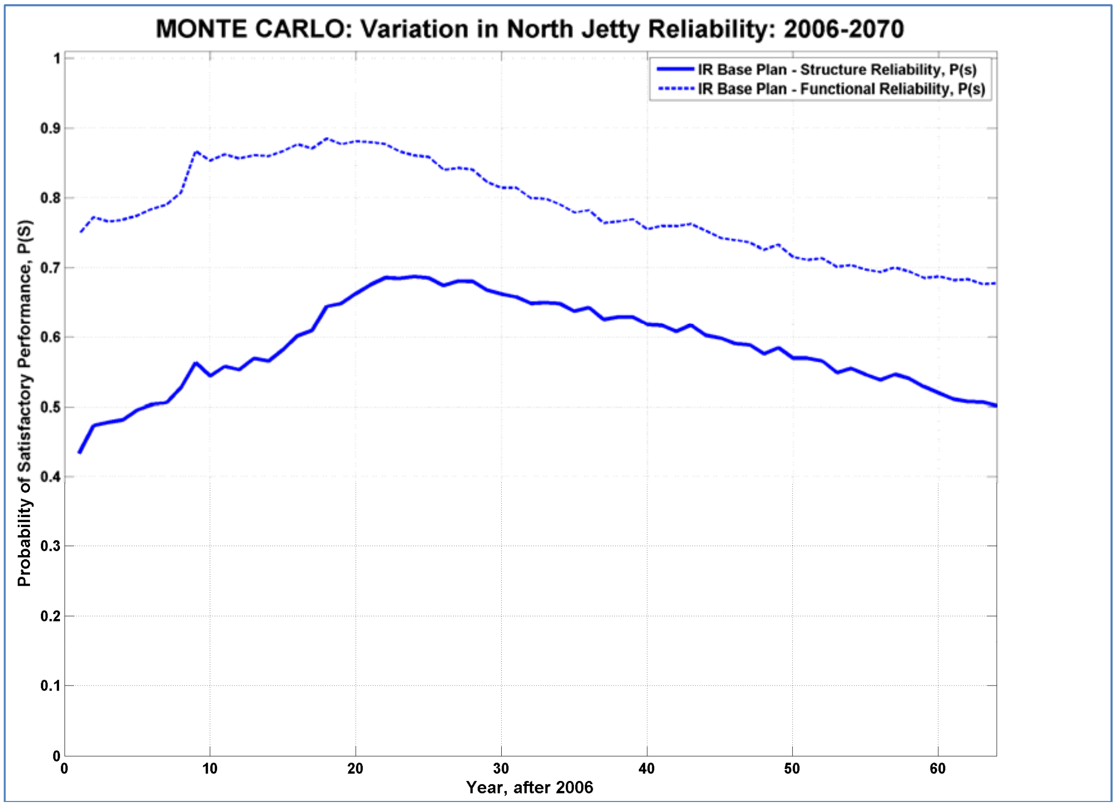

Figure A1- 257 (continued). North Jetty Base Condition

2. South Jetty Base Condition

The base condition takes no action to address the larger system degradation processes except for some shoreline stabilization work at the root of the jetty. The South Jetty head continues to recede back at a rate of 5 to 20 feet per year. The modified jetty head position at the end of the life cycle analysis is estimated to occur at approximately Station 292+00 (about 2,100 feet shorter than the current jetty head position). The base condition is expected to result in significant changes to the navigation entrance.

Figure A1- 258, shown below, illustrates the simulated South Jetty crest profile evolution over the project life. In this figure, the blue line depicts the originally constructed South Jetty showing both the authorized length and crest elevation. The green line shows the 2006 condition of the jetty and the red line depicts the changes that are predicted to occur in the jetty over the next 50 years if the jetty is maintained as described in the base condition. The second graph shows the expected breach and repair frequency and the third graph shows the functional and structural reliability over the project life.

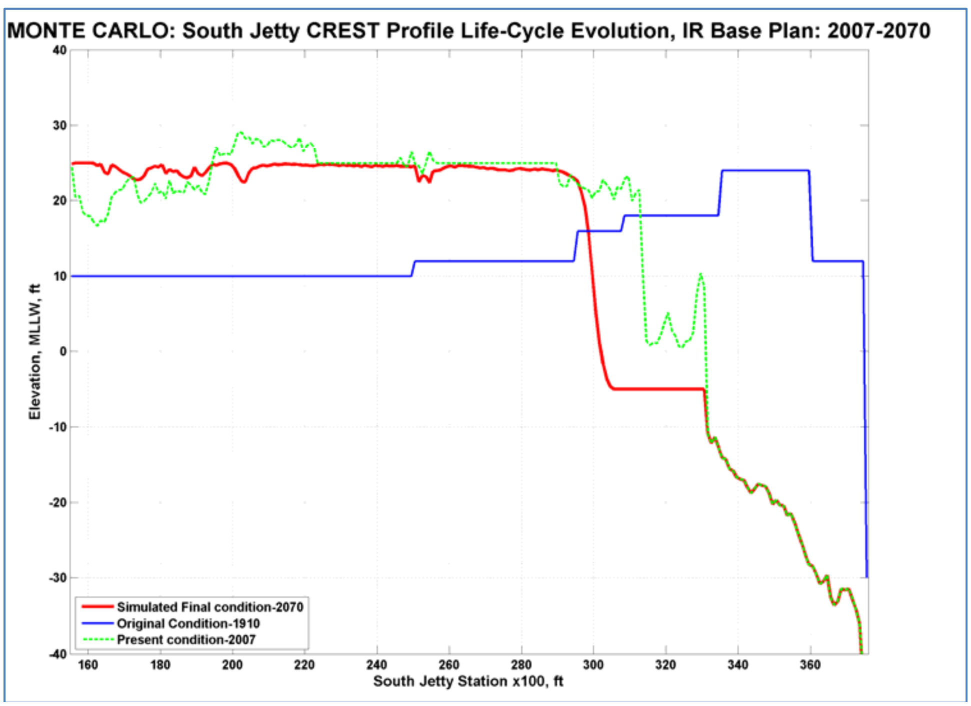

Figure A1- 258. South Jetty Base Condition

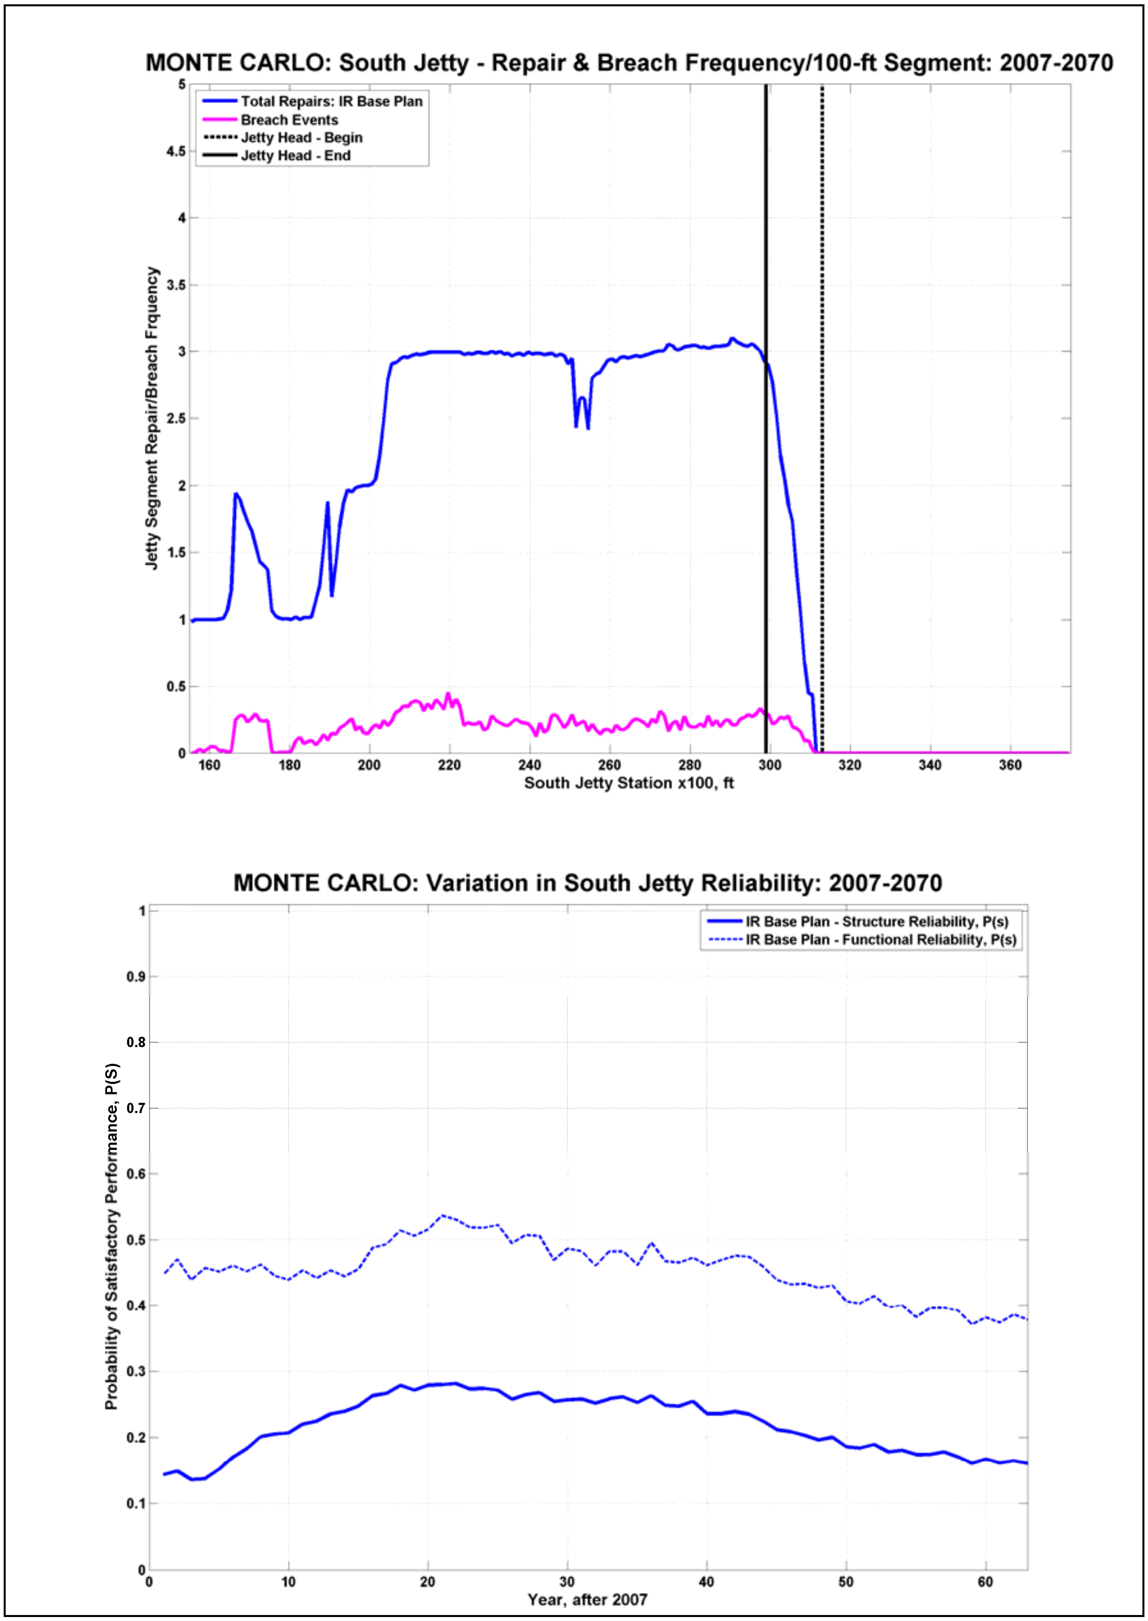

Figure A1- 258 (continued). South Jetty Base Condition

3. Jetty A Base Condition

The base condition takes no action to address the larger system degradation processes. The head of Jetty A continues to recede back at a rate of 5 to 20 feet per year. The modified jetty head position at the end of the life cycle analysis is approximately at Station 82+00 (about 600 feet shorter than the current jetty head position). The base condition is expected to result in significant changes to the navigation entrance.

In Figure A1- 259, shown below, the blue line depicts the originally constructed Jetty A showing both the authorized length and crest elevation. The green line shows the 2006 condition of the jetty and the red line depicts the changes that are predicted to occur in the jetty over the next 50 years if the jetty is maintained as described in the base condition.

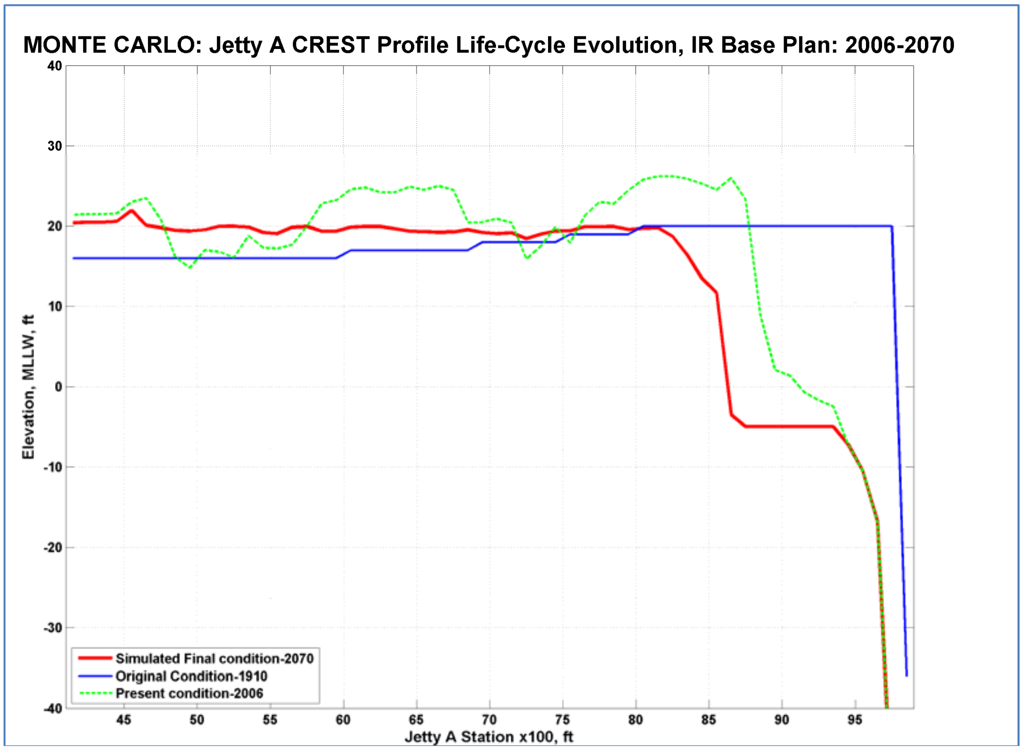

Figure A1- 259. Jetty A Base Condition

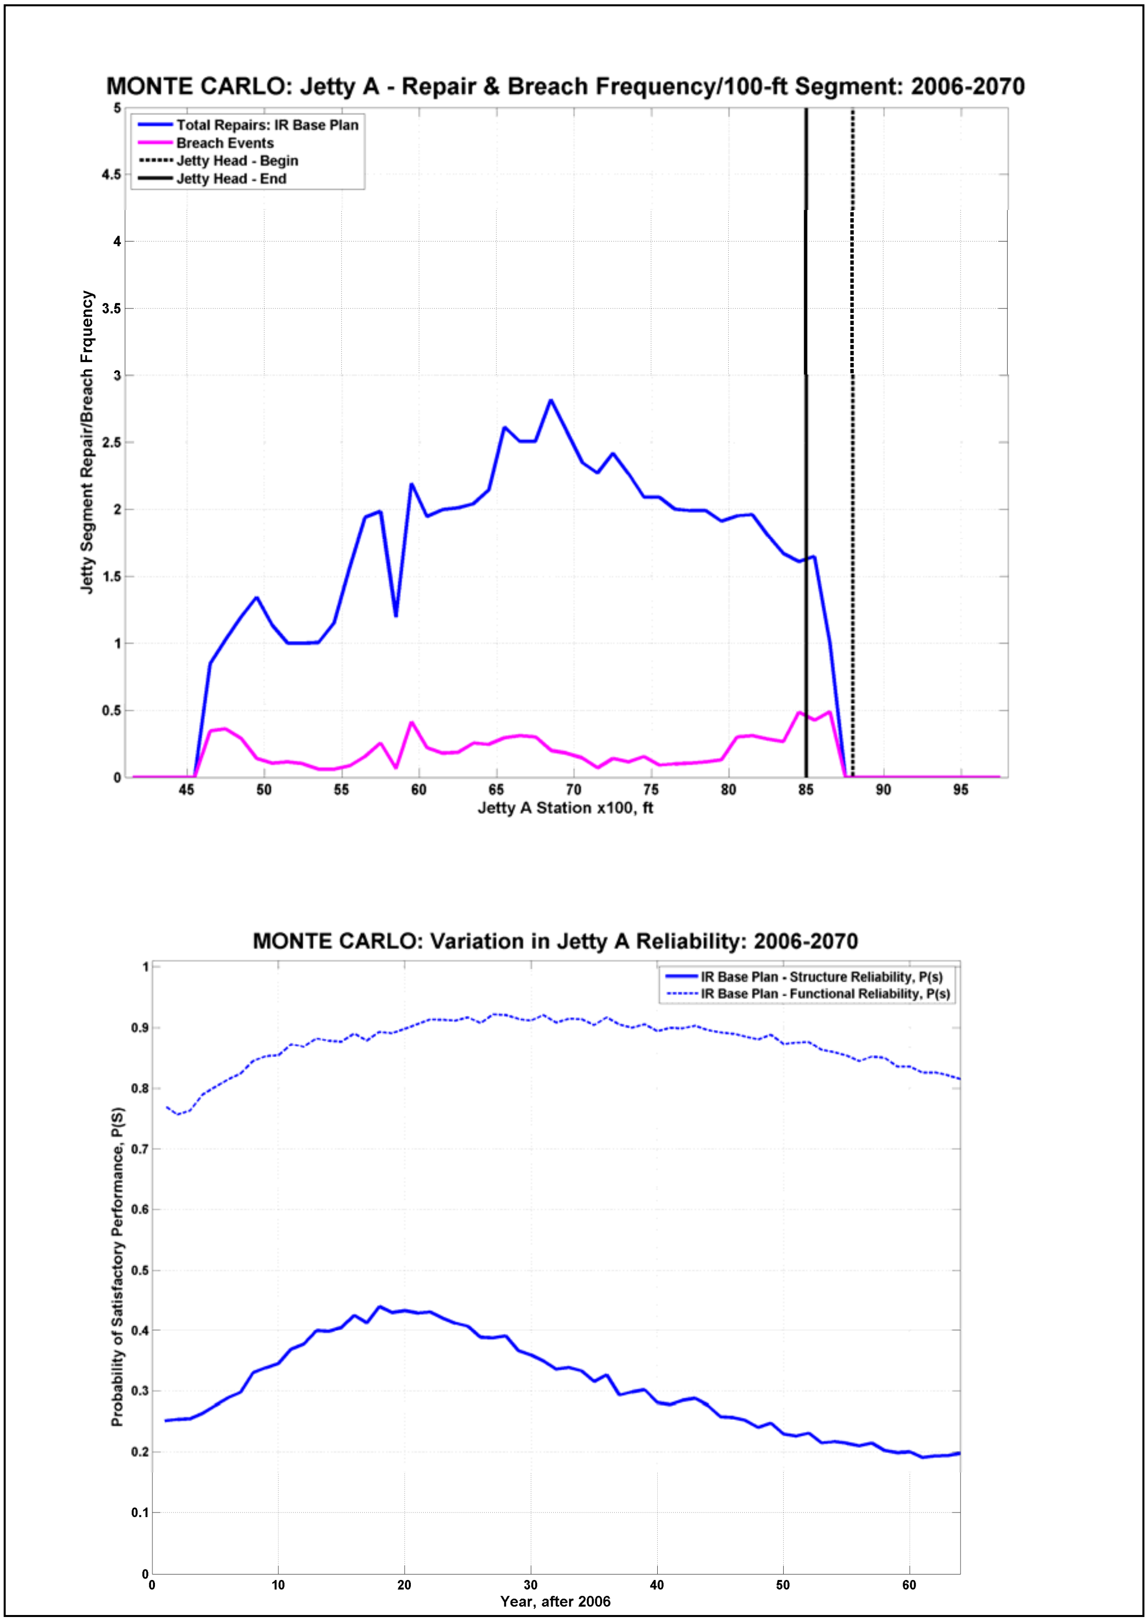

Figure A1- 259 (continued). Jetty A Base Condition

The focus of this major rehabilitation study was to identify alternatives and recommend a course of action that optimizes future reliability and life-cycle cost for the MCR jetty system. Optimized alternatives were developed through a step-wise procedure. First, the structural and functional risks affecting the present life cycle of each jetty were identified and evaluated. Second, a range of incremental alternatives were developed to mitigate present and future risks affecting the life cycle of each jetty. Alternatives included various repair maintenance scenarios, cross-section rehabilitation schemes, and several engineering features. Third, an implementation schedule was developed for each alternative to match construction timing project risk over the life-cycle period. Alternatives included non-rehabilitation based on implementing different levels of future maintenance strategies. Evaluation of alternative maintenance strategies focused on varying the threshold level for initiating jetty repairs. Non-rehabilitation alternatives avoid the initial cost of structure rehabilitation, but can incur elevated future maintenance commitment and cost by having to mitigate continual low reliability. In cases where repairs were deferred during the previous life cycle, a proactive future maintenance strategy may require online repairs very early into the future life cycle, emulating the magnitude of initial costs associated with structure rehabilitation.

c. Scheduled Repair Alternatives

This alternative consists of conducting scheduled repairs only addressing above-water structural instability of the three MCR jetties, performing repairs as needed, and performing expedited or emergency/increased routine maintenance dredging. This alternative is slightly more proactive than the without project alternative. This type of repair strategy would continue for the entire project life with only slight increases to the reliability of the jetty structures. Scheduled repairs would be somewhat more robust than repairs conducted under the without project alternative. In general, a scheduled repair could be initiated when the Portland District jetty monitoring team conducts the annual inspection and observes changes in crest width, cross section, or length, or when the Coast Guard or Columbia River Bar Pilots notify the Portland District that a significant change has occurred due to a winter storm event. Subsequent to the identification of damage areas, surveys would be conducted to determine if a scheduled repair action was justified in the near term. At that point, a decision would be made to begin the budget process to initiate the repair. Scheduled repair plans were developed with and without engineering features (spur groin and head capping for the South Jetty, and spur groin, head capping and lagoon fill for the North Jetty).

1. North Jetty Scheduled Repair Alternatives

The North Jetty was evaluated for two scheduled repair alternatives: scheduled repair without engineering features and scheduled repair with head capping, spur groins and lagoon fill (all engineering features). Both of these alternatives were evaluate with and without an option to hold the jetty head at its current location. Note that the scheduled repair cross-section template, shown in Figure A1- 260, places repair stone only in the upper portion of the cross section. Improved below water stabilization for the jetty cross section is achieved only through the placement of spur groins for one of these alternatives.

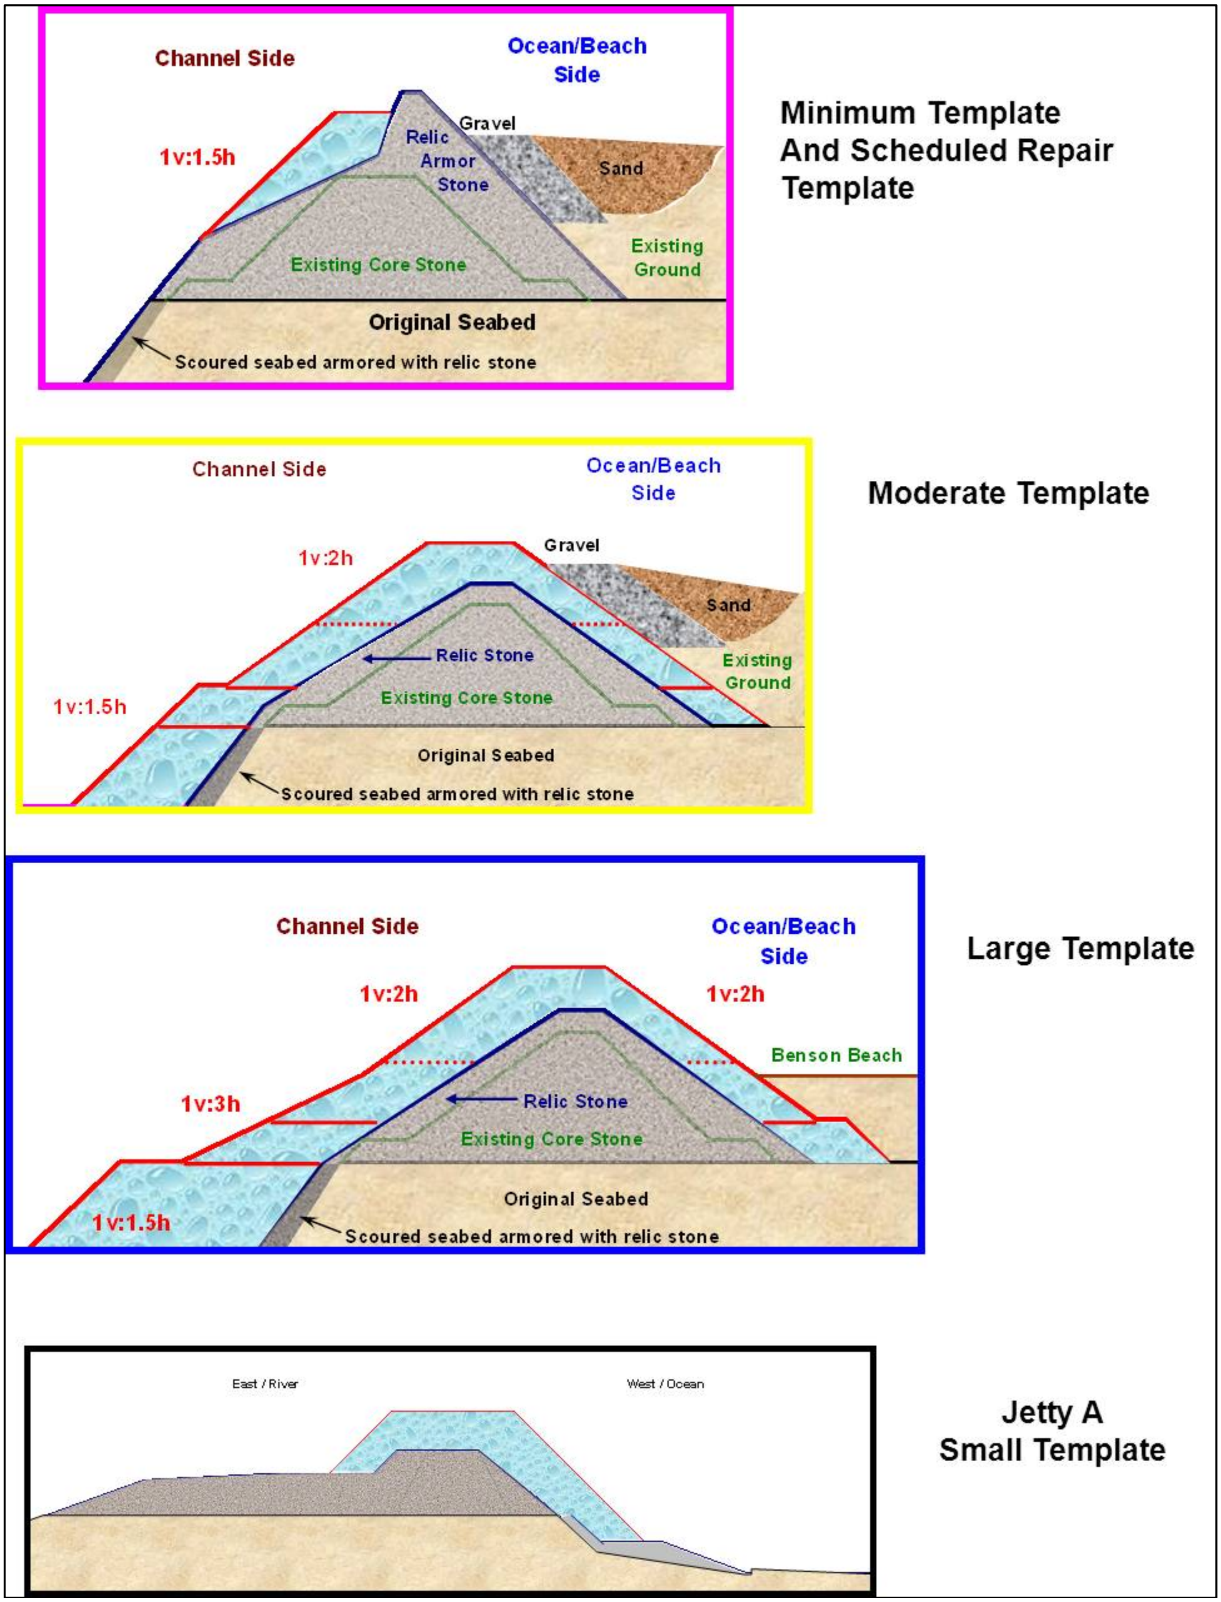

Figure A1- 260. North Jetty and Jetty A Conceptual Cross Section Templates

Model results for the two scheduled repair alternatives as compared to the base condition are shown in Figure A1- 261 and Figure A1- 262 with and without holding the head at the existing location. Due to the present deteriorated condition of the North Jetty, the scheduled repair alternatives will require an aggressive monitoring and maintenance program for the life of the project. Improved below-water stabilization for the jetty cross section is achieved only through placement of spur groins for one of these alternatives. Repairs are expected to begin immediately and extend through the period of analysis.

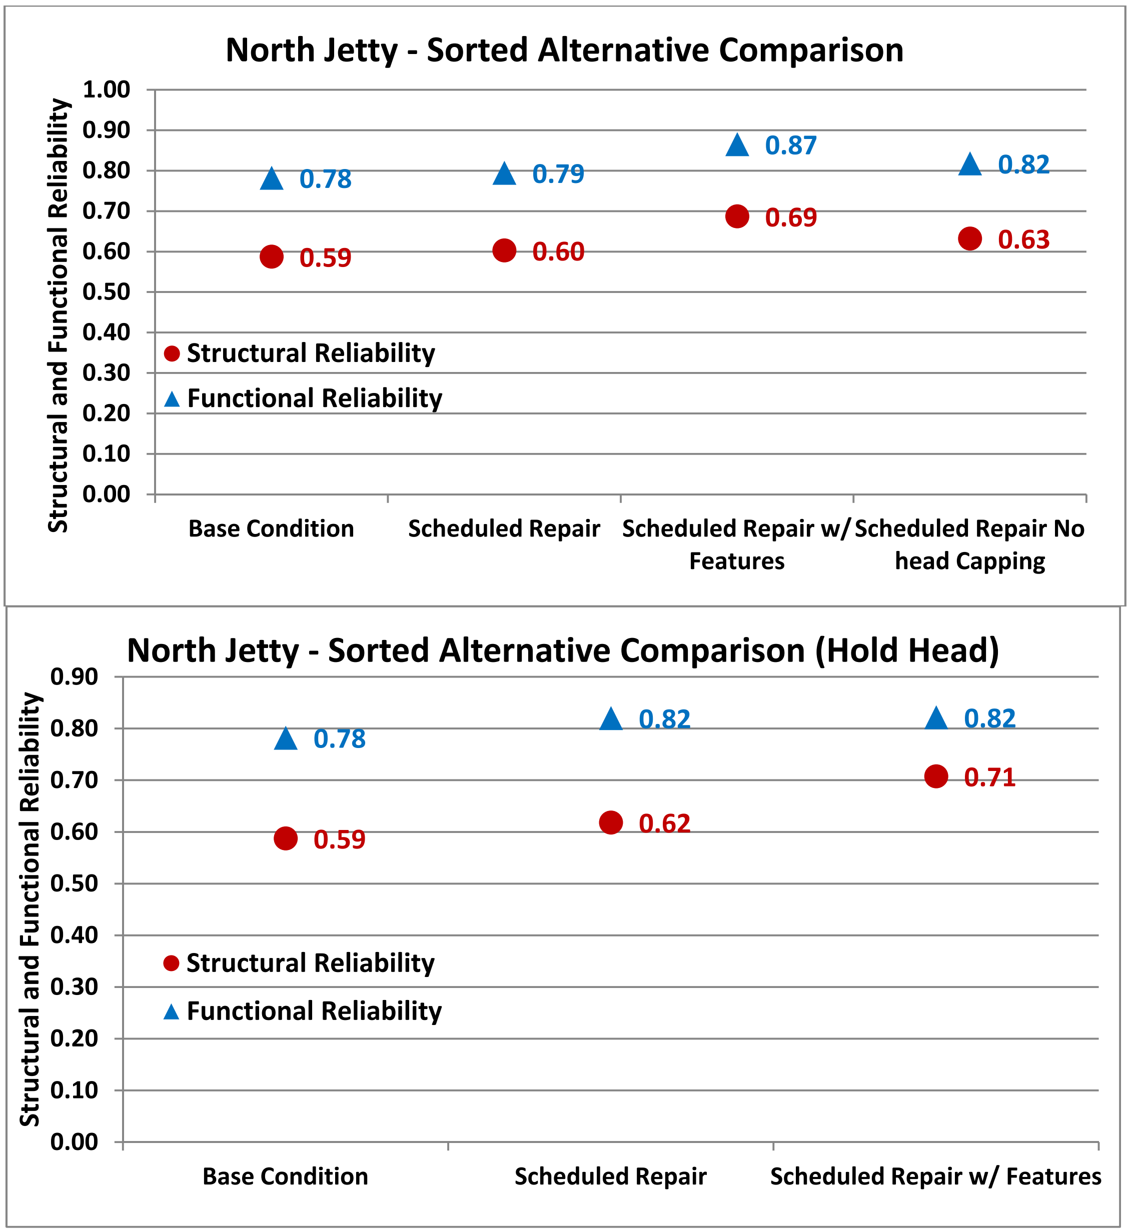

Figure A1- 261. North Jetty Base Condition and Scheduled Repair Alternatives Comparison

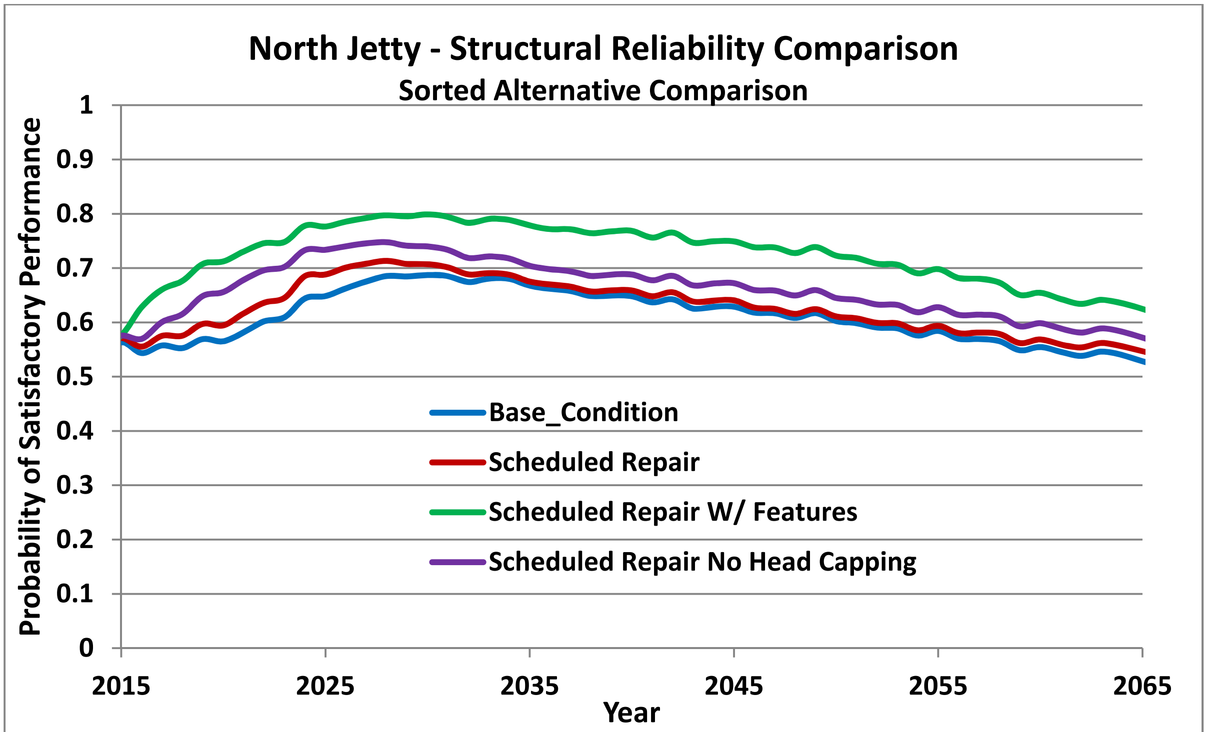

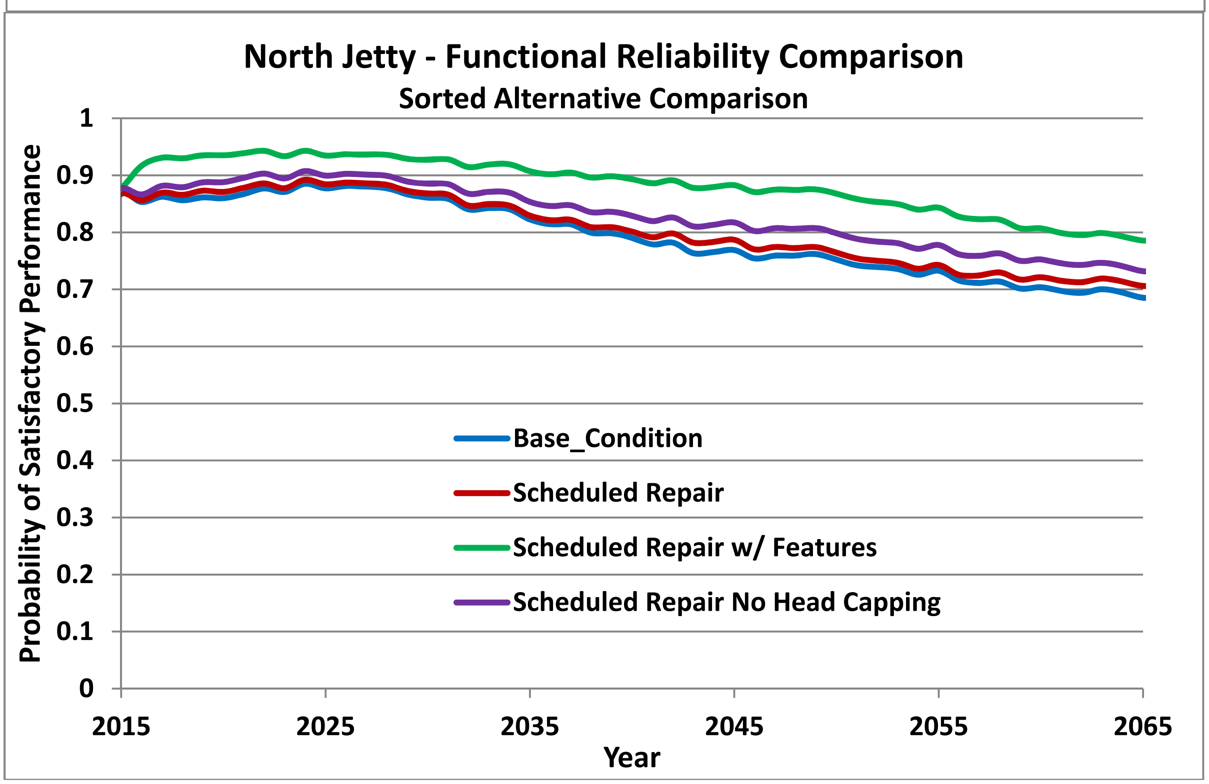

Figure A1- 262. North Jetty Reliabilities for Scheduled Repair Alternatives

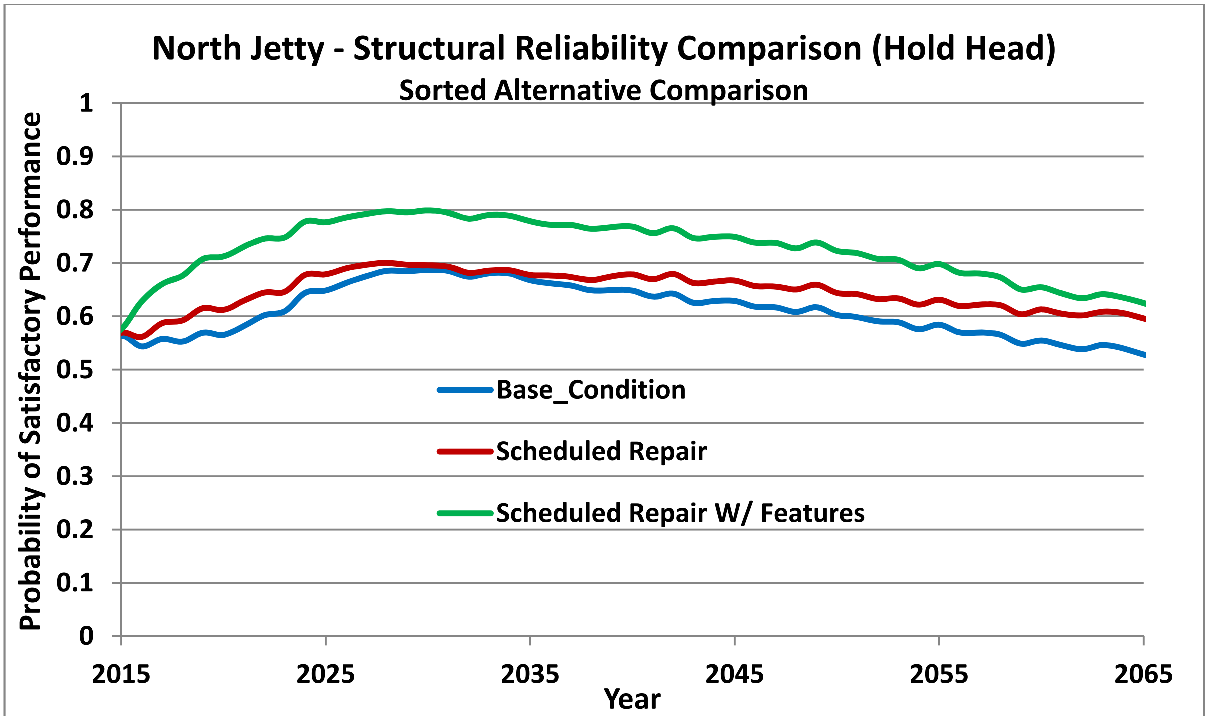
The scheduled repair alternative without engineering features takes no action to address the larger system degradation processes. Despite the aggressive maintenance program required, significant changes to the navigation entrance would be expected to occur primarily due to unchecked jetty length recession and continued foundation erosion. At the current projected rate of recession, North Jetty length loss is expected to be approximately 1,400 ft. The scheduled repair alternative with engineering features (head stabilization, spur groins, lagoon fill) addresses the larger areas of destabilization (head recession, foundation erosion, jetty root backside erosion); however, the alternative will still require an aggressive monitoring and maintenance program to maintain reliability of the structure.

Both structural and functional reliabilities are improved over the base condition and are also incrementally improved with the addition of the engineering features. This result is achieved through the execution of an aggressive and frequent maintenance program over the entire period of analysis. Figure A1- 263 illustrates the structural and functional reliability over the period of analysis for this group of plans.



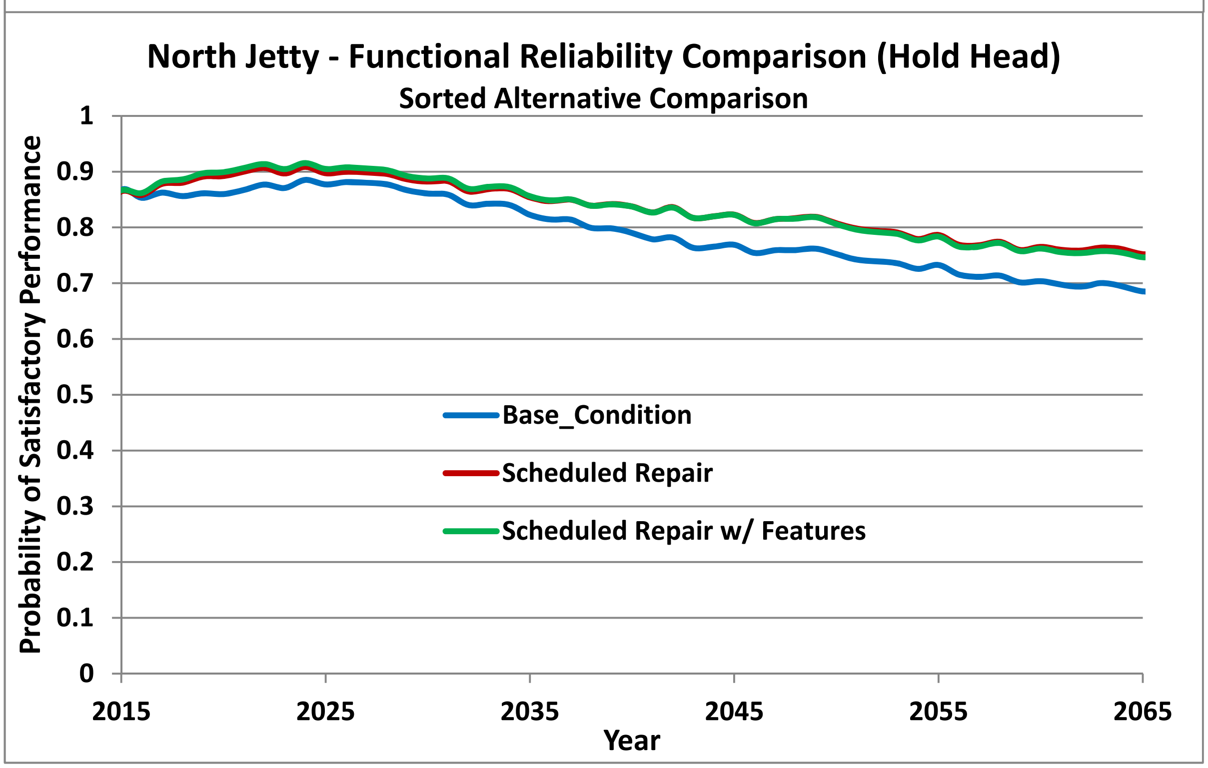


Figure A1- 263. North Jetty Reliabilities for Scheduled Repair Alternatives

The scheduled repair alternative without engineering features results in a higher additional dredging requirement related to jetty length recession, although this amount is less than the required dredging under the base condition. The jetty length recession under this plan also increases the projected jetty repair costs due to increased loading on the remaining structure. The environmental impacts are expected to be high for both the base condition and the scheduled repair alternative without engineering features primarily due to hydrodynamic and morphologic changes to the navigation entrance resulting from jetty length recession. Of these alternatives, the scheduled repair alternative with engineering features has the lowest number of projected breaches at (1.9) and the lowest number of expected future repairs (4).

2. South Jetty Scheduled Repair Alternatives

The South Jetty was evaluated for three scheduled repair alternatives: (1) scheduled repair without engineering features, (2) scheduled repair with head capping, and (3) scheduled repair with head capping and spur groins (all engineering features). All of these alternatives were evaluated with and without the option to maintain the jetty head at the existing location. Note that the scheduled repair cross-section template, shown in Figure A1- 264, places repair stone only in the upper portion of the cross section. Improved below water stabilization for the jetty cross section is achieved only through the placement of spur groins for one of these alternatives. All of these plans include work conducted to ensure shoreline stabilization at the South Jetty root. Those plans that include jetty head stabilization of the head position at approximately Station 313. Model results for these three alternatives are shown in Figure A1-265 and Figure A1- 266. Due to the present deteriorated condition of the South Jetty, all scheduled repair alternatives will require an aggressive monitoring and maintenance program for the life of the project. Repairs are expected to begin immediately and extend through the period of analysis.

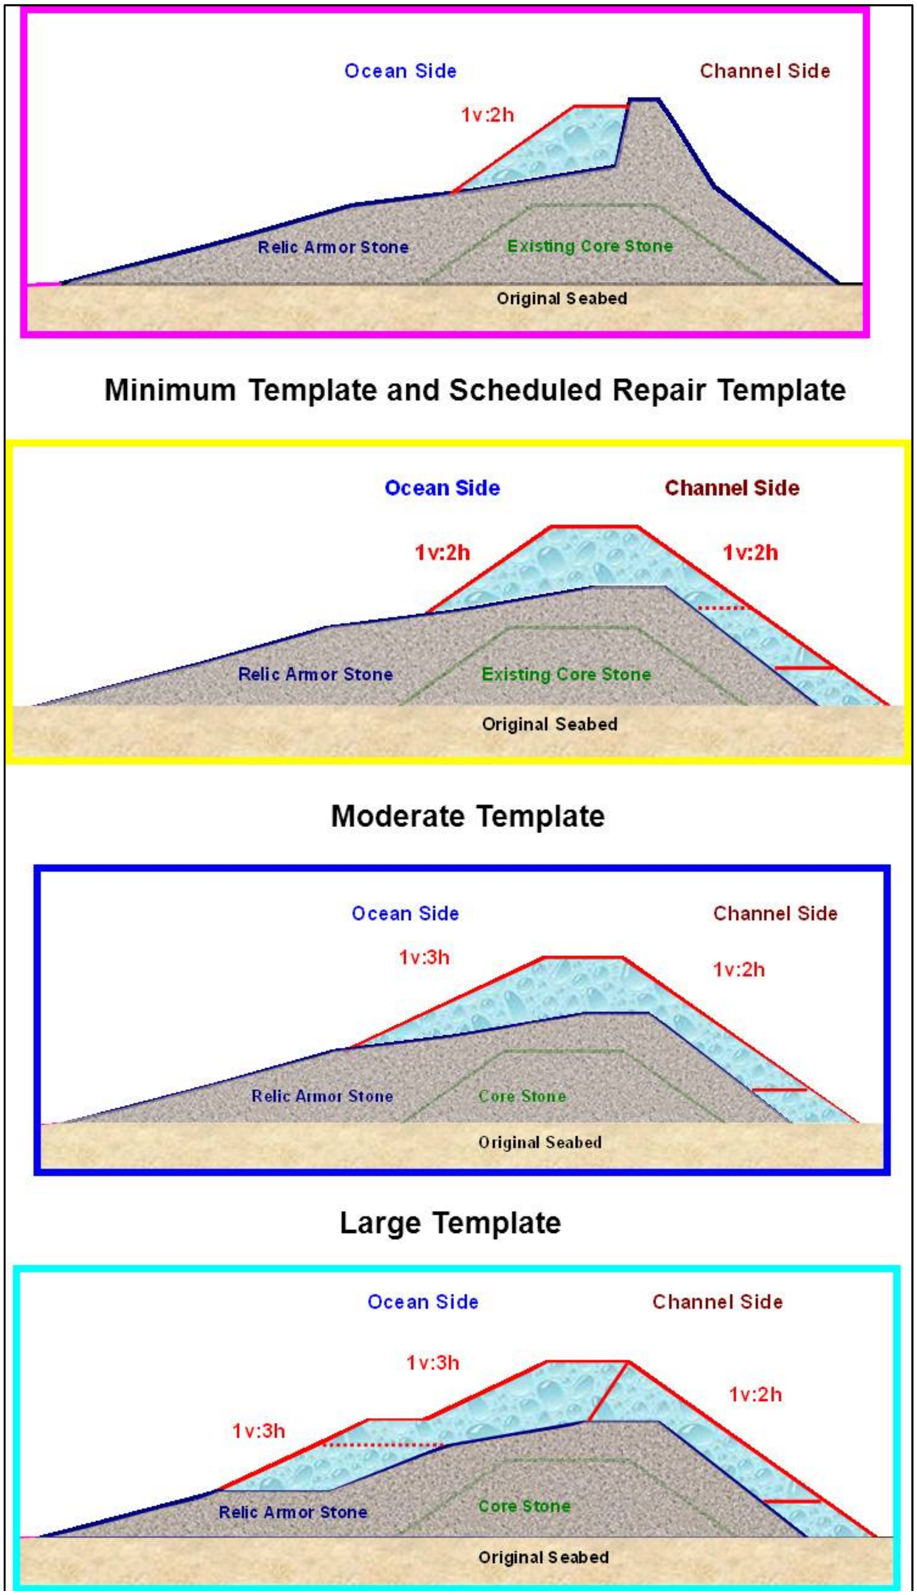

Figure A1- 264. South Jetty Conceptual Cross Section Templates

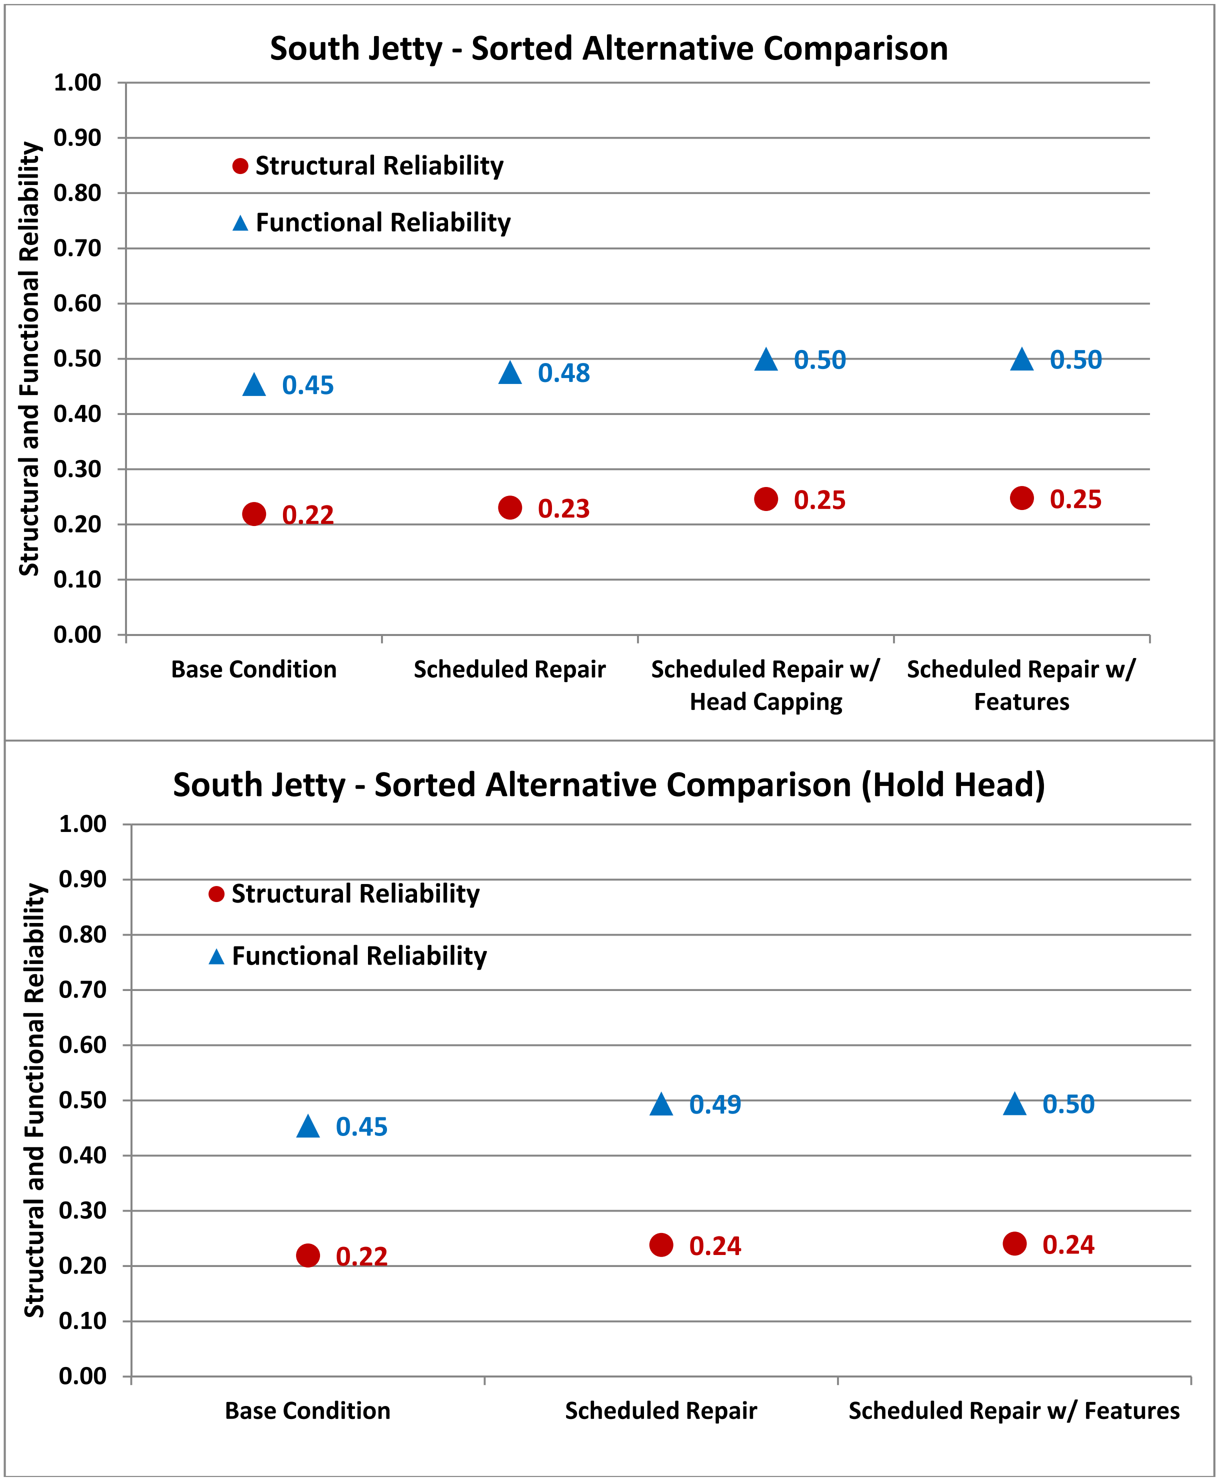

Figure A1- 265. South Jetty Base Condition and Scheduled Repair Comparison

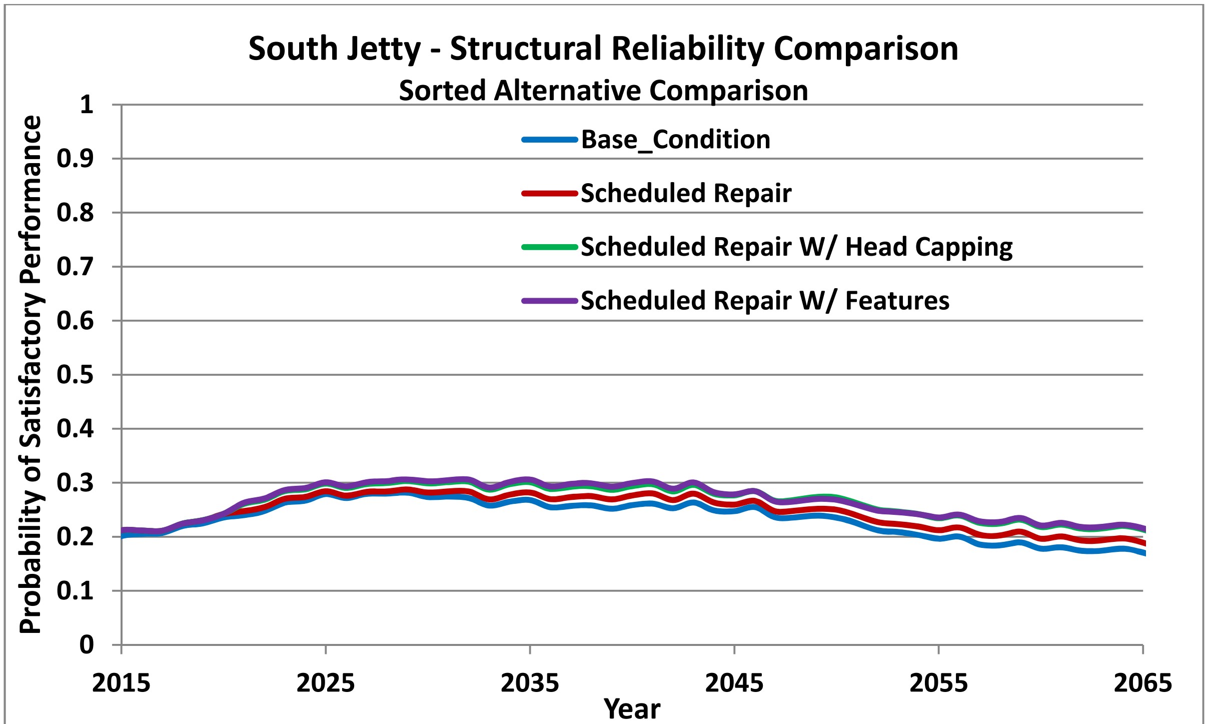

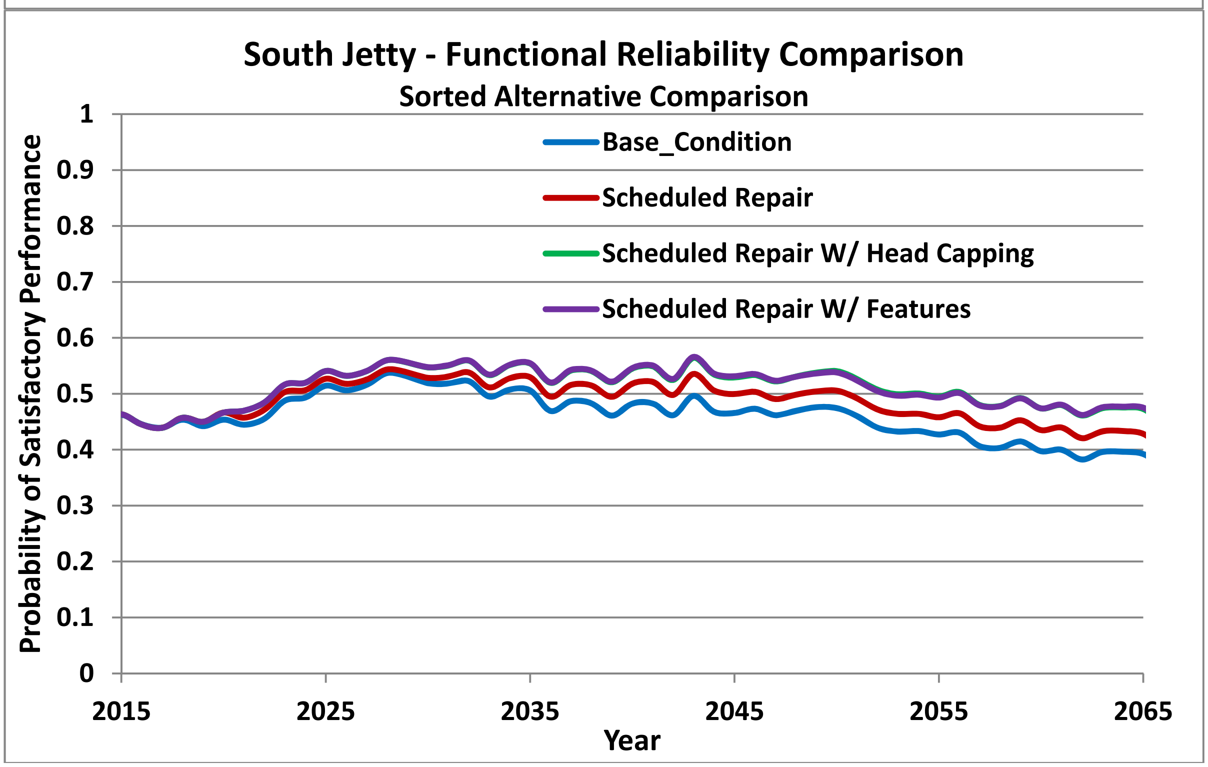

Figure A1- 266. South Jetty Reliabilities for Scheduled Repair Alternatives

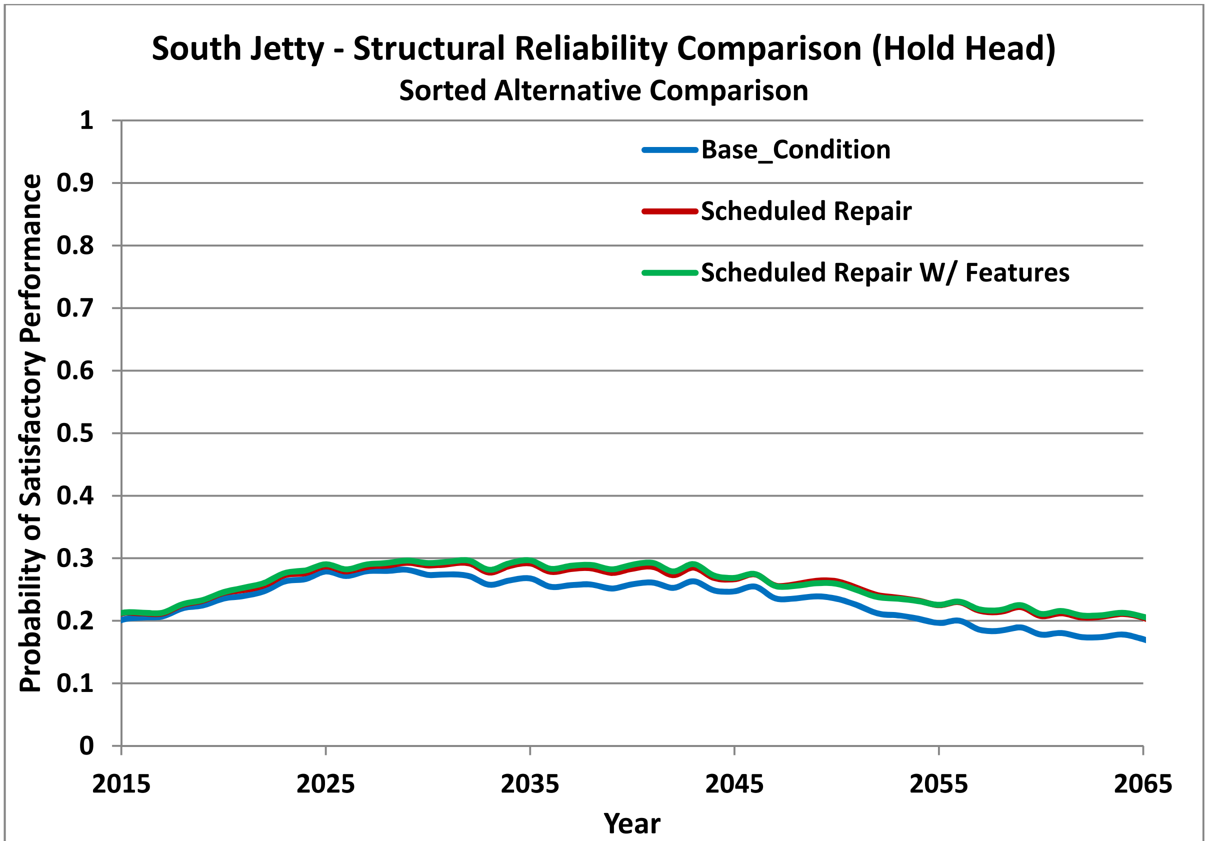

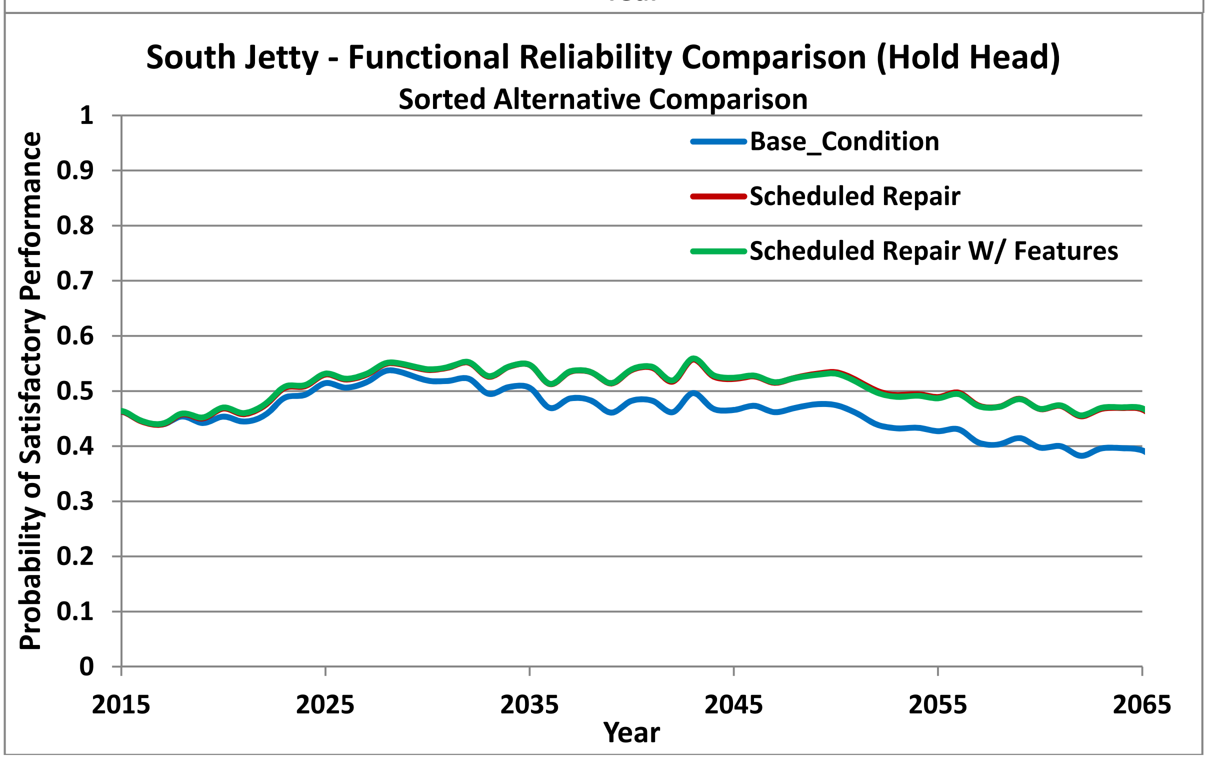

Figure A1- 266 (Continued). South Jetty Reliabilities for Scheduled Repair Alternatives

The scheduled repair alternative without engineering features takes no action to address the larger system degradation processes. Despite the aggressive maintenance program required, significant changes to the navigation entrance would be expected to occur primarily due to unchecked jetty length recession and continued foundation erosion. At the current projected recession rate, jetty length loss is expected to be approximately 900 ft.

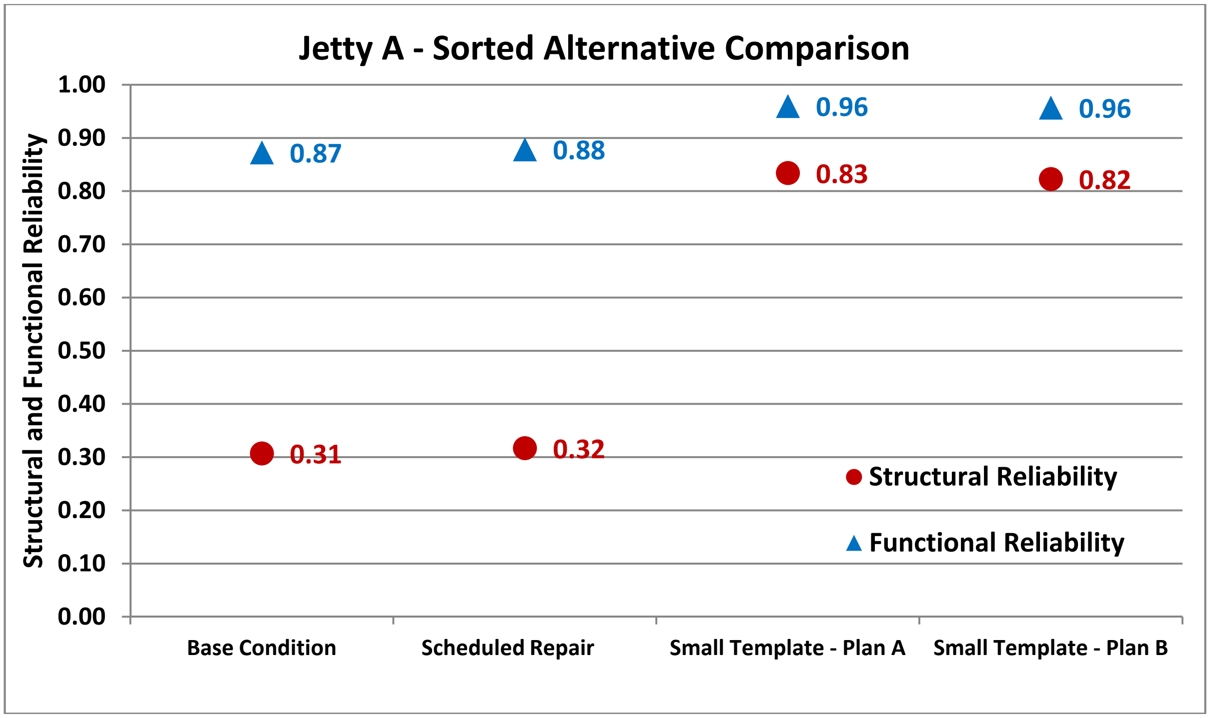
The scheduled repair alternative with head capping stabilizes the head position but due to the lack of spur groin construction, does not improve on foundation stability. The scheduled repair alternative with engineering features (head capping, spur groins) addresses the larger areas of destabilization (head recession, foundation erosion); however, it will require an aggressive monitoring and maintenance program to maintain reliability of the structure.

As compared to the base condition, the South Jetty scheduled repair alternatives are successful in reducing the total project costs over the period of analysis. Both structural and functional reliabilities are improved over the base condition and are also incrementally improved with the addition of the engineering features. This result is achieved through the execution of an aggressive and frequent maintenance program over the entire period of analysis, resulting in the expected placement of approximately 1,040,000 tons of stone through the first 20 years of project execution. Figure A1- 266 illustrates the structural and functional reliability over the period of analysis for this group of plans.

The impacts to the environment are expected to be high for both the base condition and scheduled repair without engineering features primarily due to hydrodynamic and morphologic changes to the navigation entrance resulting from jetty recession. The three scheduled repair plans have similar predicted number of breaches and number of projected repairs. The scheduled repair alternative without engineering features, however, has projected large impacts on the navigation inlet due to continued jetty recession, foundation erosion, and hydrodynamic modifications.

3. Jetty A Scheduled Repair Alternative

One scheduled repair option was considered for Jetty A, scheduled repair without engineering features, which takes no action to address the larger system degradation processes. This alternative was evaluated both with and without holding the jetty head at the existing location. Without the head stabilization option, the jetty head continues to recede back at a rate of 5-20 feet per year. The modified head at the end of the life-cycle analysis is at approximately Station 84 (about 400 feet shorter than current position). This alternative requires an aggressive monitoring/maintenance program for the life of the project. Significant changes to the navigation entrance would be expected to occur due to jetty length recession. Continued loss of length is expected to have negative impacts to the North Jetty channelside foundation. Figure A1- 267 compares the scheduled repair alternative (and two immediate rehabilitation alternatives) to the base condition. Figure A1- 268 illustrates the structural and functional reliability over the period of analysis.



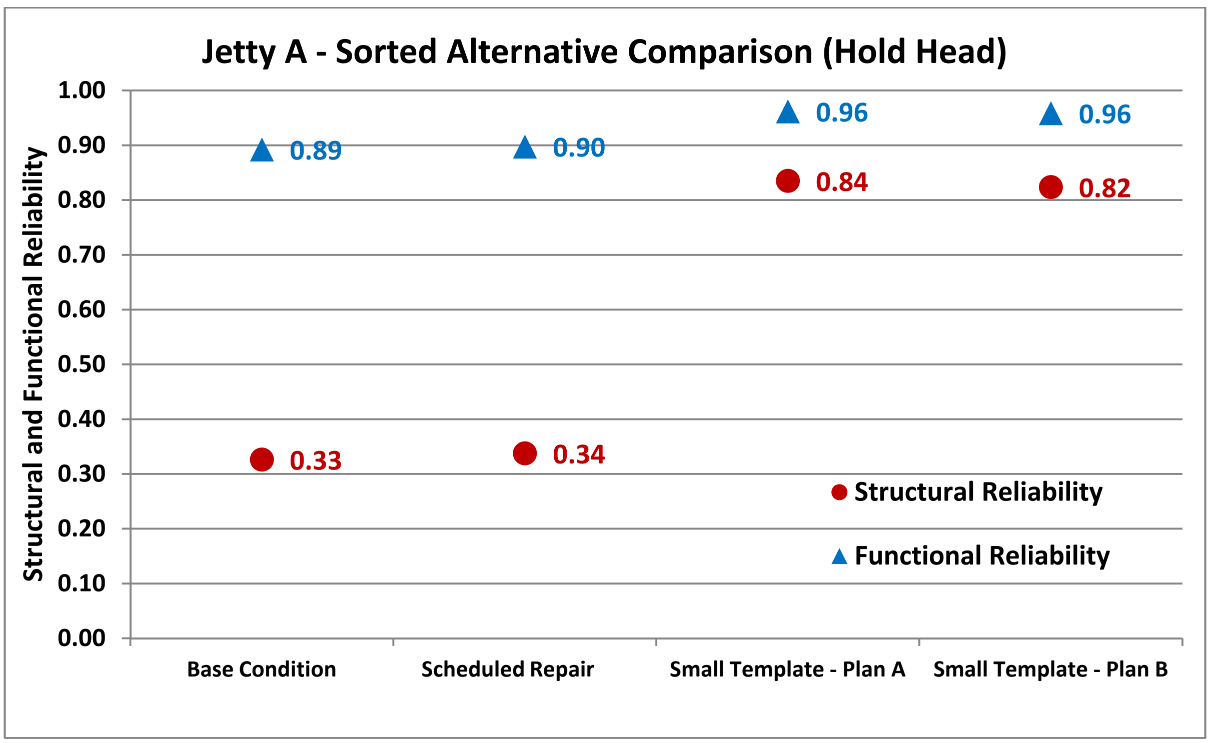


Figure A1- 267. Jetty A Base Condition and Scheduled Repair Comparison

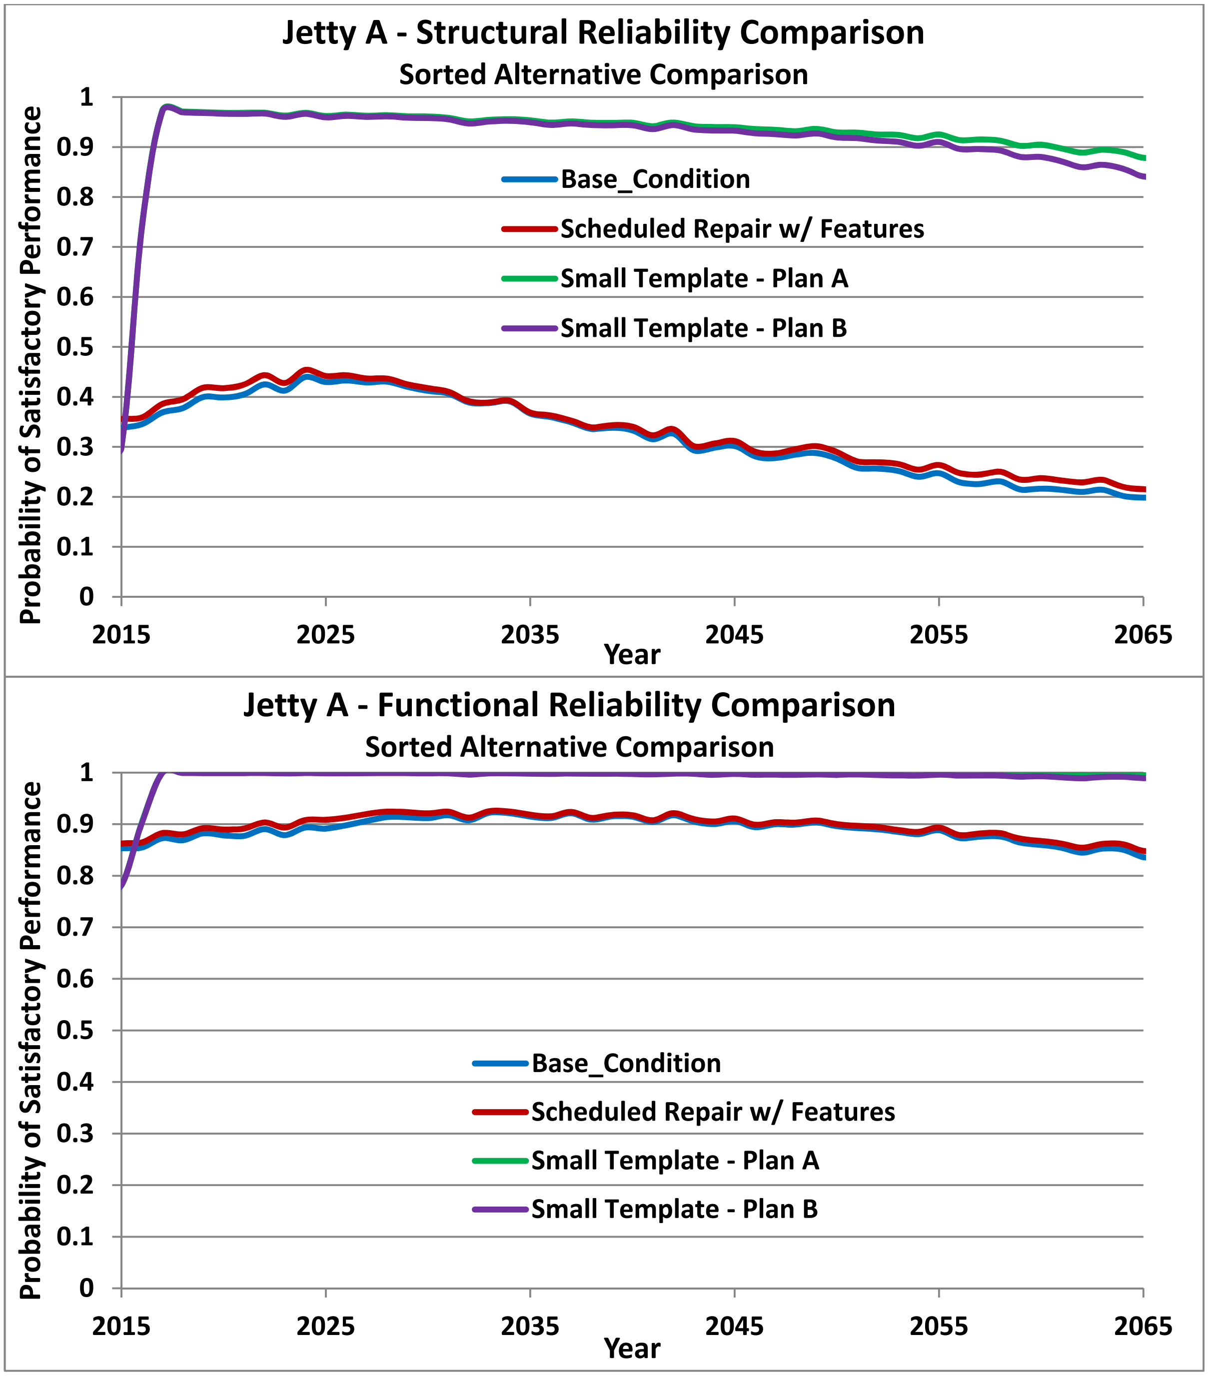

Figure A1- 268. Jetty A Reliabilities for Scheduled Repair Alternatives

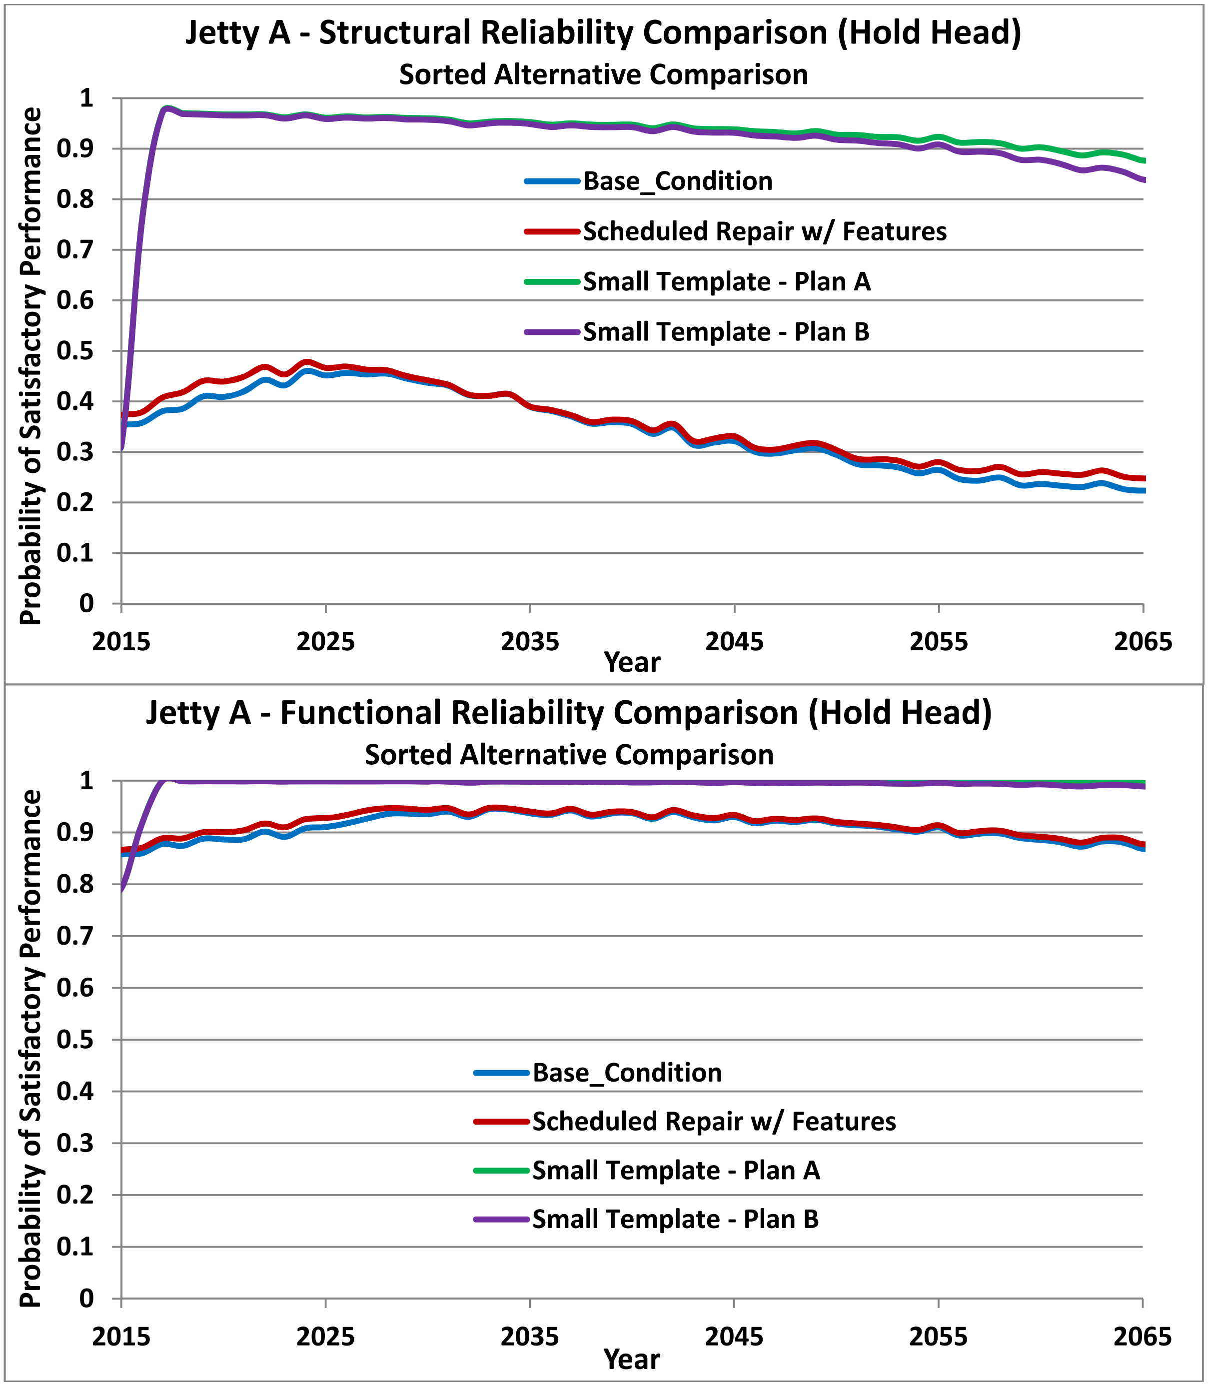

Figure A1- 268 **(continued). Jetty A Reliabilities for Scheduled Repair Alternatives**

d. Major Rehabilitation Alternatives

Rehabilitation alternatives focused on reconstructing (or enhancing) the jetty cross-section based on a range of cross-section templates that eventually informed on the development of the composite plans. Jetty rehabilitation alternatives induce a high initial cost, but restore project reliability early into the future life-cycle and can reduce the future maintenance commitment. Incremental structural enhancements (engineering features) were developed as a way to mitigate chronic effects of jetty foundation scour and jetty root degradation.

The rehabilitation alternatives include all engineering features for structure stability. The intent of rehabilitation of the MCR jetties is three-fold: (1) to improve the stability of the foundation (toe) of each jetty affected by scour; (2) to improve the side-slope stability (above and below water) of each jetty; and (3) to improve the stability of each jetty to withstand wave impact. Not all of the full rehabilitation plans address these 3 areas along each structure to the same degree. Two different methods were used to apply the rehabilitation alternatives: immediate and scheduled.

Development of the composite plans utilized the life cycle model results from the minimum, small, moderate, and large templates to establish initial transition points. Refer to Figure A1-269 for the distribution of the various templates along the jetty. The color border around each cross section corresponds to the same color bars on the jetty length. The first composite plan developed for both the North and South jetties, composite 1-large, identified the transition point along the jetty length that each jetty cross section template began to have increasing repair and breach occurrences. Therefore, the composite 1 plan for the North and South jetties is the most robust composite plan and the plan identified as best suited to resist the particular design loading along the jetty length. Subsequent composite plans were developed to optimize costs while trying to achieve an acceptable structural and functional reliability

1. Immediate Rehabilitation

Under immediate rehabilitation, actions would begin at a given year and continue annually until the entire jetty is completed. Several composite plans were developed for each of the three jetties whereby the cross-section of the jetty varies along the length of the jetty. The approximate location where the cross section is increased was based on individual model runs of one cross section applied along the entire jetty. The model results were analyzed and transition points determined based on how reliable the cross section performed over the project life and minimizing federal cost over time. All of these plans include engineering features; head stabilization at approximately Station 101, spur groins, and lagoon fill. Therefore there was no loss of jetty length for any of these plans.

The option for maintaining the jetty heads at their existing location was also evaluated for each of the rehabilitation plans. This was evaluated by utilizing the rehabilitation repair alternative rather than a head cap feature.

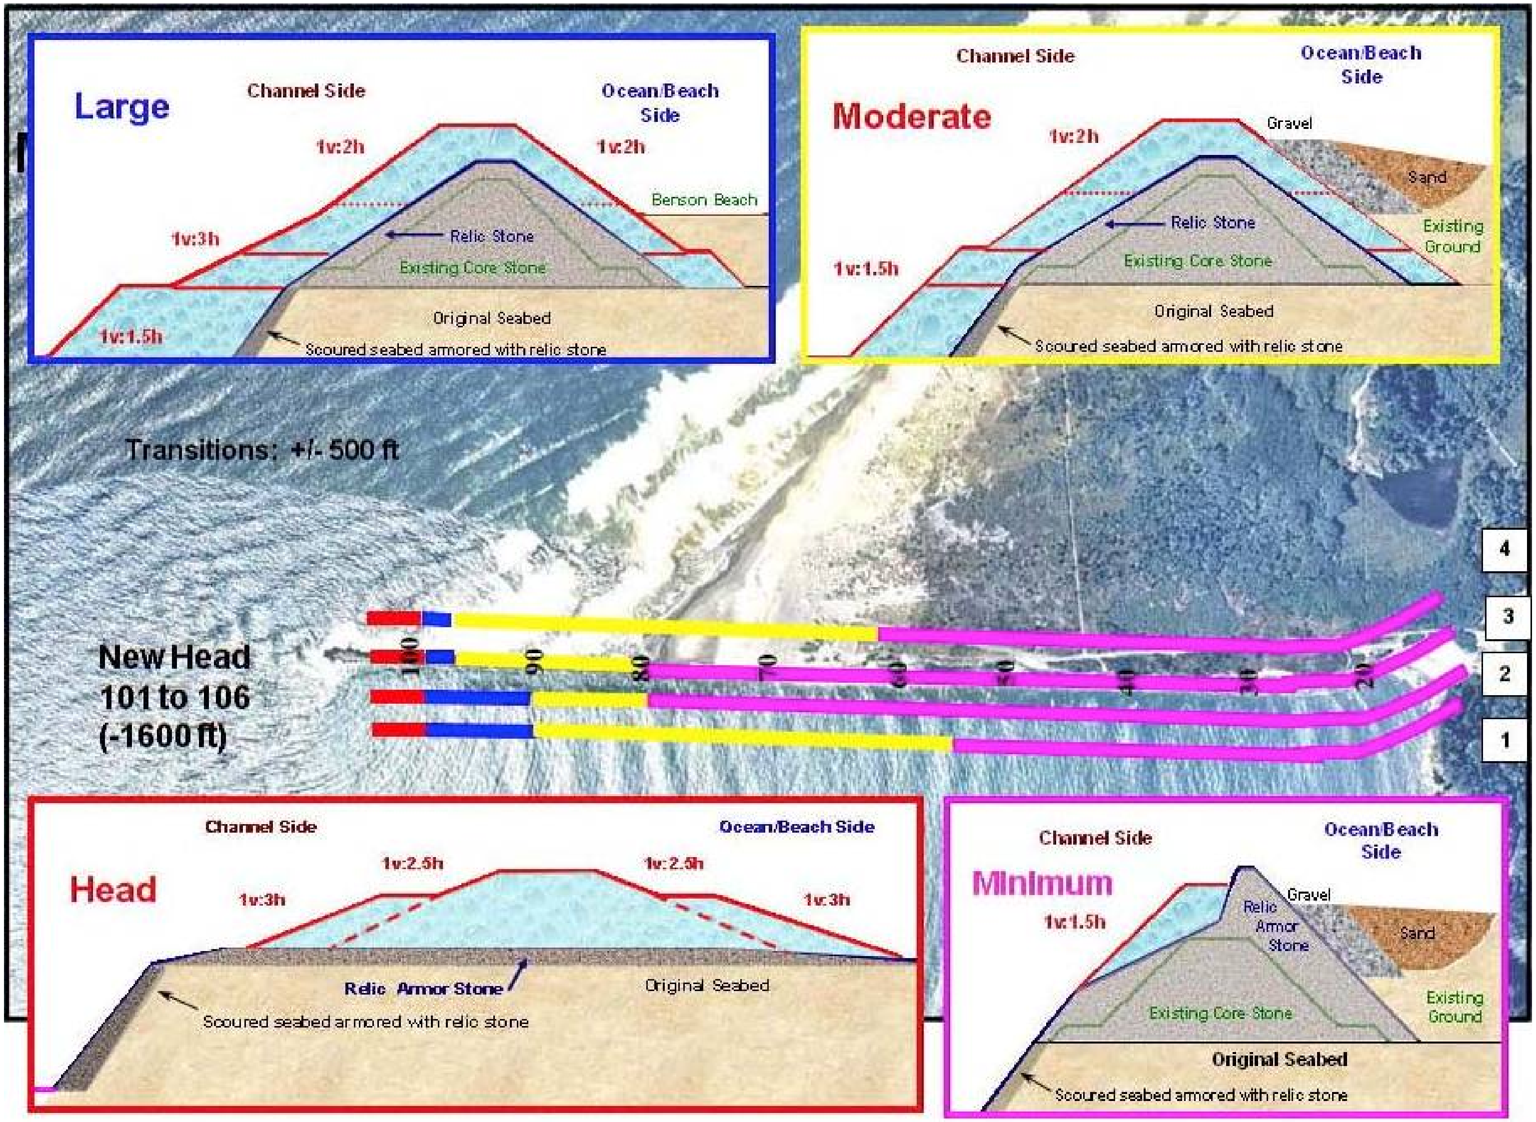

Figure A1- 269. North Jetty Immediate Rehabilitation Composite Plan Layouts

Final cost review of the results for the rehabilitation alternatives suggested these scenarios were not cost effective. Therefore, the results are not described in detail in this appendix. However, the SRB model results for all of the rehabilitation scenarios are provided in Appendix A2.

North Jetty. For the North Jetty, the following graduated cross section templates were evaluated under the Immediate Rehabilitation alternative approach: minimum, moderate and large. These cross sections were then further utilized to produce four composite plans. The small cross section was not evaluated for the North Jetty because of the contemporary depths of the channel side toe of this structure. The amount and placement of stone necessary to attain a stable slope and base would automatically exceed descriptive thresholds of a small cross section. The results are summarized
Four composite plans were developed for the North Jetty; each plan uses the cross sections discussed above but transitions the cross sections at different locations along the North Jetty. The first composite plan, composite 1 – large, utilized the model output for each of the minimum, moderate, and large alternative plans to identify the most robust transition points. The first composite plan, composite 1, applies the minimum template to Station 55 at which point the moderate template is applied to the reach of jetty which experiences greater channel depths and greater loading from waves. Further seaward the large cross section and head capping are applied. Subsequent composite plans were developed to optimize costs while trying to achieve an acceptable structural and functional reliability.

The first two composite plans were eliminated from further consideration under the immediate rehabilitation alternative because the composite 3 – small and composite 4 - small modified plans optimized the cross section for the longest length (least cost) while providing acceptable functional reliability. The layout of those plans is shown in Table A1- 13. Using composite 4, the critical area between Stations 60 and 80 is protected by a robust design template which addresses both the above and below portion of the jetty, reducing the risk in this area for breach events resulting in sediment infill to the navigation channel.

Table A1- 13. North Jetty Immediate Rehabilitation Composite Plans.

North Jetty Immediate Rehabilitation	
Composite	**Cross Section Transition Station**
Composite 3-Small	Minimum cross section - Stations 10-80 Moderate cross section - Stations 80-98 Large cross section - Stations 98-100 Head capping - Station 101
Composite 4 - Small Modified	Minimum cross section - Stations 10-62 Moderate cross section - Stations 62-98 Large cross section - Stations 98-100 Head capping - Station 101

South Jetty. For the South Jetty, the following graduated cross section templates were evaluated under the immediate rehabilitation alternative approach: minimum, small, moderate, and large. These cross sections were then further utilized to produce five composite plans, starting with composite 1 - large alternative which utilizes the graduated cross section template model output to select the most robust jetty cross section template along the length of the South Jetty. Due to the significant length of the South Jetty and the degree of exposure during construction, construction of any of the alternative plans is already very similar to a scheduled rehabilitation. The minimum template alternative was run using a scheduled implementation and is shown with the immediate rehabilitation results. All of these alternatives include the engineering features, head capping and spur groins. The head is projected to be capped at approximately Station 313.

Final cost review of the results for the rehabilitation alternatives suggested these scenarios were not cost effective. Therefore, the results are not described in detail in this appendix. The SRB model results for all of the rehabilitation scenarios are provided in Appendix A2.

Five composite plans were evaluated for the South Jetty; composite plan layouts along the jetty are shown in Table A1- 14 and Figure A1- 270. All composite plans included engineering features - head capping and spur groins.

Table A1- 14. South Jetty Immediate Rehabilitation Composite Plan Layout

South Jetty Immediate Rehabilitation	
Composite	**Cross Section Transition Station**
Composite 1-Large	Minimum cross section - Stations 155-175 Small cross section - Stations 175-180 Moderate cross section - Stations 180-265 Large cross section - Stations 265-311 Head capping - Station 313
Composite 2-Modified 1	Minimum cross section - Stations 155-200 Small cross section - Stations 200-265 Moderate cross section - Stations 265-290 Large cross section - Station 290-311 Head capping - Station 313
Composite 3-Small	Minimum cross section - Stations 155-245 Small cross section - Stations 245-290 Moderate cross section - Stations 290-310 Large cross section - Stations 310-311 Head capping - Station 313
Composite 4-Medium	Minimum cross section - Stations 155-180 Small cross section - Stations 180-230 Moderate cross section - Stations 230-285 Large cross section - Stations 285-311 Head capping - Station 313
Composite 5-Modified 2	Minimum cross section - Stations 155-215 Small cross section - Stations 215-260 Moderate cross section - Stations 260-285 Large cross section - Stations 285-311 Head capping - Station 311

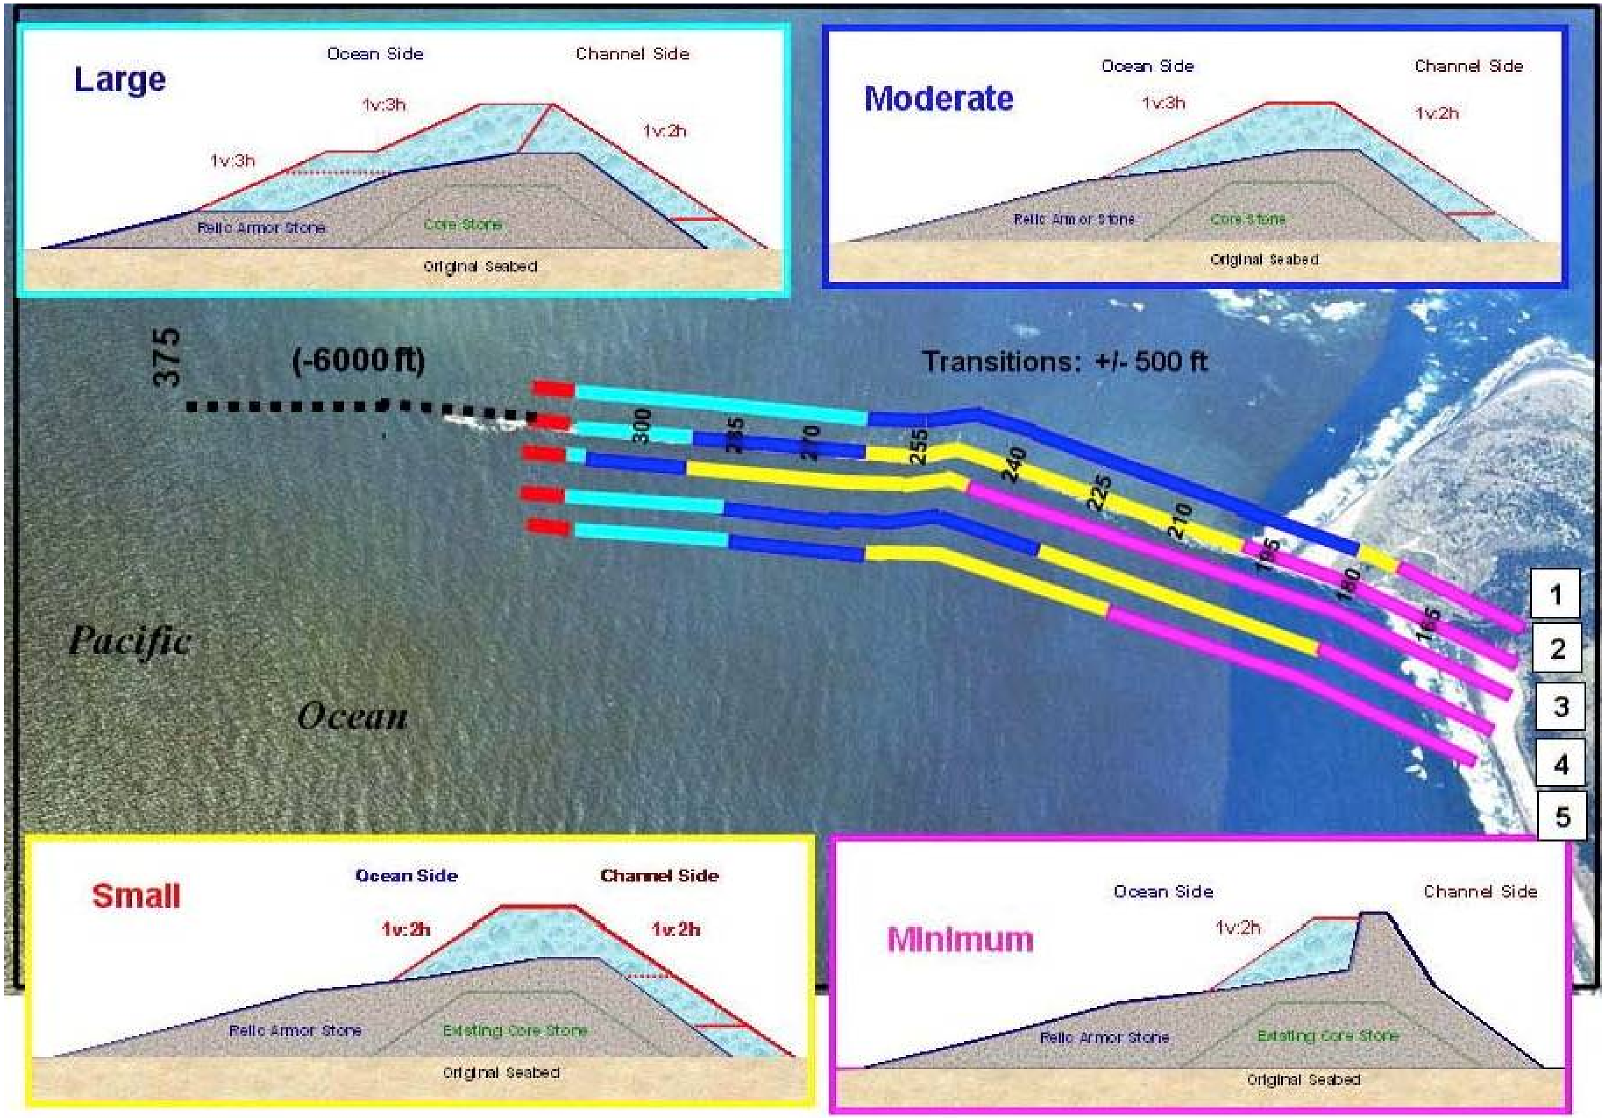

Figure A1- 270. South Jetty Composite Plans Immediate Rehabilitation

2. Scheduled Rehabilitation

Under a scheduled approach, the timing of the rehabilitation would be staged by applying the rehabilitation only to a portion of the jetty when it was needed, which would postpone the federal outlay of funds throughout the 50-year project life span. Depending on funding and equipment availability, completion of each alternative could take even longer than the estimates predicted below.

Due to the size of the jetties and the limited construction window, any rehabilitation work on the jetty structures would need to occur over a number of years. A scheduled rehabilitation alternative would implement the rehabilitation of specific reaches of each jetty at designated times to address the most vulnerable reaches first. It would repair the cross section above and below the waterline, repair foundation instability issues where needed, and includes construction of spur groins, North Jetty lagoon fill, jetty head capping, and improving the shoreline near the root of the South Jetty at Trestle Bay. Rehabilitation would not be conducted until conditions indicate that there is a need at specific portions of the jetty. Conducting the rehabilitation when needed, instead of continuously as in the immediate rehabilitation alternatives, would increase the length of time construction occurs to about 15 years, although construction would actually occur only 11 years out of that total (construction is not expected to occur on all jetties at the same time).

North Jetty. The Scheduled Rehabilitation approach for the North Jetty evaluated the minimum template as well as four composite plans. Each of these alternatives was evaluated both with and without maintaining the jetty head at the existing location. The layout of these four composite plans is shown in Table A1- 15. All of these plans incorporate all of the engineering features for the North Jetty, including capping the jetty head at approximately Station 101. The schedule developed for implementation was determined using model output which identified the projected sequence and timing of vulnerable reaches of the jetty combined with practical limitations such as weather windows for construction and limiting placement rates of stone.

The results of the model evaluation for these alternatives are presented in Appendix A2.

Table A1- 15. North Jetty Scheduled Rehabilitation Composite Plans

North Jetty Scheduled Rehabilitation	
Composite	**Cross Section Transition Station**
Composite 1-Large	Minimum cross section - Stations 10-55 Moderate cross section - Stations 55-90 Large cross section - Stations 90-100 Head capping - Station 101
Composite 2-Medium	Minimum cross section - Stations 10-80 Moderate cross section - Stations 80-90 Large cross section - Stations 90-100 Head capping - Station 101
Composite 3-Small	Minimum cross section - Stations 10-80 Moderate cross section - Stations 80-98 Large cross section - Stations 98-100 Head capping - Station 101
Composite 4-Small Modified	Minimum cross section - Stations 10-62 Moderate cross section - Stations 62-98 Large cross section - Stations 98-100 Head capping - Station 101

South Jetty. Two scheduled rehabilitation plans were initially evaluated for the South Jetty because the length of the jetty (over 6 miles) meant that there was no significant difference in construction timing and sequencing between immediate and scheduled rehabilitation. These plans were not developed to the same level as the other plans because results showed that constructability and timing of the scheduled rehabilitation alternative would not offer benefit to the South Jetty, as was the case for the North Jetty.

Jetty A. The scheduled rehabilitation with small template alternative for Jetty A addresses the larger system degradation processes. The Jetty A head is stabilized at approximately Station 92. Potential repairs are expected to occur approximately in year 2046 and extend throughout the life of the project.

1. INTRODUCTION

a. Scope

Appendix A2 describes how reliability methods and life-cycle concepts were used to evaluate alternative plans for improving future performance of the three jetties at the mouth of the Columbia River (MCR). The three MCR jetties have been in service for 70 to 100 years and are essential for maintaining deep draft navigation through the 6-mile long inlet. Many areas of each jetty are presently in an advanced stage of degradation. The MCR jetties continue to incur damage, motivating the need to systematically address the life-cycle of these structures. To address this need, the U.S. Army Corps of Engineers (USACE), Portland District, developed a stochastic risk-based (SRB) model to evaluate alternatives for optimally managing the life-cycle of jetty infrastructure. The SRB model was developed specifically for the MCR jetty system in support of this major rehabilitation study and was used to assess both the historical and future performance of MCR jetties. Accurate portrayal of historical jetty performance was necessary to perform model calibration and provide the basis for forecasting future life-cycle performance. Formulation of the project event tree, reliability analysis, and SRB life-cycle simulation are discussed in this appendix.

Topics in this appendix are described sequentially, from the general to the detailed view. The first part of the appendix describes the SRB model's structure and how the model relates environmental forcing to jetty performance. The present condition of each jetty is summarized in terms of realized life-cycle performance. The physical processes that are addressed within the SRB model, and related jetty response, are also provided as an overview. Later, individual components of the SRB model are described. Finally, details of the SRB model are integrated with details of MCR inlet physical processes which affect jetty life cycle performance. Some repetition of topics occurs though the appendix and was needed to provide an incremental description of the SRB model, inlet processes, and affected jetty performance. Appendix A1, *Coastal Engineering* and Chapter 3 of the *Major Rehabilitation Evaluation Report* describe how output from the SRB model was used to evaluate future life-cycle performance of the MCR jetties.

1. Deep-Draft Navigation at MCR and Life-Cycle Analysis of Jetties

During 1885-1939, phased construction of the three MCR jetties reformed a broad and treacherously variable 5.5 mile-wide inlet into a stable 2 mile-wide inlet having a consistent channel suitable for year-round navigation. Refer to Figure A2- 1 and Figure A2- 2 for a view of the present MCR inlet. The central project feature at the MCR inlet is the deep draft navigation channel (-48 to -55 ft MLLW), which is 2,640 ft wide and 5 miles long and extends through the inlet, connecting the lower Columbia River navigation channel with the

Pacific Ocean.

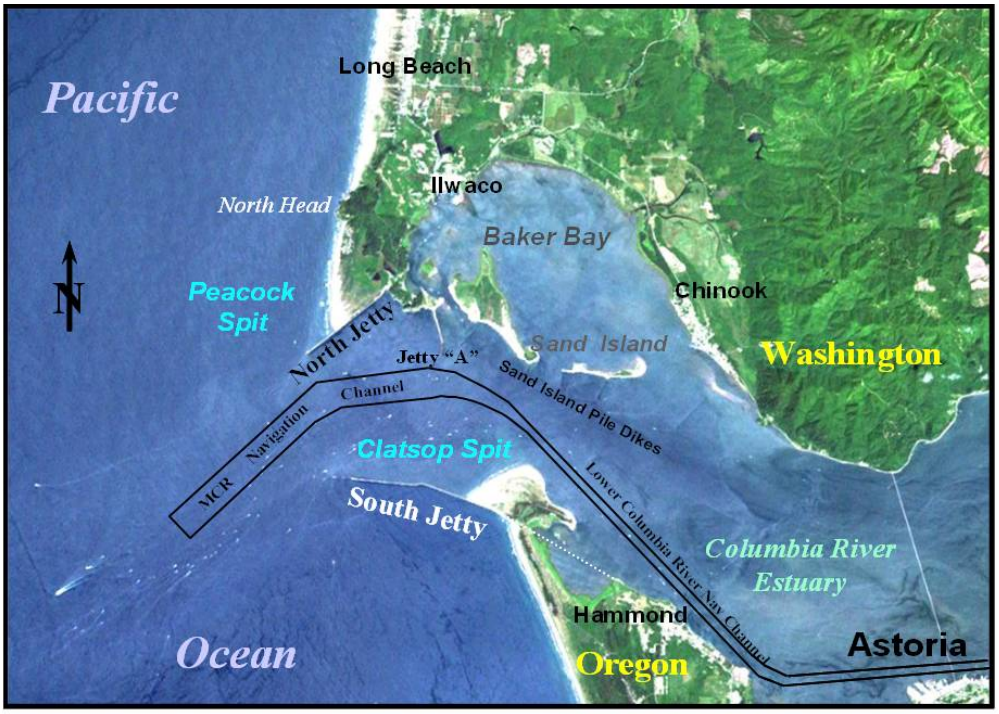

Figure A2- 1. MCR Inlet, Jetties and Navigation Channel

Mouth of the Columbia River (MCR) Inlet and the Three Jetties which Secure the Deep Draft Navigation Channel.

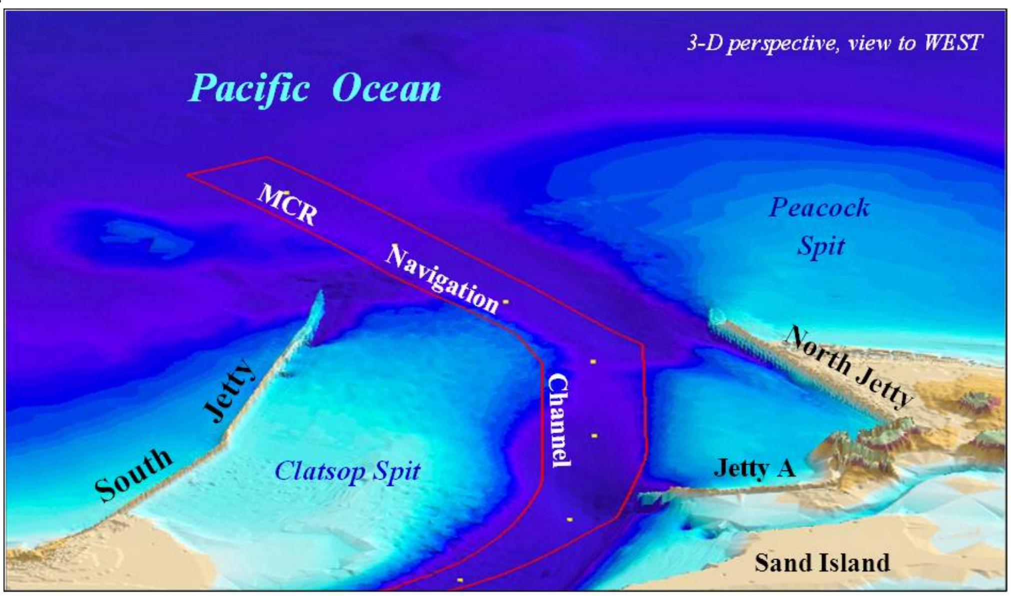

Figure A2- 2. Perspective View of the MCR

Perspective view of the Mouth of the Columbia River, showing the morphology on which the three jetties are founded. The distance between the seaward ends of the North and South Jetties is 2 miles. Water depth within the MCR thalweg varies from 43 to 110 ft.

Mean lower low water (MLLW) is approximately equal to -3.5 ft NGVD. Each jetty acts to stabilize large shoals that would otherwise enter the navigation channel. The jetties facilitate deep draft navigation by favorably redirecting currents through the inlet and protecting the inlet's interior from large waves. Continued function of the MCR jetties is essential for maintaining the inlet's present configuration and securing the deep draft navigation channel, which facilitates $16 billion in annual commerce. The MCR jetties have been in service for multiple decades and have, for the most part, functioned well. However, the recent onset of deferred maintenance, accelerating damage, and evolving site conditions has significantly degraded the resilience of the MCR jetties. Reduced resilience can lead to an unexpected loss of functional performance. Loss of jetty function could compromise deep-draft navigation at the MCR.

Active monitoring of vulnerable navigation structures at MCR has facilitated real-time risk assessment and immediate contingency planning. However, managing infrastructure at the threshold of functional loss may not be a cost-effective option, over the long-term, at an inlet such as the MCR [USACE 2005, Moritz 2008]. It has become necessary to assess future life-cycle conditions to enable optimal formulation of long term investment strategies; including the option of jetty rehabilitation. A firm understanding of a structure's present condition and loading and response characteristics is required before one can successfully optimize life-cycle management strategies. Refer to Appendix A1 for a full discussion of the MCR jetties.

2. Problem Statement and Objectives

The MCR jetties have experienced significant deterioration since initial construction, necessitating multiple repair campaigns. Jetty deterioration at MCR is motivated by foundation instability (toe scour) associated with the erosion of tidal shoals on which the jetties were built and extreme incident wave impact on the structures. Despite intermittent repair and rehabilitation campaigns over their respective service lives and a low rate of maintenance investment, the present condition of the jetties is one of moderate-severe deterioration which, if allowed to progress unabated, will result in progressive loss of jetty function. As the seaward end of each jetty (head) is damaged and recedes landward, the morphology on which the jetty is founded is incrementally dissipated by wave and current action. Progressive loss of the inlet's morphology due to jetty deterioration motivates shoaling within the navigation channel and increases wave and current action along each jetty and within the inlet. In certain failure scenarios, loss of jetty function could be abrupt, resulting in a breached jetty, whereby a large volume of sand shoal could be activated to deposit within the MCR navigation channel significantly impairing deep-draft navigation at the MCR.

Aspects of jetty performance are described by life-cycle metrics, provided as SRB model output, which provide an objective basis to compare alternative plans. Neither the SRB model nor this appendix conducts alternative plan selection. Chapters 3 and 4 describe how SRB model output (data and metrics) were used for alternative plan development, evaluation, and selection. Analyses described in this appendix were performed pursuant to applicable guidance for life-cycle analyses and rehabilitation of coastal navigation infrastructure [USACE-IWR 1992, USACE 1992, 1997, 2006, 2008]. The SRB model provided an evaluation frame-work to address the following rehabilitation study objectives:

- Improve the reliability of the MCR jetty structures.
- Extend the functional life of each jetty, as a system of structural elements.
- Reduce jetty life-cycle costs.
- Maintain deep-draft navigation at MCR.

3. SRB Model Framework

The SRB model is a computer simulation (MALTAB®) that stochastically evaluates the environmental loading affecting each jetty, and relates structural response (cross-section evolution) of each jetty to functional performance. The structure response is evaluated in terms of cross-section area change (loss) over time due to jetty degradation. Jetty repairs are activated within the SRB model, after the jetty cross-section is reduced below a specified threshold value. Jetty repairs are calculated in terms of the tonnage of armor stone required to re-establish the jetty cross section to its standard dimensions. Life-cycle costs estimated by the SRB model include jetty repair and incremental dredging attributed to jetty degradation and loss of function. Because life-cycle costs are estimated using stochastic methods, their realization can be considered probabilistic. Although reliability is also calculated within the SRB model, reliability is not used to simulate structure response and related consequences (life-cycle cost). Reliability is used as a supplemental metric to inform on overall jetty performance. The SRB model is considered to be an *engineering model* and was developed based on USACE guidance for major rehabilitation evaluation and life-cycle analysis. Details of the model are discussed in Section 5 of this appendix. Table A2- 1 summarizes the physical processes that affect jetty life-cycle performance vs. how those processes are addressed in the SRB model.

Table A2- 1. Physical Processes and Jetty Responses Emulated within the SRB Model

DEFINE INITIAL CONDITIONS Hindcast or Forecast →	SIMULATE ENVIRONMENTAL FORCING & STRUCTURE RESPONSE →	EVALUATE END STATE
Jetty Segment Attributes	**Environmetal Forcing and Jetty System Response**	**SRB Life-Cycle Performance Metrics**
(mean value, std dev)	(mean value, std dev for each side of jetty)	(mean value, std dev)
toe elevation	time-varying shoreline evolution	time-varying structural reliability
crest elevation	time- and spatially-varying scour rates	time-varying functional reliability
crest width	time- and spatially-varying wave conditions	timing and location of repairs
jetty side slope	time-varying water levels	repair tonnage & shoaling volume
armor stone size	variable jetty root degradation rates	jetty breach occurrence
armor stability number	repair history by jetty segment	components of life cycle cost
stone density	tonnage placed on the jetty	jetty crest elevation change
core stone presence	cost functions for jetty repair scenarios	cross-section evolution
jetty head position	channel shoaling associated with jetty performance*	jetty end state
	cost functions for dredging effect scenarios*	

*** = used for life-cycle cost forecasting**

The SRB model does not calculate the impact of jetty performance on navigation or commodity markets. Changes in navigability through the MCR inlet which may be attributed to jetty degradation (and related shoaling or morphology change within the inlet) are not addressed within the SRB model. The SRB model was used to estimate life-cycle engineering data for each MCR jetty, in terms of repair/rehab tonnage placed on a jetty and the incremental volume of sediment entering the MCR channel associated with jetty performance. A separate economic evaluation (external to the SRB model) utilized the SRB life-cycle cost data to determine the economic characteristics for a given jetty configuration. The overall time span for assessing the future life-cycle condition of the MCR jetties spans from 2006 to 2070. The period of analysis for this rehabilitation study included 2015 to 2064, which was based on a 50-year period beginning with an on-line year of alternative implementation (base year). The base year was assumed to be 2015 for all alternatives and for each jetty. Refer to Appendix C, *Economic Analysis*, for economic evaluation details.

4. Alternative Synthesis Using the SRB Model

Within the SRB model, each jetty is treated as an integrated system of components interacting with the inlet's forcing environment and morphology. The SRB models were calibrated by simulating (hindcasting) the historical life-cycle for each jetty. Relevant SRB parameters were adjusted to achieve hindcast model results that matched observed condition. Calibrated SRB models were used to forecast the future "baseline" condition for each jetty, against which a battery of alternative future conditions where compared. The "baseline" condition represents the no-action plan; structure repairs are deferred for as long as possible and no improvements are implemented to prolong the life-cycle.

Both with- and without-project alternatives were developed to address the objectives of this rehabilitation study. Without-project alternatives centered on a range of jetty maintenance strategies to address options for advance jetty maintenance of the standard design (existing) jetty template. Development of with-project alternatives was based on the incremental variation of jetty cross-section templates, additional engineering features, rehabilitation maintenance options, and implementation sequences (construction scheduling). The SRB model was used to estimate life-cycle metrics for all with- and without-project alternatives considered within the study. Appendix A1 gives a detailed description of the MCR project setting and discussion of rehabilitation alternative development.

Selection of a "preferred" plan, to manage the future life-cycle of each jetty, was based on the alternative that minimized future life-cycle costs, as represented by the monetary metric of average annual cost (AAC). To the extent possible, the preferred plan was based on supplemental consideration for the above non-monetary metrics. Comparative assessment of life-cycle metrics was performed by the Project Delivery Team (PDT) to arrive at an optimized plan. Through the course of alternative synthesis, the comparative assessment of life-cycle options evolved to a trade-off analysis of initial and large capital reinvestment versus incremental and deferred reinvestment. Refer to Chapters 3 and 4 in the *Major Rehabilitation Evaluation Report* for alternative plan development, evaluation, and selection.

5. Life-Cycle Metrics

The SRB model incorporates principles of performance-based design to evaluate the MCR jetties in hindcast or forecast mode. Performance-based design is a framework that relates performance requirements to respective metrics [Burcharth 1991 and Takahashi 2003]. A common set of life-cycle metrics were estimated by the SRB model to describe the performance for each jetty within a historical and future context. Metrics used to describe *historical* performance include: jetty repair aspects (timing, frequency, location), jetty geometry configuration (crest profile, cross-section, jetty head location), and jetty reliability. Metrics used to describe *future* jetty performance and compare alternatives for rehabilitation include:

- Annual and cumulative life-cycle stone replacement tonnage.
- Components of life-cycle jetty repair, incremental dredging, rehabilitation.
- Reliability (probability of a project feature to perform satisfactorily).
- Timing and frequency of repairs (time to first repair after project implementation).
- Timing and frequency of significant jetty breach events.

The monetary metric used to portray future life-cycle cost is expressed as a single amortized value, referred to as AAC. The AAC and derivative monetary metrics (benefit-to-cost ratio [BCR], etc) were calculated externally from the SRB model, using engineering cost data provided by the SRB model. Refer to Appendix C for AAC calculation methodology.

Specific events associated with timing and frequency of risk (realized negative project performance) are not directly conveyed within the AAC. Consideration of non-monetary life-cycle metrics (noted above) in conjunction with AAC can supplement the process of alternative development and assessment, and optimize the process of evaluating alternative plans to enable the selection of a preferred plan. Chapters 3 and 4 in the *Major Rehabilitation Evaluation Report* describe how ACC was used in conjunction with non-monetary metrics to evaluate alternative plans and select a preferred plan for each jetty.

b. SRB Life-Cycle Simulation

SRB life-cycle simulations are used to characterize the time-varying risk of structures subjected to complex loading and response scenarios. SRB models can simulate non-stationary processes that affect structure performance, which may be a requisite element to correctly simulating the life-cycle of infrastructure within the coastal margin. The three MCR jetties based on the project event tree (Figure A2- 3 through Figure A2- 11) simulate the life-cycle of each jetty for past and future conditions. The SRB models were used to formulate optimal long term investment strategies; including options for jetty rehabilitation.

The SRB model is stochastic because it integrates an annualized cycle of environmental loading in terms of random variables defined by specific probability density functions. Many of the parameters affecting structure response and life-cycle management outcomes are also expressed as random variables and treated stochastically. To emulate jetty damage resulting from wave attack, the SRB model uses wave-structure damage functions, developed through scaled physical model studies. Jetty damage resulting from foundation scour is also emulated within the SRB model.

It must be stressed that the consequences (jetty repair tonnage, incremental channel shoaling, and associated life-cycle costs) produced by the SRB model are driven by the stochastic processes and responses described above, and not by reliability. Although reliability is also calculated within the SRB model, reliability is not used to simulate structure response and related consequences (life-cycle cost). Reliability is used as a supplemental metric to inform on overall jetty performance.

The SRB model evaluates the structural and functional performance of jetties in terms of a reliability index (beta-value) which is expressed as reliability (Ps). As the cross-section of a jetty changes through time (due to cumulative damage or repairs), the reliability also changes. The SRB model uses the Monte Carlo method to increase the confidence of life cycle estimates and allows for an evaluation in the variance of life-cycle cost and other metrics.

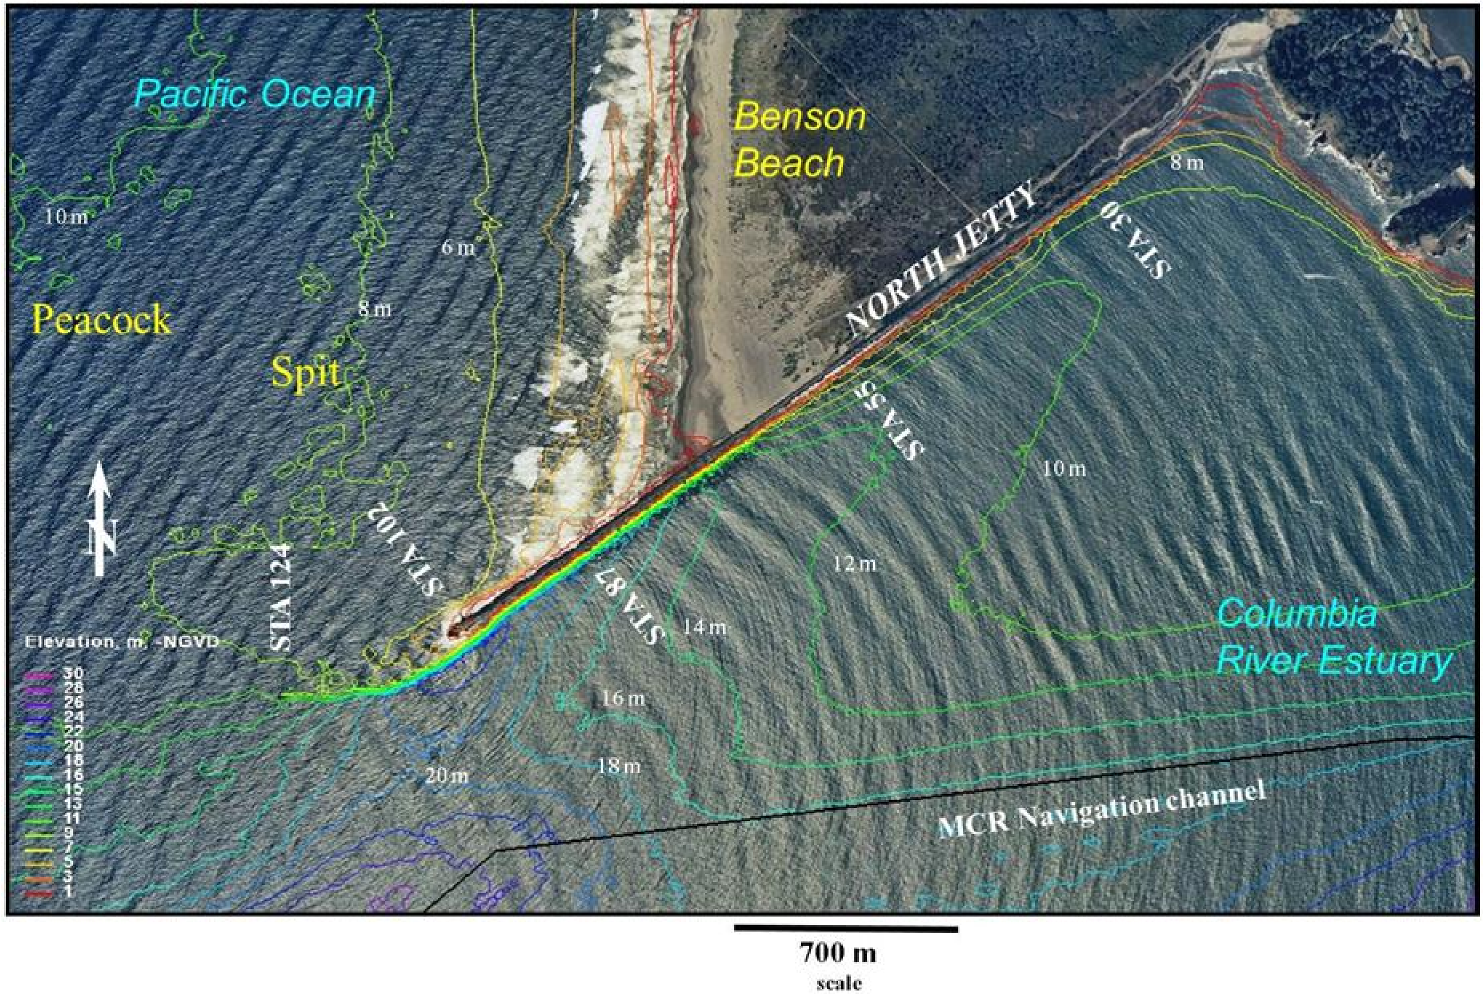

Figure A2- 3. North Side of the MCR

North jetty shown with Bathymetry 2007, elevation is in meters below NGVD. Present jetty head is located at Sta. 102. Head constructed to Sta. 124 in 1917, and re-established at Sta. 110 in 1939 and 1964. Sand shoal formed along channel side of jetty during 1999-2005 by sand being transported through the jetty from ocean side; when jetty cross-section became jeopardized by wave and scour damage.

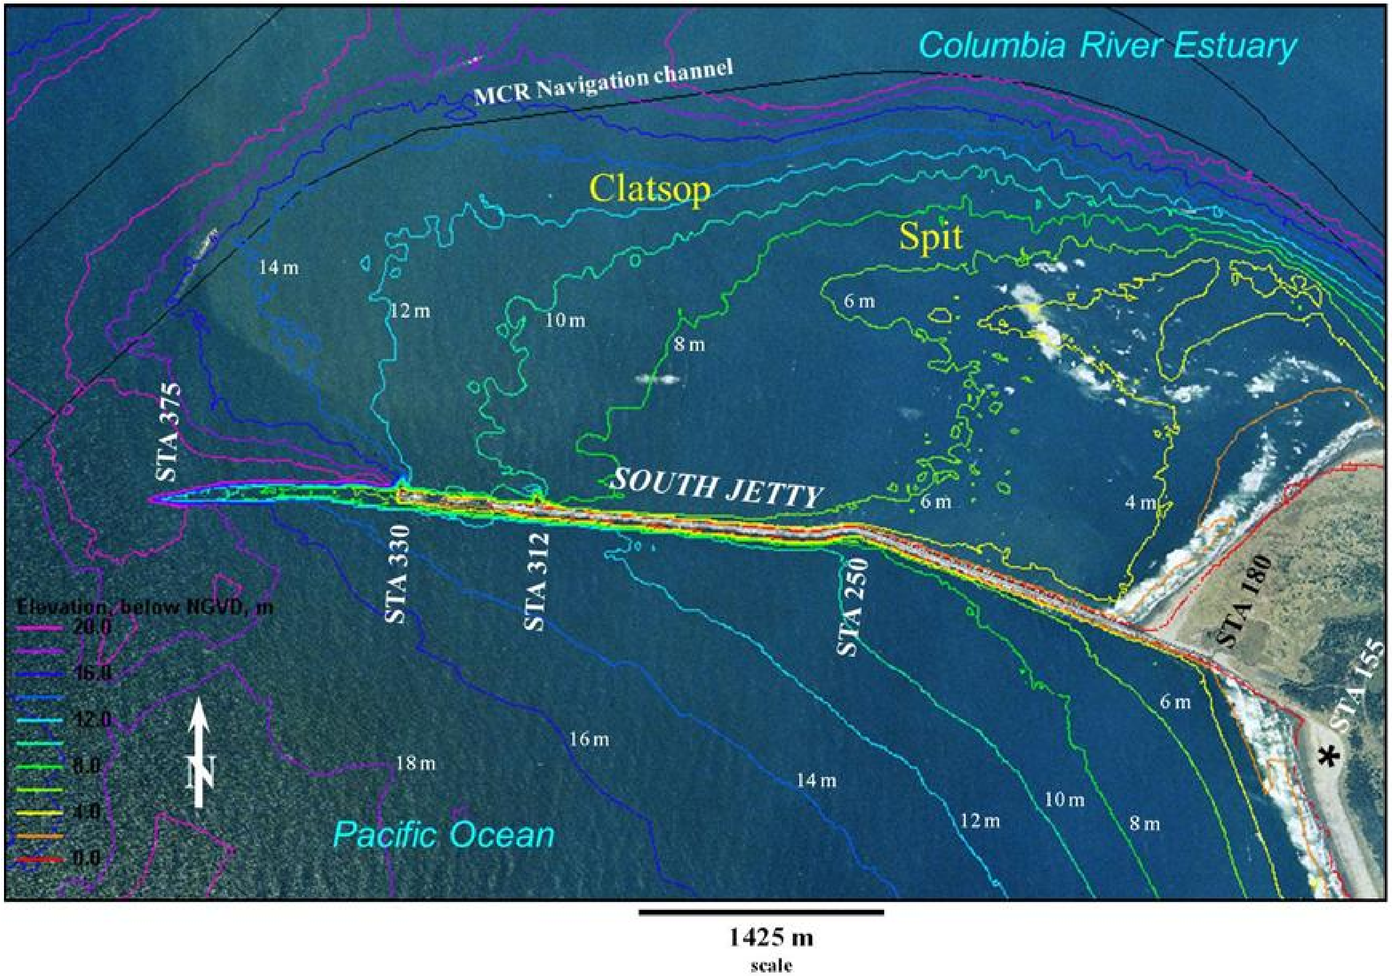

Figure A2- 4. South Side of the MCR

South jetty shown with Bathymetry (2003), elevation is in meters below NGVD. Existing spurs at Sta. 330 and 312 (channel side) reduce scour along the channel side of the jetty. The seaward end of the concrete monolith terminates at Sta. 330. Existing shore attached head of jetty is at Sta. 314. Jetty head was re-established at Sta. 354 in 1935 and Sta. 330 in 1940.

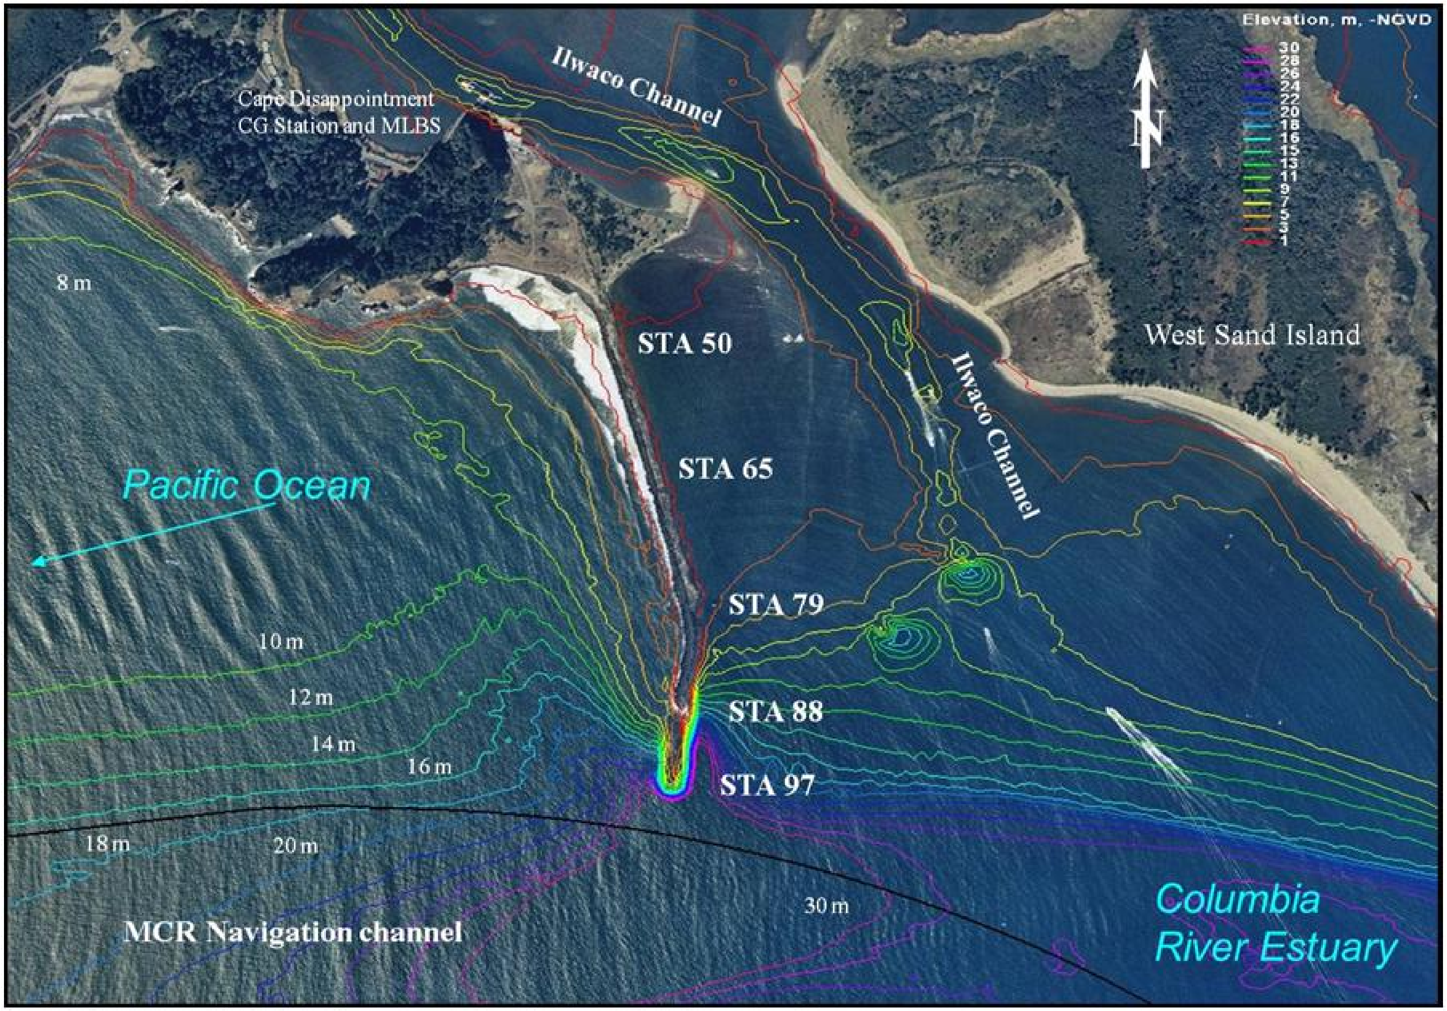

Figure A2- 5.   Jetty A Orientation with North Side of MCR

Jetty A shown with 2007 bathymetry, elevation is in meters below NGVD. Present jetty head is located at Sta. 88. Head constructed to Sta. 97 in 1939, and re-established at Sta. 90-97 during 1946 - 1962. Seaward end of Jetty A has been threatened by significant scour, while the inshore areas facing the ocean have been threatened by heavy wave action. Jetty A acts to stabilize the north side of the MCR inlet.

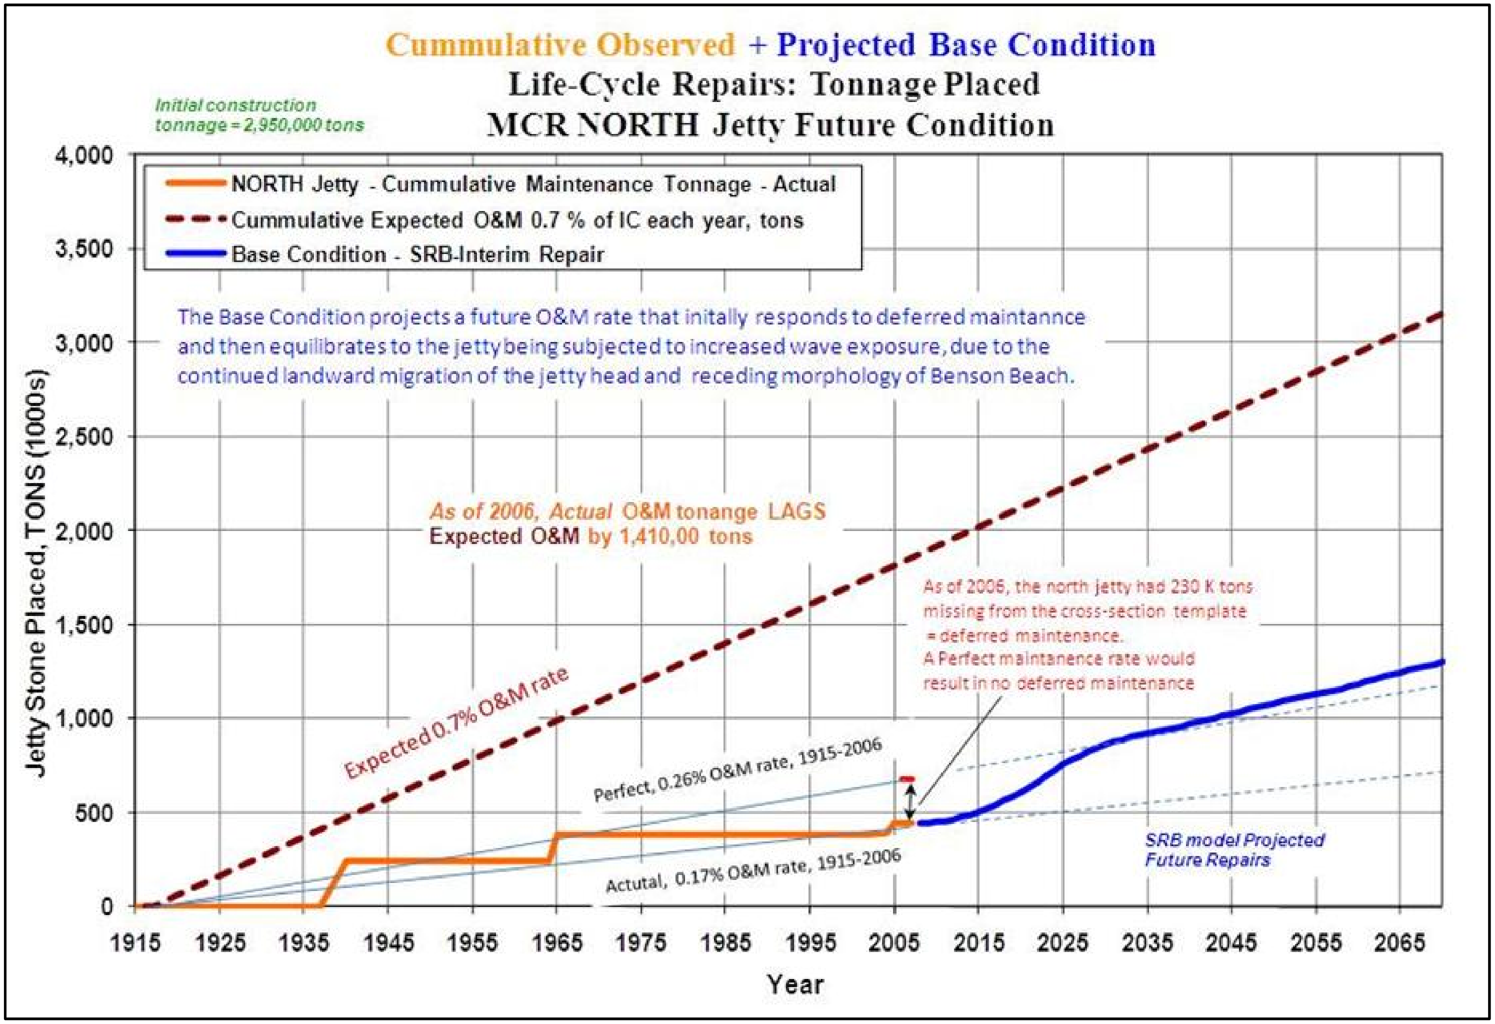

Figure A2- 6. North Jetty Maintenance Rate, Past-Observed and Future-Projected Base Condition

Repair tonnage for MCR North Jetty. Projected estimate is based on the project base condition (no action plan) and begins in 2006, which the last time that the North Jetty was fully surveyed.

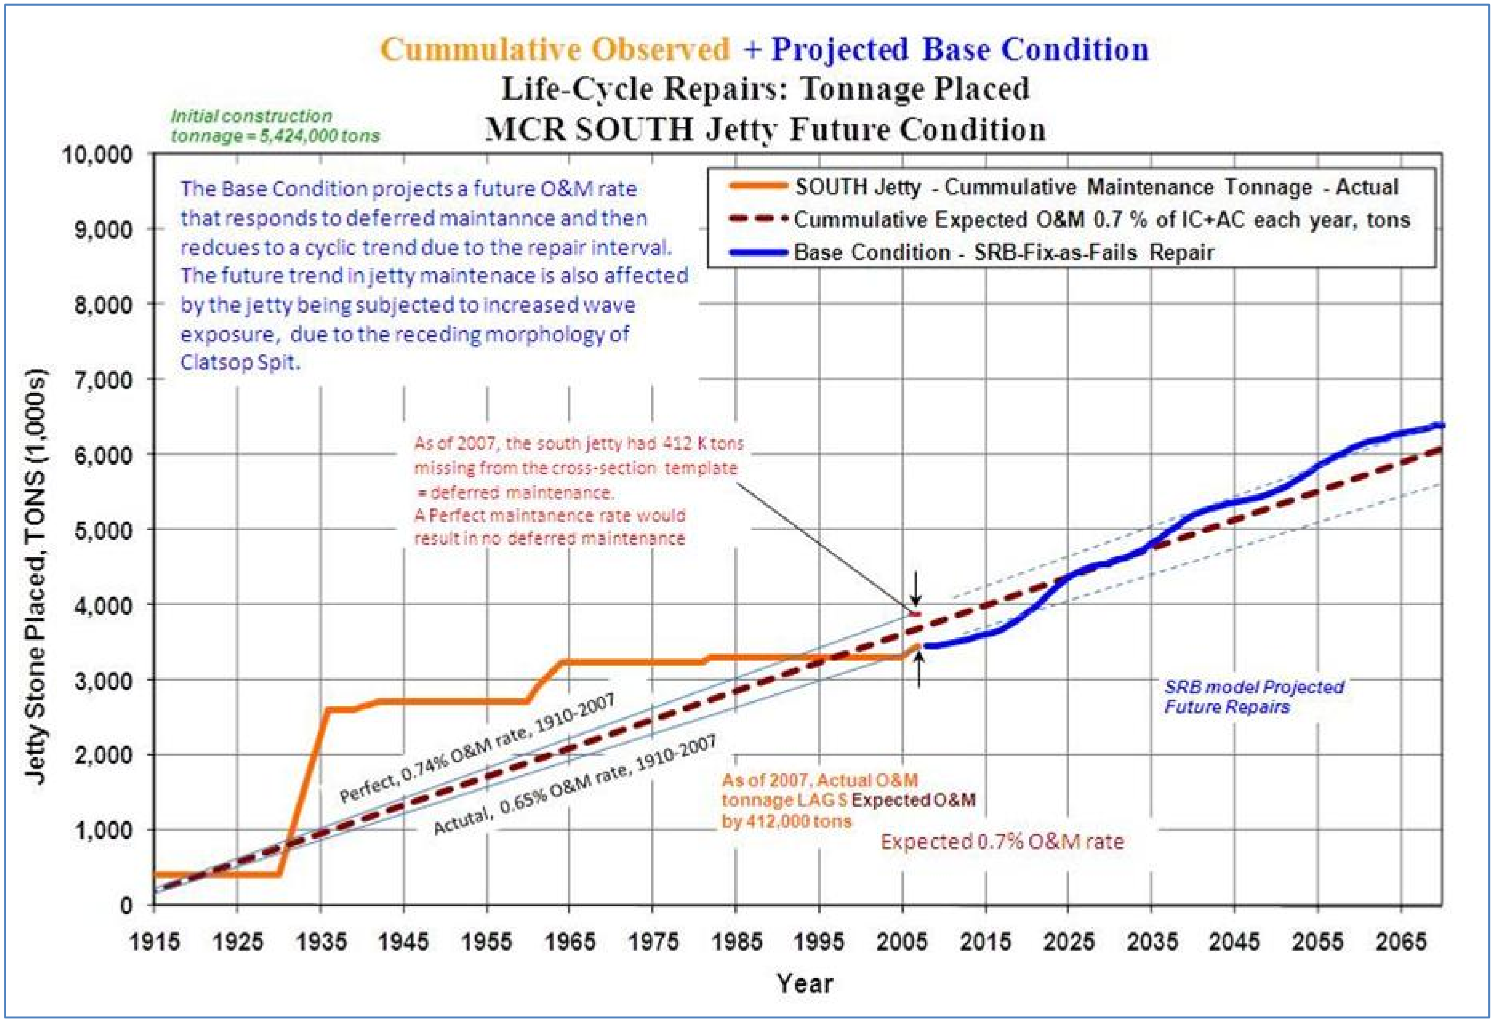

Figure A2- 7. South Jetty Maintenance Rate, Past-Observed and Future-Projected Base Condition

Repair tonnage for MCR South Jetty. Projected estimate is based on the project base condition (no action plan) and begins in 2007, which the last time that the South Jetty was fully surveyed.

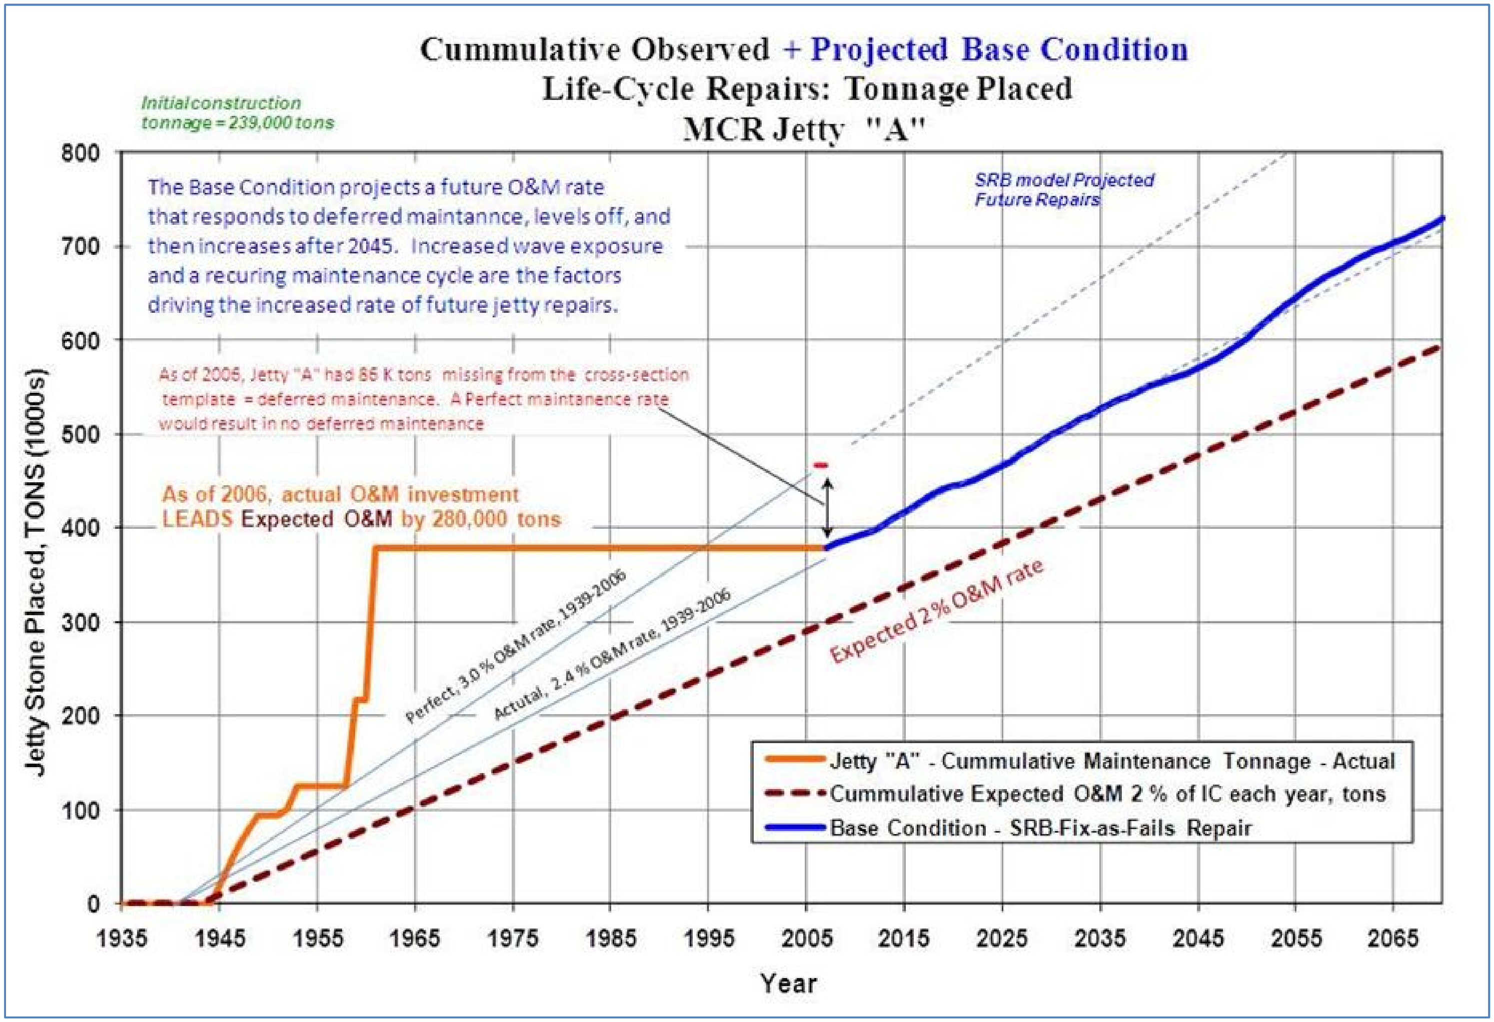

Figure A2- 8. Jetty A Maintenance Rate, Past-Observed and Future-Projected Base Condition

Repair tonnage for MCR Jetty A. Projected estimate is based on the project base condition (no action plan) and begins in 2006, which the last time that jetty "A" was fully surveyed.

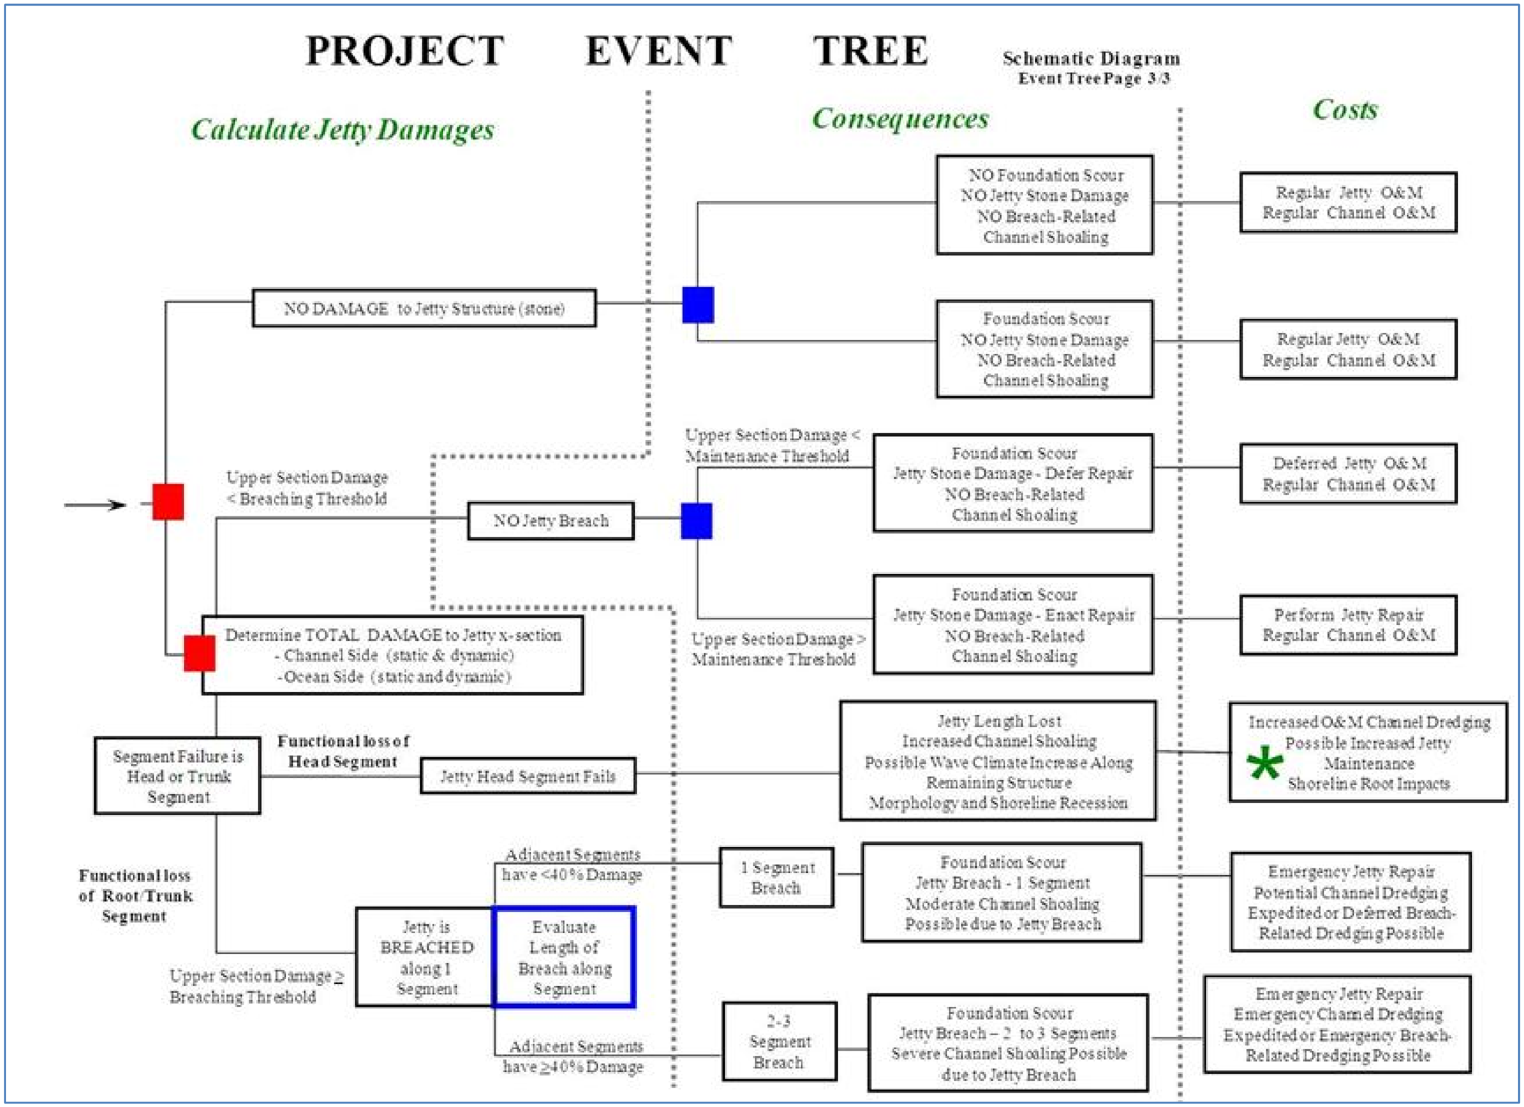

Figure A2- 11. Expanded Detail of MCR Jetties Event Tree, Part 3 of 3

1. Modeling Jetty Performance at the MCR Inlet

The three MCR jetties interact with each other and the inlet's morphology to secure the federal deep-draft navigation channel. Knowledge of these interactions is used to assess the time-varying condition of each jetty within the context of inlet evolution. A SRB model was developed for each jetty to relate environmental loading to jetty structure response and functional performance. Due to the complexities of the MCR jetty system, an integrated analysis of the life-cycle performance for all three jetties was not attempted. Rather, each jetty was analyzed independently. The SRB model for Jetty A does account for effect of scour at North Jetty, should the head of Jetty A recede landward.

The SRB model evaluates time-varying degradation of a jetty's geometry (cross-section), structural and functional reliability, location cost and timing of jetty repairs, and incremental dredging costs related to jetty degradation.

The time-varying reliability of a given jetty (or jetty segment) can be affected by the degree of cumulative damage sustained by the structure. Within the SRB model, the method used to evaluate reliability is independent from the procedure used to estimate the amount (level) of cross-section degradation. Reliability is dependent upon the degree of cross section damage.

2. Jetty Reliability and Cross-Section Damage

As stated above, calculations for jetty reliability and cross-section damage are handled separately within the SRB model. Generalized (rubble-mound armor) stability equations are evaluated to estimate the time-varying reliability for discrete areas along each jetty. Note that jetty reliability is based on both the present forcing environment and the present condition of the jetty; each of which can vary from year to year. Reliability indicates the likelihood of a jetty to resist damage (and function satisfactorily) in the presence of wave action. Reliability does not define how much jetty degradation would incur, if the jetty were damaged.

<u>Cross-Section Damage</u>. The degree and rate of structure degradation (as affected by wave action) is evaluated using damage functions which are based on incident wave height vs. incremental cross-section damage. The damage functions were developed through detailed physical model studies conducted at ERDC, featuring MCR jetty cross-section attributes [Ward et al., 2007]. Within the SRB model, wave- induced jetty damage is calculated for each storm event realized within each year, using wave-damage functions. A description of how the SRB model emulates cross-section damage is presented in Section 2 and Section 5 of this appendix.

<u>Reliability</u>. Time-varying reliability aggregate value, calculated using the mean value and standard deviation for the annual storm climate which varies for each year within the SRB simulation. An annual wave and water level environment is generated for each year within the SRB life-cycle simulation. There can be 1 to 11 storm events affecting the MCR inlet per year, having offshore significant wave height ≥ 22 ft. The annual (1-year) storm event has an

offshore significant wave height of 29 ft, and the 25-year storm event has an offshore significant wave height of 46 ft. A description of jetty reliability calculations within the SRB model is presented in Section 3 of this appendix. Refer to Section 6 of this appendix for a description of the MCR forcing environment and how it was simulated in the SRB model.

In summary, evaluation of jetty damage is performed independently of the reliability calculation. Jetty reliability can be affected by the degree of damage sustained by the structure's cross-section; however, the degree and extent of cross-section damage is not directly predicated by the structure's reliability.

c. Current Condition of MCR Jetties – Previous Life-Cycle

Despite the formidable challenges faced by the engineers to implement the original MCR jetties (severe working environment), lack of established design criteria, and limitations encountered during initial construction, the MCR jetties have performed rather well during their previous life-cycle. While the original project authorization was expected to be for a 50-year life, by default the service life of the original jetty structures has extended to an approximate life of 100 years. The present length of service for each of the MCR jetties ranges between 70 and 100 years and each jetty has been subjected to unique and severe loading induced by the region's environmental forcing. The jetties were originally constructed and repaired over the life cycle using progressively larger stone sizes and larger design templates as design criteria changed and equipment capacity evolved. At the same time, the surrounding loading climate was being altered.

If viewed strictly in terms of *realized* vs. *expected* maintenance costs (or repair tonnage), the North and South Jetties have performed as expected or better. However, what may be considered as good project performance (low O&M expenditure realized to date) may actually be an issue of deferred maintenance. Evaluation of a structure's present condition can inform whether a low maintenance expenditure rate is indicative of good structure performance or deferred maintenance. The following paragraphs provide a three-way comparison between: A) an expected rate of maintenance for MCR jetties, B) the realized maintenance rate for each jetty, and C) the present condition of each jetty. It is important to note that the stream of realized maintenance costs may not compare 1:1 with realized maintenance tonnage, if the unit cost for repairs was not consistent through time. For this reason, realized maintenance tonnage will be used to assess prior maintenance activity.

1. Expected Annual Maintenance - General Considerations vs. MCR Jetties

The annualized expenditure rate needed to maintain water resource infrastructure is typically based on an equivalent replacement value, accrued over the expected service life of the asset. In many cases, the maintenance rate is equivalent (or at least correlated) to a structure's estimated degradation rate. For a perpetual asset that is initially constructed with a 50-year service life, an expected maintenance rate would be 2%, expressed as percentage of initial structure construction tonnage (or cost, if repair unit costs are consistent). The above example assumes that the <u>entire</u> asset would be affected by some form of expected degradation. The asset would either be incrementally maintained throughout its 50-year service life or be replaced/rehabilitated after the 50-year period.

For many coastal navigation structures (jetties, breakwaters, revetments, seawalls), active degradation may be limited to an "affected" part of the structure where wave action or other active forcing is manifest. This would be the case if the structure was located in relatively deep water, where wave damage would be limited to the upper part of a structure (and there was now foundation-related degradation to affect the lower part of the structure). However, if a given structure was located in relatively shallow water and wave loading was both severe and depth-limited, then the entire cross-section could be degraded by wave action (from the structure toe to the crest). If the foundation of a structure was subjected to severe toe scour or slope instability, then much of the structure's entire cross-section could be degraded within the expected life-cycle.

2. Limited Vertical Extent of Wave Damage and Minor Toe Scour Effects:

If the structure's foundation does not experience severe degradation (scour or slope failure) and wave action does not affect the lower part of the structure, then the lower part of the structure could remain intact through a given life-cycle. Depending upon the water depth and wave action affecting the structure, only the upper 1/2 to 2/3 of the jetty cross-section may need to be replaced over the service life if the structure was <u>not</u> subjected to foundation degradation. In the absence of adverse foundation effects, the expected maintenance rate for a 50-year service life would correspond to 1% (upper 1/2 of the x-section x 2%) to 1.3% (upper 2/3 of x-section x 2%) of the initial structure construction tonnage.

3. Full Extent Wave Damage and Significant Toe Scour Effects:

If the structure's foundation were subjected to severe scour and wave action frequently affected the entire cross of the structure (from toe to crest), then the entire cross-section would be expected to degrade over a given life-cycle. The expected maintenance rate for a properly designed structure to function for a 50-year life-cycle would be 2%; the entire cross-section could require replacement within the life-cycle. If the wave action and toe scour was severe, and measures were not undertaken to mitigate either process, the maintenance rate could be 4%. This high maintenance rate may be considered unacceptable over a 50-year life-cycle, but could occur due to the entire cross-section being affected by two independent degradation processes.

Whether by design or by default, the MCR jetties have achieved an expected service life of 50-100 years. Assuming that foundation scour was not severe and that degradation due to wave action was limited to the upper half of the cross-section, the rate of maintenance needed to maintain the MCR jetties would be expected to vary from 0.5% (1/2 x 1%) to 1% (1/2 x 2%) per year. Based on this rationale, a maintenance rate of 0.7% was used to represent a favorable value for the MCR North and South Jetties. Table A2- 2summarizes annual maintenance rates for several hypothetical levels of MCR jetty performance, and compares these values to realized performance. Refer to Appendix A1 for detailed review of historical jetty cost expenditures at MCR.

Table A2- 2. Generalized Ratings for Annual Maintenance of Rubble-mound Structures Compared to Maintenance Realization for MCR Jetties Based on a 50-100 yr life-cycle

NJ & SJ ratings assume that the entire length of the structure has been adequately maintained with no deferred maintenance and that excessive foundation scour does not occur along entire structure.

MCR Project Feature	**Annualized Life Cycle Repairs Costs (in $ and tons of stone)** Expressed as a Fraction of Initial Construction*			
	Unsatisfactory 2%	**Marginal 1%**	**Excellent 0.35%**	**Actual Realization North & South Jetties**
North Jetty (cost)	$ 6.9 M/yr	$3.5 M/yr	$ 1.2 M/yr	**$ 0.5 M/yr**
(stone)	59 K tons/yr	30 K tons/yr	10 K tons/yr	**4.3 K tons/yr**
South Jetty (cost)	$ 15.7 M/yr	$7.8 M/yr	$ 2.7 M/yr	**$ 3.1 M/yr**
(stone)	108 K tons/yr	54 K tons/yr	20 K tons/yr	**33 K tons/yr**
JA ratings assume that the entire length of the structure has been adequately maintained with no deferred maintenance and that significant foundation scour occurs along much of the structure.				
	Unsatisfactory 4%	**Marginal 2%**	**Excellent 1%**	**Actual Realization Jetty A**
Jetty "A" (cost)	$ 0.76 M/yr	$0.38 M/yr	$ 0.19 M/yr	**$ 0.4 M/yr**
(stone)	9.4 K tons/yr	4.7 K tons/yr	2.3 K tons/yr	**5.7 K tons/yr**

* = Initial cost for North (South) Jetty was $345.8 million ($642.8 million). Present life cycle in 2010 for North (South) Jetty was 89 years (100 years). Initial cost for Jetty A was $19 million and life cycle during 1939-2007 was 68 years. **"Favorable" = average between marginal and excellent = 0.7 %.**

If foundation degradation was severe along the entire length of the jetty and wave action affected the entire cross-section, then the expected maintenance rate could be 1% (1 x 1%) to 2% (1 x 2%) per year. If the structure was not designed or maintained to address the severe wave of scour degradation, the (un)expected maintenance rate could be 2% (2 x 1%) to 4% (2 x 2%) per year. Based on this rationale, a maintenance rate of 1.5% was used to represent a favorable value for the MCR Jetty A. It is noted that the favorable maintenance rate for Jetty A assumes that the structure was designed to accommodate severe wave action and scour effects.

4. Realized Maintenance Rate & Current Condition of North and South Jetties

The average rate of maintenance realized to date for the North and South Jetties has been 0.15% and 0.45% per year, respectively (in terms of initial construction cost). If expressed in terms of repair *tonnage*, the realized maintenance rate for the North and South Jetties is 0.17% and 0.65% per year, respectively. Note the difference between maintenance rates based on cost vs. tonnage. This is due to unit repair costs ($/ton) being lower than initial construction costs. Realized maintenance rates were calculated by dividing the total maintenance effort (cost or tonnage) realized since jetty construction by the number of years for the present jetty life-cycle. The present life-cycle for the North Jetty is 93 years (1917-2010); and 100 years for the South Jetty (1910-2010). Figure A2- 6 and Figure A2- 7 show the actual maintenance rates (repair tonnage) for North and South Jetties, as compared to the expected rate. Based on the actual maintenance rate of 0.17%, the North jetty has performed much better than the expected maintenance rate of 0.7%. The favorable project performance is motivated by the formation of Benson Beach (Figure A1-35) protecting the North Jetty from wave action and scour along much of the ocean side of the jetty. The South Jetty has performed slightly better than expected, based on the actual maintenance rate of 0.65%; which is more than twice the maintenance rate of the North Jetty. Unlike the North Jetty, the South Jetty has been exposed to wave action and some excessive scour effects since its initial construction and consequently has a significantly higher maintenance rate than the North Jetty. But what does a low rate of maintenance say about jetty performance and the present condition of each jetty? A comparison between actual life-cycle costs realized to date and the present jetty condition can provide an indication if jetty repairs have been deferred.

During 2005-2007, interim repairs were completed "just-in-time" at specific areas of the North and South Jetties to prevent breaching at their most severely damaged areas. Many areas of each jetty remained in damaged condition following these interim repairs. Based on the most recent survey data (2006-2007), which included the post-constructed interim repairs, the amount of maintenance needed to restore each jetty to a minimal design configuration was estimated to be 237,000 tons for North Jetty and 412,000 tons for South Jetty. This tonnage deficiency represents the amount of deferred jetty maintenance, as of 2006-07. Expressed in terms of cost (2010 dollars), these deferred repair estimates translate to $46 million for North Jetty and $86 million for South Jetty. These estimates do not include additional jetty degradation since 2007, which has been documented in annual jetty monitoring reports [USACE 2011]. If the jetties had been maintained such that there was no deferred maintenance (perfect maintenance), the realized maintenance rate for the North and South Jetties would have been 0.26% and 0.74%, respectively. Actual maintenance rates for the North and South Jetties were 0.17% and 0.65%, respectively (Figure A2- 6 and Figure A2- 7). Based on the recent just-in-time repairs needed to avert imminent breaching along the North/South Jetties and the preset need for additional repairs, the difference between the actual maintenance rate vs. non-deferred maintenance rate indicates that repairs have been deferred.

5. Realized Maintenance Rate & Present Condition of Jetty A

To date, the average annual rate of maintenance actually expended on Jetty A has been 2.4% of the structure's initial construction tonnage (Figure A2- 8). This is considerably higher than a value of 0.7%, which is the expected value for MCR North and South Jetties. The expected maintenance rate for a structure such as Jetty A is 1.5%, due to the relatively large extent over which this structure is affected by both wave action and scour effects. Given the above qualifying considerations, Jetty A has performed poorer than the maintenance rate expected for this type of jetty structure.

The present life-cycle for the Jetty A is 68 years (1939-2010). The surrounding morphology was rapidly modified in response to the circulation changes induced by Jetty A construction, acting to increase wave action and scour along the jetty. As originally constructed, the entire vertical extent of the Jetty A cross-section was exposed to wave action. The jetty was initially constructed in shallow water using low resilience cross-section. A high level of maintenance was expended on Jetty A soon after construction to address extreme foundation scour along the outer 1/3 of the structure and low resiliency of initial jetty construction (to resist wave action). Repair actions implemented for Jetty A during the 1940s-1950s utilized readily available (but undersized) rock from a nearby quarry which produced a rebuilt cross-section of low resilience. The rebuilt jetty was rapidly damaged, requiring rehabilitation of the jetty during 1961-1962 following a breach event during the 1950s. The last time that Jetty A was repaired was in 1962.

Based on the most recent survey data for the MCR jetties (2006-2007), the amount of maintenance needed to restore Jetty A to a minimal design configuration is estimated to be 87,000 tons. Expressed in terms of cost (2010 dollars), this deferred repair estimate translates to $23 million. This estimate does not include additional jetty degradation since 2006, which has been documented in annual jetty monitoring reports [USACE 20011]. If Jetty A had been maintained such that there was no deferred maintenance, the realized maintenance rate would have been 3.0%, respectively (as compared to 2.4%, Figure A2- 8). Many areas along Jetty A are degraded and presently require repair, and Jetty A continues to sustain and accumulate damage each year. Based on the present condition of Jetty A, it can be concluded that maintenance has been deferred for this structure.

6. Jetties and Transient Morphology

The forcing environment affecting the jetties today is not the same as it was 70 or 100 years ago. At the time of jetty construction and shortly thereafter, the jetties were protected by the broad shallow sand shoals on which they were built. Initially, incident waves were severely depth-limited along much of each jetty and currents were reduced by the presence of shallow shoals. In some localized areas, jetty construction promoted shoaling along the jetty, further protecting it from wave and current action. In other areas, jetty construction motivated rapid dispersal of the sand shoals near the jetty, allowing larger waves and currents to affect the structure. The seaward terminus of each jetty experienced rapid deterioration immediately after initial construction due to the jetty head extending to the outer limit of the inlet's shoals, exposing the jetty head to severe current and wave action. As the seaward ends of jetties recede landward, the inlet morphology also recedes, promoting incremental shoaling of released sediment within the MCR inlet/channel, and allowing larger waves to enter the inlet's interior. Figure A2- 3 through Figure A2- 5 illustrate the integrated effect that the MCR jetties have with adjacent morphology. Note the submerged jetty heads in all three figures and differing bathymetry from one side of each jetty to the other (channel side to ocean side).

The stability of the present MCR inlet and adjacent coastal margins are dependent upon both the jetties and the tidal shoal morphology, on which the jetties were constructed. Figure A2-12 shows how the shoreline (0 MLLW) has responded due to jetty construction. Accretion of Benson Beach (in response to North Jetty construction, 1917) has protected most of the ocean side North Jetty from wave action and scour, while the jetty's channel side has been affected by morphology recession motivating scour and increased exposure to wave action.

The south side of the MCR inlet responded with both accretion and recession in response to South Jetty construction (1885-1910) protecting the inner 1/3 of the jetty from waves and scour (east of Sta 155). The shoreline and morphology along the outer 2/3 of the South Jetty has receded in response to jetty construction exposing this area of the jetty to increased scour and wave action. The shoreline and morphology response due to Jetty A construction (1939) is complicated by the overall response of the MCR inlet due to the long-term evolution of Baker Bay (1840-1939) combined with the post-construction response due to North and South Jetties. Local effects of Jetty A construction motivated significant recession of the morphology near the jetty, resulting in significant scour along the jetty and increased exposure to wave action from the ocean.

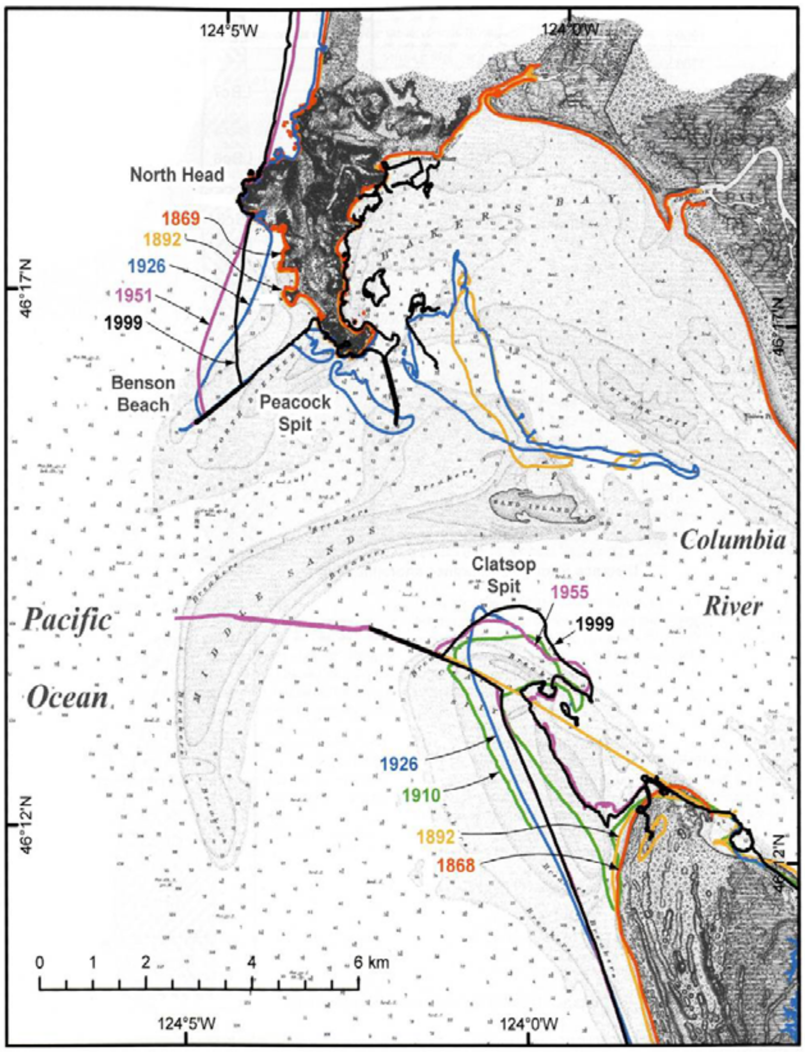

Fig. 6. 1870 U.S. Coast and Geodetic Survey – Mouth of the Columbia River, with historical shorelines.

Figure A2- 12. Historical Shoreline Response at the MCR

Mouth of the Columbia River historical shorelines. Base map is 1870 US Coast and Geodetic Survey (Kaminsky et al 2010). South Jetty constructed 1885-1910, North Jetty constructed 1913-1917, and Jetty A constructed 1938-1939.

Over time, the MCR tidal shoals, spits, and MCR jetties have evolved to function symbiotically. The interaction between jetties and morphology can be summarized by noting that the jetty is a long, thin, narrow backbone of solid material, resting upon a very doubtful foundation, against which the forces of nature have accumulated large quantities of shifting sand. These shoals break the force of the waves and protect the jetty from destruction. Jetty integrity and the permanence of the channel over the bar depend upon the amount of sand that can be accumulated [USACE 1905]. At present, each of the MCR jetties is acting to retain 10's of millions cy of sediment within and adjacent to the MCR inlet.

Due to the continual evolution of tidal shoals at MCR, the sand foundation of each jetty has receded and the resiliency of the jetties has been progressively compromised. The South Jetty has lost 4,200 ft of subareal length along its seaward end, and the seaward end of North Jetty has receded 1,800 ft due to morphology loss and erosion of the jetty foundation. Jetty A has lost 900 ft of length. The rate of morphology recession has decreased along some jetty reaches, most notably at areas near the original heads for Jetty A and South Jetty. Other areas continue to experience a constant rate of recession, such as Peacock Spit and areas of Clatsop Spit which affects the stability of the North and South Jetties. Some areas along Jetty A are showing signs of continued morphology reduction. At present, the seaward end for all MCR jetties is receding landward due to wave action. Foundation scour is also affecting the present outer end of the jetties and areas along the jetty toe.

As the seaward end of a jetty recedes landward, larger waves and stronger currents are able to attack the leeward jetty and the remaining morphology underneath; acting to increase the loss of the jetty section and foundation, leading to additional failure of each jetty. This is a self-perpetuating and coupled process of morphology loss and jetty deterioration. What this means is that the environmental loading along the MCR jetties has been increasing over time because of the evolving inlet and loss of supporting morphology. As the inlet's morphology has receded, larger waves are able to reach the inlet and attack the jetties. Depth-limited wave height along the jetties is increasing over time. The depth-limited wave height affecting the jetties has increased by greater than 30% since initial construction along many reaches of the MCR jetties. At the same time, the foundation along various reaches of each jetty has been compromised due to erosion of the shoals on which the jetty is founded. Vertical scour along the toe of the MCR jetties has exceeded 10 meters in some reaches [Moritz et al., 2007]. The extent over which the jetties continue to experience increased forcing continues to change and constitutes a non-stationary loading condition. The inlet's post-jetty morphology will continue to evolve, affecting large-scale changes for waves and circulation.

7. Alternative Measures to Address Transient Morphology

As part of the district's O&M dredging program, Regional Sediment Management (RSM) is being implemented at the MCR to abate the consequential inlet's large-scale recession, by maximizing the volume of dredged material that can be placed within the coastal near shore zone of the inlet [Moritz 2008]. The preference for near shore placement of dredged material at MCR is based on the objective to reduce the rate of morphology loss at the inlet. Abatement of localized sediment transport processes that actively degrade jetty stability was a primary objective for this study. These localized processes are addressed by alternative cross-sections for jetty rehabilitation and engineering feature alternatives (Main Report-Section 3.5, Appendix A1, and Section 5 of this Appendix). Figure A2- 3 through Figure A2- 5 illustrate how the present bathymetry and morphology adjacent to the three MCR jetties produces an elevated state of project risk. Each jetty is preventing a very large volume of sediment from entering the inlet and, ultimately, the MCR navigation channel. If prudent measures are undertaken, the heads of the jetties can be stabilized by building exclusively on the relic stone and by not over-extending jetty head reconstruction into excessive scour-prone areas.

8. Historical Breach Events for MCR Jetties

North Jetty. During 1999-2004, reaches of the North Jetty had experienced rapid deterioration. By 2002, several areas of the North Jetty were on the verge of breaching motivating interim repairs to be performed just-in-time in 2005. The jetty cross-section between stations 57-70 was degraded such that sediment was being transported through the jetty during high-tide storm wave conditions. Before completion of the North Jetty interim repairs in 2005, 100,000-200,000 cy of sand (from Benson Beach) had passed through the damaged cross section of the North Jetty. The sand deposited along the channel side of the North Jetty and was not transported toward the navigation channel due to lack of hydraulic forcing. The interim repairs were intended to last 5-10 years (from 2005) until the North Jetty could be rehabilitated. Refer to Chapter 1 of the Main Rehabilitation Evaluation Report for additional information.

South Jetty. During the 1920s, the South Jetty experienced severe degradation, resulting in a 1928 breach through the jetty cross-section near the shore connection (root) of the jetty. The consequences of the breached South Jetty were significant, a large volume of sediment passed through the breach (from south to north) and deposited within the inlet, changing the inlet's morphology. Much of the sediment along the ocean shore south of the inlet was transported by flow through the breached jetty (narrowing the margin between the ocean and Trestle Bay). Storm surge overtopped the ocean shore south of the South Jetty and passed into Trestle Bay, threatening the stability of the entire inlet. Tidal circulation through the South Jetty breach promoted the northward migration of Clatsop Spit, which changed the morphological character of the inlet, and adversely impacted navigation through the MCR.

The 1928 South Jetty breach event motivated a 9-year jetty rehabilitation program for the North and South Jetties, and included the construction of Jetty A to stabilize the MCR inlet. Refer to Chapter 1 of the Main Rehabilitation Evaluation Report for additional information. During 1999-2004, reaches of the South Jetty had experienced rapid deterioration motivating interim repairs to be performed just-in-time during 2006-2007. Due to localized areas of vulnerability along South Jetty, an advance contracting initiative (ACI) was executed in January 2006 to provide emergency repair contingency measures should the inner area of the South Jetty breach before the interim repairs could be implemented in summer 2006 (during the construction season). The outer reach of South Jetty experienced a partial breach in February 2006 and was repaired in 2007; the event was not severe enough as to motivate sand transport through the jetty. The South Jetty interim repairs were intended to last 5-10 years (from 2007) until the South Jetty could be rehabilitated.

Jetty A. Jetty A was constructed in 1939 to halt northward migration of the inlet and re-direct currents away from the North Jetty. In 1950, a 300-ft long breach developed at the mid-span of Jetty A allowing ~200,000 cy to be transported (eastward) over the jetty and toward Ilwaco channel. During 1951-61, approximately 500, 000 cy passed thru the Jetty A breach. Jetty A was rehabilitated in 1961-1962 to restore function and prevent further sediment encroachment (closure) of the Ilwaco navigation channel. Refer to Chapter 1 of the Main Rehabilitation Evaluation Report for additional information.

9. Summary of Current Jetty Vulnerability – Breaching

The current channel-side toe of the North Jetty is severely compromised due to foundation scour (note the low bathymetry elevations in Figure A2- 3), while the ocean side of the North Jetty is flanked by higher elevation bathymetry. The elevation difference of the bathymetry/topography from the ocean side to the channel of the North Jetty exceeds 10 meters along much of the jetty. Both sides of the North Jetty area exposed to large waves. The North Jetty acts as a wing dam to prevent Peacock Spit and Benson Beach from entering the inlet. More than 20 million cy of sediment is being retained by the North Jetty. Note the proximity of the MCR navigation channel to the North Jetty. The North Jetty is preventing a 10-meter high wall of sediment from entering the inlet. If the North Jetty were to be breached and hydraulic connection was established between the ocean and estuary (through the North Jetty), a substantial volume of shoal material (~2 to 8 million cy) could be released and transported into the inlet. Depending on the location and severity of a North Jetty breach, approximately 0.1 to 2 million cy of released sediment could be deposited within the navigation channel by flood tidal currents within 2-4 months of a jetty breach occurrence.

A similar breach vulnerability condition exists for the South Jetty. There is more than 30 million cy of sediment being retained by the South Jetty. The channel side of the South Jetty is in the lee of waves approaching the jetty directly from the Pacific Ocean. The channel side of the South Jetty is flanked by the high elevation bathymetry of Clatsop Spit; while the ocean side of the jetty is exposed to larger water depths and the direct attack of the Pacific Ocean wave environment. Note the proximity of the navigation channel to Clatsop Spit. If the South Jetty breaches, Clatsop Spit could be destabilized by tidal currents passing through the jetty, resulting in increased shoaling within the MCR channel. The rate and degree of channel shoaling associated with a South Jetty breach would be less than for the North Jetty. The ocean side root area of the South Jetty (sta. 165-195) is severely weakened and could be comprised (see the "*" shown in Figure A2- 4). The same is true for the present foredune along the South Jetty root location (sta. 155), that if breached could result in destabilization of the MCR inlet.

The vulnerability of Jetty A is motivated by its exposure to severe foundation scour along the outer end of the jetty (Figure A2- 5). The ocean side of Jetty A is pounded by ocean waves entering the MCR inlet, whereas the lee side sees practically no wave action. Due to the low elevation of the cross-section template used for Jetty A, the lee of the jetty can be destabilized by waves overtopping the jetty from the ocean side. Note the proximity of the navigation channel to the end of Jetty A and how the jetty anchors the entire north side morphology of the MCR inlet (from the eastern end of Sand Island to the North Jetty) Should Jetty A breach, Ilwaco channel would be compromised and the MCR channel would be impacted by increased shoaling. The stability of the North Jetty is linked to Jetty A. As the southern end of Jetty A recedes northward, Clatsop Spit migrates northward toward the MCR channel. Refer to Appendix A1 for a detailed discussion of MCR jetty vulnerability and breaching consequences.

10. Present Life-Cycle Issues for the MCR Jetties

A significant proportion of the remaining above-waterline elements of each jetty have deteriorated and the condition is worsening with time. Jetty repairs costing $26 million were recently completed in 2007 to address the most acute damage along limited reaches of the North and South Jetties. The 2007 jetty repair was required to prevent loss of jetty function (breach) and interruption of navigation through the MCR inlet. Many other locations of the all three jetties are in need of repair and degradation of the jetties continues. Continued degradation drives project reliability downward. Based on present damage trends and a lean maintenance strategy, the MCR jetties appear to be approaching a condition of continual repair. Risk-based methods were used to perform life-cycle analyses of the MCR jetties to address the following asset management concerns:

- What does the future hold for MCR jetties, in terms of expected damage trends?
- At which point will the opportunity to repair a failing jetty section before it loses function and navigation is affected be missed; what is the risk of this scenario?
- Is there an improved maintenance strategy for dealing with these aged structures?
- Is there an optimal way to increase the long-term reliability of the jetty system at MCR and minimize project cost outlays?

Evaluation of jetty damage is performed independently of the reliability calculation. In other words, cross-section degradation can affect the reliability estimate of a jetty, but changes in reliability do not affect jetty degradation; as emulated within the SRB model.

2. RELIABILITY AND RISK CONCEPTS

An engineered structure is a system of components which operate together to provide a specific function (or set of functions). Individual components must function satisfactorily in order for the overall structure to perform satisfactorily. Deep-draft navigation at the MCR inlet is secured by three MCR jetties. The three jetties act as a system; if one jetty fails to perform its function, navigation at the inlet can be compromised. Each jetty is composed of a system of structure components, each described by a performance mode. If a jetty component fails, the function of the entire jetty can be compromised, jeopardizing the function of the inlet. The MCR inlet can be considered to be a system of systems.

In engineering, *reliability* is defined as the probability of a structure (or component) to perform satisfactorily (Ps). By accounting for the randomness of system attributes, reliability-based design methods minimize the uncertainty associated with estimating engineering/design parameters and related economic projections [USACE-IWR 1992]. Judicious application of reliability-based methods can optimize project decision making by reducing the likelihood of over- or under-estimating project feature attributes required for cost-effective and reliable implementation. The consequences of implementing an over-estimated design feature can produce excessive initial cost expenditures resulting in lost opportunity for capital investment at other priority projects, and a perception of resource misallocation. Implementing an under-estimated design feature can lead to a wide range of unintended consequences, such as increased structure damage trend with unexpected higher and more frequent maintenance costs, sudden loss of project function, collateral damage to other infrastructure, and expedited corrective intervention.

Reliability-based design is intended to evaluate, reduce, or at least manage project risk. Project risk is defined as the probability of an essential project feature not performing its intended function (project failure probability) multiplied by the consequence of function loss (failure consequence). An example of project risk would be the realization of jetty function loss at a regionally important coastal inlet, resulting in the impairment of the inlet's navigation function. If the probability for jetty function loss in a given year is Pu and the consequence for the event of jetty functional loss is $-event, then project risk = Pu × $-event. An essential output provided by life-cycle analysis is time-varying project cost. Cost-related consequences that happen in the future, when discounted, are not as significant as things that happen today. In this case, reliability and other non-monetary metrics can be evaluated in conjunction with monetized data to give added insight for minimizing risk factors not explicitly defined within monetary metrics.

a. Project Event Tree – General Considerations

Complex decisions are the result of progressing through a series of sequential elementary choices and evaluating the consequences of each choice to reach a final "best" decision [USACE-IWR 1992]. An example is cast in terms of a future life-cycle scenario for the MCR North Jetty. As the North Jetty is intermittently damaged by progressive foundation scour and wave damage, areas of the jetty become weakened to the point where the structure has an elevated risk of failing. Several choices are available; continue to defer repairs, perform minimal localized repairs, perform jetty rehabilitation, and/or implement features to address processes affecting chronic damage. Each choice can produce different consequences. What is the consequence of not repairing the jetty? If repairs are to be made, how robust should the repairs be, and at what point in time should the jetty be repaired; should the jetty be rehabilitated? An event tree can be used to visually portray sequential decision problems and identify critical sequences in the life-cycle of a given structural feature or system. For the MCR jetties rehabilitation study, a project event tree was developed and used to link reliability and stochastic processes-responses to risk-based consequence.

An event tree is a schematic diagram that defines all permutations involving relevant structure performance modes and relates reliability-based outcomes to quantifiable consequences. The compilation of all consequence permutations results in an event tree. An event tree consists of decision points, probabilities of event occurrence, and conditional outcomes (composed of consequence and engineering cost assessment). The decision points within an event tree are usually defined by the reliability (or probability) for a given event realization, as affected by specific performance modes. An event realization results in a specific outcome, described by consequences and the intervention to manage the project features.

The event tree used for the life-cycle analysis of MCR jetties implemented decision points that were defined by stochastic conditional assessment, rather than a pre-determined reliability. Each decision point within the project event tree was the result of a probabilistic outcome which varied slightly from year to year and life-cycle to life-cycle. Reliability was calculated as a supplemental life-cycle metric to inform life-cycle performance for a given jetty scenario, but it was not used to define life-cycle evolution (event tree decision points).

b. Specific Considerations for the MCR Jetty Event Tree

The project event tree for the MCR jetties is shown in Figure A2- 9 through Figure A2- 11. The event tree diagram summarizes the annual functionality for a jetty in term of structural performance modes (static and dynamic), sustained damages, consequences, and costs. The event tree starts with the initial condition at year i; the forcing environment for year "i" is realized through stochastic simulation, jetty performance modes are assessed for each jetty segment "j" based on the realized forcing environment, and jetty damage for year "i" are stochastically evaluated. Cumulative damages for each segment "j" are evaluated at year "i" based on the previous years' performance. Finally, the consequences and costs for year "i" jetty damage are calculated. Consequences for year "i" can include repair activities for jetty segments, functional loss of a jetty segment, and incremental channel dredging due to segment function loss. Implementation of jetty repairs as year "i" is based on a threshold evaluation. Jetty repairs are enacted if the jetty cross-section at a given segment falls below a specified maintenance threshold, which is a random variable. If a jetty segment sustains a loss of function within a given year "i" (jetty head recession or a jetty breach), then additional adverse consequences may be realized in terms of added channel dredging costs; which is also a random variable. The event tree diagram is repeated for n-years for all jetty segments, until the entire life-cycle period is realized. As described above and shown in Figure A2- 9, the project event tree provided the basis for evaluating various life-cycle stages for each of the three (3) MCR jetties. Life-cycle stages evaluated within this report included:

A. Hindcast life-cycle (original jetty construction to present condition-2007). Dredging costs are not included in hindcast evaluations.
B. Future life-cycle (2007 to 2070) for the present jetty condition and present *baseline* maintenance strategy.
C. Future life-cycle realizations based on various optional *maintenance* strategies, which may or not include adding engineering features to a given jetty.

D. Future life-cycle realizations based on various *rehabilitation* strategies, which include additional engineering features.

The following sections describe concepts of reliability and risk and how these parameters were evaluated within the SRB model to provide life-cycle metrics for the MCR jetties.

c. Elements of Reliability

There are two general elements of reliability: structural and functional. *Structural reliability* is the likelihood that a structure will not be damaged, within a given time interval. If the structure is susceptible to damage, structural reliability indicates the relative degree of damage that could occur. In many cases, a structure or project feature can incur damage (or degradation) without affecting the overall function of the structure. The capacity for sustaining damage without failing is called *resilience*. When a structure sustains cumulative damage (deferred maintenance) to the point of exceeding its resilience, the structure can lose the ability to perform its intended function. At this point the structure fails. *Functional reliability* is the likelihood that a structure will satisfactorily perform its intended function, within a given time interval. Functional reliability is derived by combining structural reliability metrics with metrics that describe the present structure cross-section configuration. Unchecked degradation of a structure (reduction in structural reliability) leads to reduced functional reliability.

d. Life-Cycle Risk

Project life-cycle costs are affected by two risk elements. *Structural risk* is associated with consequences of a structure being damaged and is driven by structural reliability. Consequences of incurring structural risk are realized when the cumulative damage exceeds a given threshold maintenance level, motivating repairs to maintain the structure at a minimal level of resilience. The consequence of structural risk can occur frequently and usually carries a low to moderate cost per realized event, provided that the structure expresses an acceptable level of resiliency. Structure resiliency and threshold maintenance level is an important consideration governing life-cycle management of infrastructure.

Function risk is related to a structure's functional reliability, and is associated with the consequences of a structure failing to provide its intended function. Function risk and project risk are synonymous. Realization of functional failure can occur when the jetty cross-section area is reduced below a critical threshold, to a value below the maintenance threshold. In the case of the MCR jetties, a jetty breach can occur when the upper cross-section is damaged (reduced) by more than 80%. At this point, a breach occurrence is simulated as a random event having a 50% likelihood of realization in a given year. A breached jetty corresponds to function reliability = 0. Consequences of being on the wrong side of project risk (experiencing functional failure) are realized as infrequent events having a range of outcomes which can add moderate to high costs to the life-cycle. The consequences associated with function risk are usually the element of focus when investigating a structure's future life-cycle due to the high costs associated with loss of project function. Note that the cumulative aspect of incurring structure risk (damage) can add significant cost over time to a structure's life-cycle and should be considered with the same emphasis as function risk (breach).

The difference between structural and functional reliability is indicated by the ability of a structure to incur damage (expressing structure unsatisfactory performance) before losing function (functional failure). A structure that has no capacity to incur damage before losing function will express a functional reliability that is the equivalent to structural reliability. Resiliency is the marginal difference between structural and functional reliability.

e. Incremental Development of Alternatives Based on Risk and Reliability

The focus of this rehabilitation study was to identify and evaluate alternatives and recommend a course of action that balances future reliability and life-cycle cost for the system of jetties at MCR. A range of alternatives were developed through a step-wise procedure. First, the structural and functional risks affecting the present life-cycle of each jetty were identified and evaluated. Second, a range of incremental alternatives were developed to mitigate present and future risks affecting the life-cycle of each jetty. Alternatives included various without-project maintenance strategies, with-project initiatives, and several types of engineering features. Third, an implementation schedule was developed for each alternative to match construction timing with project risk over the life-cycle period.

The entire ensemble of with-project and without-project alternatives was evaluated using the SRB model to investigate the incremental improvement in project performance, as indicated by non-monetary metrics describing structural risk. In this sense, structure risk is a function of repair timing (when do repairs occur), frequency (how often), and location. The recommended plan for each jetty was selected by optimizing the initial cost of structure rehabilitation, optimizing future maintenance costs, considering the time-varying reliability of the jetty, and considering the potential for incurring pronounced channel shoaling arising from loss of jetty function. Refer to Chapter 4 of the Main Rehabilitation Evaluation Report for discussion of alternative selection.

Without-project alternatives included implementing different levels of future maintenance strategies. Evaluation of alternative maintenance strategies focused on varying the threshold level for initiating jetty repairs. Without-project alternatives avoid the initial cost of structure rehabilitation, but can incur elevated future maintenance commitment and cost by having to mitigate continual low reliability. In cases where repairs were deferred during the previous life-cycle, a proactive future maintenance strategy may require online repairs very early into the future life-cycle, emulating the magnitude of initial costs associated with structure rehabilitation.

With-project alternatives (rehabilitation) focused on reconstructing or enhancing the jetty cross-section based on a range of cross-section templates. Jetty rehab alternatives induce a high initial cost, but restore project reliability early into the future life-cycle and can reduce the future maintenance commitment. Discrete structural enhancements or engineering features were developed as a way to mitigate the chronic effects of jetty toe scour affecting jetty root degradation (jetty spur groins) and jetty head recession affecting morphology loss (jetty head cap). Engineering features are considered to be incremental with-project alternatives.

Minimum rehabilitation is appropriate in cases where the forcing-loading environment is stationary and not severe, and the structure can be adequately maintained in the future. In cases where the present loading environment is moderate to severe (or is non-stationary, increasing over time), more robust rehabilitation alternatives are required to increase project resilience and address increased structure loading. This approach may also be needed to address certain areas of a structure that cannot be easily maintained (difficult construction access). Applying engineering features along a given jetty can mitigate foundation scour and other jetty-specific degradation issues. Additional discussion concerning alternative plan development can be found in Chapters 3 and 5 of the Main Rehabilitation Evaluation Report, Appendix A1, Appendix C, and later in this appendix.

f. Estimating Structure Reliability

Composite structure reliability is based on the integration of all relevant performance modes affecting a structure. A performance mode is defined as a particular action-reaction response for a given structure component and is quantitatively described in terms of a design relationship expressed as a factor of safety. Each pertinent design parameter within the design relationship is expressed in terms of a random variable, rather than a point value, as is the case in deterministic design methods. In a simplified approach, a random variable can be bounded by a mean value, standard deviation, and prescribed statistical distribution. In a more rigorous approach, a prescribed probability density function is used to describe a given random variable. Reliability-based design is well suited to the coastal-ocean engineering discipline, where a high degree of randomness precludes accurate estimation of point-value parameters, based on incomplete data which can be biased by subjective assumptions.

A performance mode refers to a specific process affecting structure reliability, such as the loss of a jetty cross-section by wave overtopping. The “performance function” is a mathematical expression involving the random variables that govern a given performance mode. The performance function can be represented in terms of a factor of safety (FS), which is expressed in terms of capacity of the structure to resist loading (C) divided by the demand imposed on the structure due to loading (D); FS = C/D. Alternatively, the performance function can be represented in terms of the safety margin (SM); SM = C-D.

1. Reliability from Safety Factor

Figure A2- 13 illustrates how the FS is portrayed on context of random variable for C and D. The mathematical representation of the FS is called a “performance function” and was used to estimate reliability indices. The reliability index (β) for a given performance mode is defined as the number of standard deviations the mean FS is above the limit state (FS=1.0 or SM = 0). Figure A2- 14 illustrates how β, capacity (C), and demand (D) are related. Note that reliability index (β) can increase with an increase in mean FS (μ). Reliability index increases with decreasing variability of FS (standard deviation, σ), and β decreases with increasing FSσ. When $\mu_{SF} = 1.0$, $\beta=0$, and P(s) or reliability = 0.5, this condition is defined as the "limit state" [Harr 1987, USACE 1992].

All that is needed to solve for β and determine and P(s) is the mean and standard deviation for each pertinent variable within the performance function. Since capacity and demand are considered to be log-normally distributed, β can be defined from the mean (μ) and the standard deviation (σ) of the logarithm of FS (or C/D) through the following [USACE 1992]:

$$\beta_{FS} = \frac{\mu_{\ln(FS)}}{\sigma_{\ln(FS)}} \qquad \text{where,} \qquad \sigma_{\ln(FS)} = \sqrt{\{\ln[1 + (\mu_{FS}/\sigma_{FS})^2]\}}$$

$$\mu_{\ln(FS)} = \frac{\ln[\mu_{FS}] - \sigma^2_{\ln(FS)}}{2}$$

$$\sigma^2_{FS} = \sum_{i=1}^{n} [\{\partial FS/\partial Xi\} * \sigma_i]^2$$

Xi = variable of interest and n is the total number of variables in FS
ln = natural logarithm

An approximate solution for σ_{FS} was determined using an approach similar to the first order second moment method (FOSM), according to EC 1110-2-6062 [USACE 2008]. Rather than evaluating the performance functions to first order as in FOSM, the analysis featured in this appendix expanded the performance functions to third order to account for the non-linear nature of the random variables. The result (σ_{FS}) was applied within the SRB model to solve for β. This process was done for each performance mode of interest, at each jetty segment, and for each year within a given life-cycle simulation.

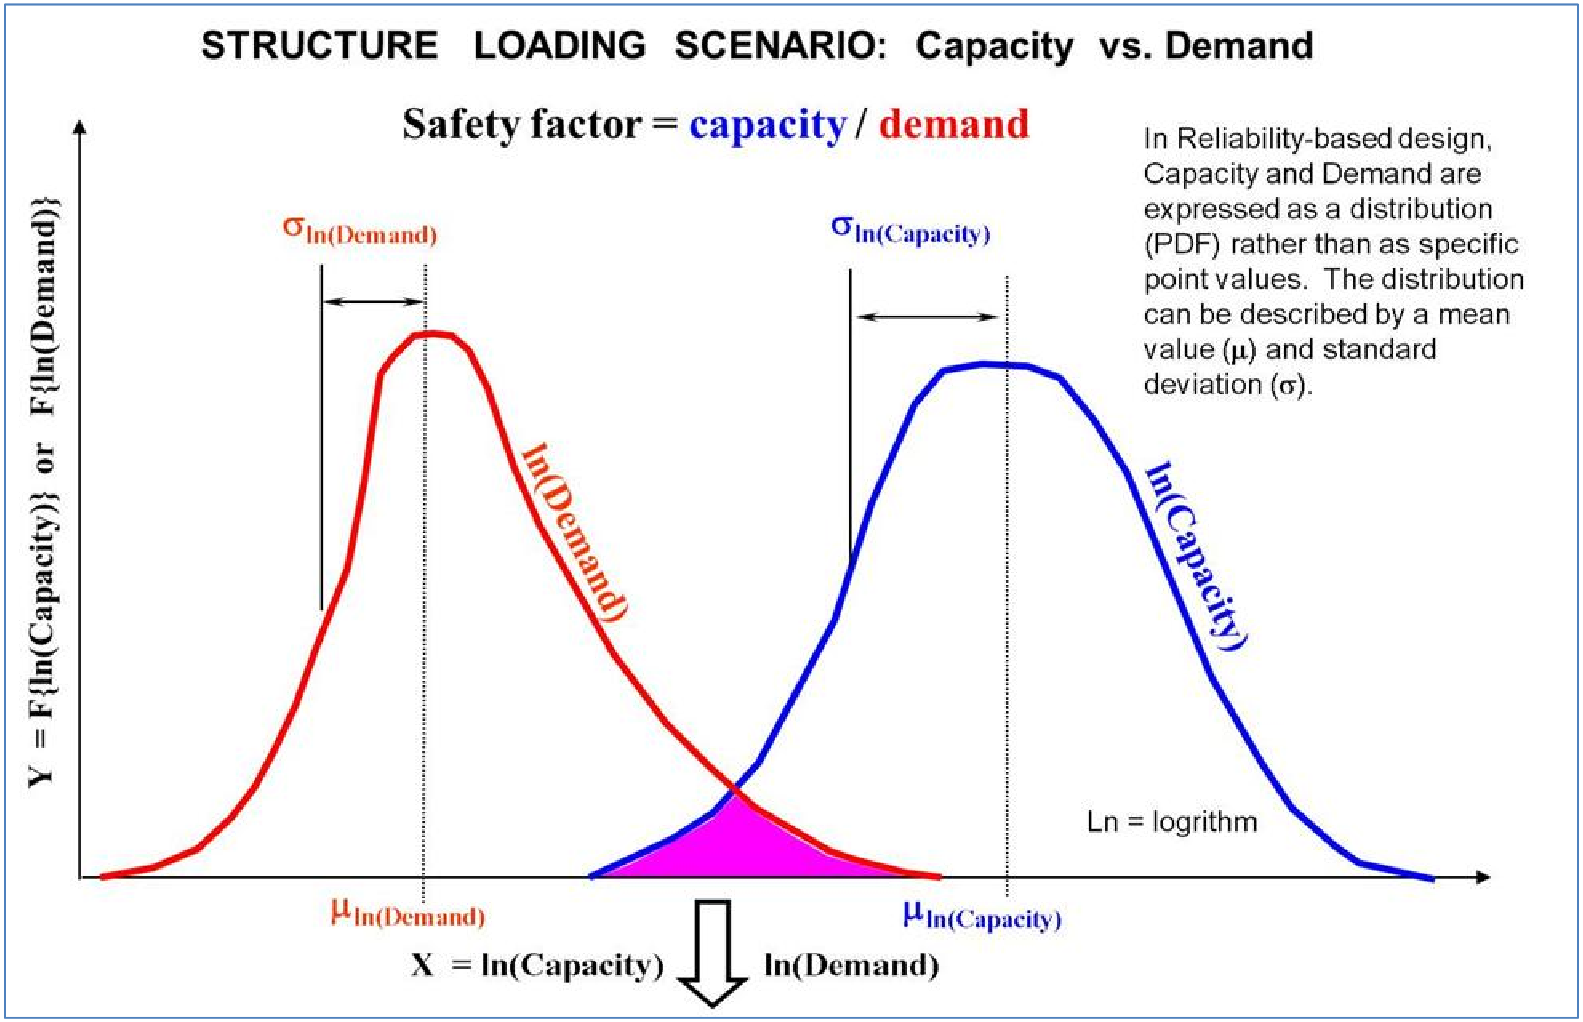

Figure A2- 13. Definition of Capacity and Demand in Reliability-Based Design

For a given structure performance mode, capacity is the ability for a structural element to resist imposed loads for a given mode of performance. Demand is the load imposed on a structural element. The region where there distribution for capacity and demand overlap identifies the potential for when demand may exceed capacity for a given performance mode.

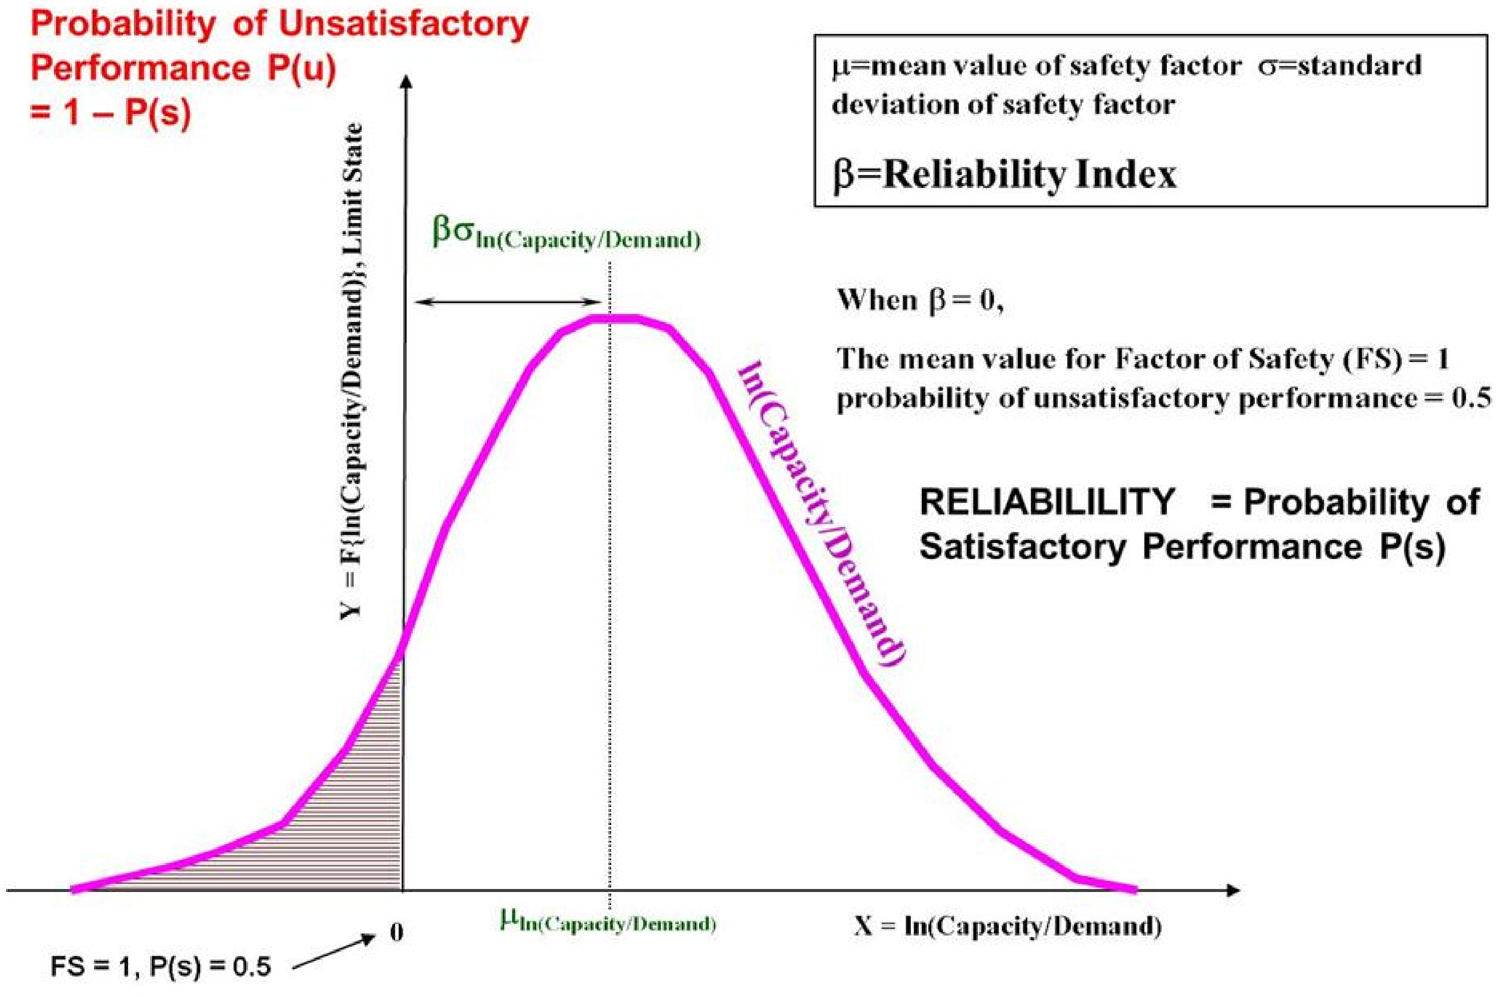

Figure A2- 14. Definition of Reliability Index for a given Structure Performance Mode

As described by the ratio of capacity to demand. In most cases, the reliability index is considered a standard normal variable, which allows direct estimation of reliability, P(s).

2. Reliability from Safety Margin

Alternatively, β can be estimated from a performance function based on the safety margin (SM = C-D) according to the relationship given below. When $\mu_{SM} = 0$, $\beta = 0$, and P(s) or reliability = 0.5, this condition is defined as the "limit state" [Harr 1987, USACE 2008]. Use of a SM-based performance function may be advantageous to stabilize the non-linear effects associated with the ratio of capacity (C) and demand (D), when D becomes less than unity. Evaluating C/D can be challenging if D is a non-linear function of random variables.

$$\beta_{SM} = \frac{\mu[C] - \mu[D]}{\sqrt{\sigma^2[C] - \sigma^2[D]}} \qquad \text{where,} \qquad \sigma[C] = \sqrt{\sum_{i=1}^{n} \sigma^2[c_i]}$$

$$\sigma[D] = \sqrt{\sum_{i=1}^{n} \sigma^2[d_i]}$$

c_i = capacity variable of interest (i) and *n* is the total number of variables in capacity
d_i = demand variable of interest (i) and *n* is the total number of variables in demand

β values were estimated using both the SM and FS methods. Comparison of SM and FS derived β-values indicated that the two methods produce similar results. There are subtle differences between the two β estimates when β approaches small negative values. To address potential uncertainty in estimating β, the SRB model combined the results from both the SM and FS methods to produce a blended estimate (root-mean square) for β. Since β is considered a standard normal random variable, it can be used to directly determine reliability in terms of P(s) for a given performance mode [Harr 1987, USACE 2008]. Time-varying βs and corresponding values for P(s) were determined for the individual performance modes for the historic and future life-cycle of each jetty. The probability of unsatisfactory performance, P(u), is the compliment of satisfactory performance and is determined by:

P(u) = Probability of unsatisfactory performance
= 1-P(s) *where* P(s) = Probability of satisfactory performance

Table A2- 3 summarizes target reliability indices and corresponding P(u) for structure performance, in reference to major rehabilitation guidance presented in ETL 1110-2-532. Note that the values shown in Table A2- 3 indicate the likelihood of a structure to exceed a given performance limit state, or the probability to experience unsatisfactory structural performance P(u). Unsatisfactory structural performance occurs when a structure incurs damage. The values shown in Table A2- 3 are intended to be used only for the MCR project; these values are not to be used for citation. Note that the values shown in Table A2- 3 do *not* indicate the likelihood for a structure to fail (lose its function), which occurs for a condition of unsatisfactory functional performance. However, continual unsatisfactory structural performance indicates that the structure is accumulating damage. At a critical threshold of structure degradation (breach threshold), there is not enough cross-section area remaining to maintain structure function. At this point, the structure can fail to perform its intended function (realization of unsatisfactory functional performance). In this sense, functional performance is related to structure reliability (performance) and the amount of cross-section area remaining on the structure.

Table A2- 3. Target Reliability Indices for Structure Performance

Values for conventional practice apply to rigid non-compliant steel structures such as bridges, lock gates, or vertical walls. Values and corresponding consequences given for rubble-mound structures are applicable for MCR jetties ONLY and are assumed to have two or more layers of armor units protecting core material.

Expected Performance Level Conventional Practice (steel structures) ETL 1110-2-532	Rubble-mound Structures @ MCR^	**Beta (β)**	**Probability of Unsatisfactory *Structure* Performance** P(u)	**Potential Structure Consequences to MCR Jetties**
High	***Excellent***	5	0.0000003	No likelihood of any structure degradation
Good	***Excellent***	4	0.00003	
Above Average	***Very High***	2	0.023	Little Likelihood of any structure degradation
Below Average	***High***	1.2	0.10	-Low likelihood for any structure degradation in response to extreme waves
Poor	***Good***	0.8	0.2	-Low likelihood for Minor structure degradation in response to extreme waves
Unsatisfactory	***Average***	0.5	0.3	-Moderate likelihood for Minor structure degradation in response to extreme waves
Hazardous	***Below Average***	0	0.5	High likelihood for Minor structure degradation in response to extreme waves
---n/a---	***Poor***	-0.2	0.6	-Low likelihood for elevated structure degradation
---n/a---	***Unsatisfactory***	-0.5	0.7	-Moderate likelihood for elevated structure degradation
---n/a---	***Hazardous***	<-0.8	>0.8	High likelihood for elevated structure degradation.

^ = This table and the values presented within are applicable ONLY to the rubble-mound MCR jetties. This table shall not be used for citation or reference.

After obtaining values of P(s) for the individual structure performance modes of a given jetty configuration, the composite structural and functional reliability for each jetty (and for each alternative configuration) can be estimated. Composite structural reliability was computed assuming the individual performance modes act in a series system. Composite reliabilities are important metrics that were used in conjunction with projected life-cycle costs to compare alternatives for future maintenance strategies and rehabilitation plans. Figure A2-15 shows how the composite structural reliability can change over time for a specific jetty location.

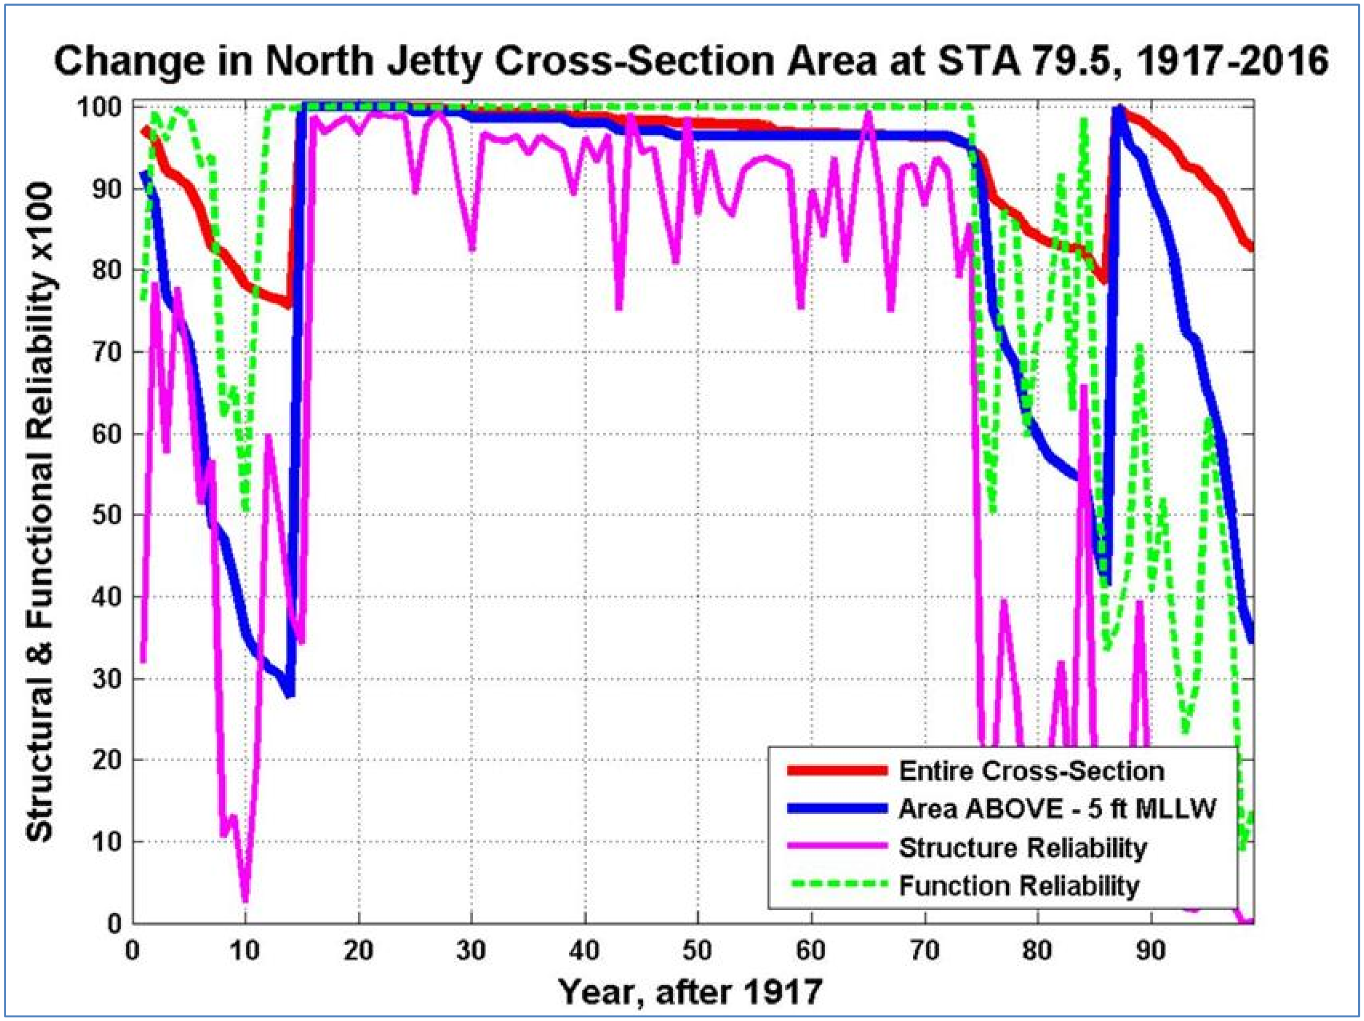

Figure A2- 15. Simulated Change in Jetty Cross-Section Area and Reliability

g. Reliability of Rubble-Mound Structures

Conventional civil engineering structures are composed of “rigid” elements; i.e., damage sustained by one component can jeopardize the functional performance of the entire structure. A rigid component possesses little margin (resilience) for sustaining damage before the element fails; if the component is damaged it can fail. In conventional civil engineering practice, load and resistance (demand and capacity) scenarios for structures such as bridges, dams, levees, and vertical walls are rarely designed with FS less than 1.2. Conventional (non-compliant) structures typically achieve a reliability index β range of 3<β<5 [USACE 1992]. This range of structural reliability is expected for design applications where structure capacity and demands are well known and have low coefficients of variation (σ/μ). Such may not be the case for many types of compliant maritime structures, where both the loading scenarios (demands) and structure response scenarios (capacity) can exhibit high coefficients of variation (0.3).

The MCR jetties are rubble-mound structures. A rubble-mound structure is composed of several layers of variable sized/shaped stone randomly placed to create the structure’s core. The core of a jetty is protected using a cover layer of selectively placed armor units of either quarry stone or specifically shaped concrete units (armor layer). Maintaining the stability of the armor layer is integral for achieving satisfactory performance of a rubble-mound structure. Yet, because the armor layer for the MCR jetties is composed of many semi-independent interlocking units, the jetties can withstand a finite amount of damage without being functionally compromised (fail). The concept of finite damage makes the jetties compliant or “resilient.” In many cases, the armor layer for rubble-mound coastal structures may be designed using performance functions (FS) which approach 1.0.

Coastal structures composed of concrete armor units (CAUs) are not compliant and possess little margin for resiliency. The same can be stated for a rubble-mound structure incorporating only one layer of armor stone. Concrete armor units rely on interlocking to achieve stability; a displaced CAU loses much of its stability and can reduce the stability of neighboring units from which the displaced armor unit originated. Most types of CAUs are fragile in that a displaced unit usually breaks, rendering it useless. Although stone armor units are more resilient on a unit basis (displaced stone armor units do not readily break and they retain some of their stability after being displaced), a 1-unit thick armor layer provides no added resiliency after the armor units have been displaced, exposing core material to wave action. In the above cases, the armor units would be designed with safety factors and reliability indices similar to conventional civil engineering practice.

Table A2- 3 compares structural reliability (β values) applicable for conventional steel frame structures to values developed for mound structures at MCR. The structure consequences for MCR jetties and corresponding reliability (β) values were developed by comparing the calculated β (Ps) to a specific loading and structural condition for a given MCR jetty segment, at a given point in time. A lower reliability index (β) indicates that the jetty has a higher likelihood to incur damage. The process of calibrating β values and structure consequences for MCR rubble-mound jetties was based on the approach used for the major rehabilitation study at Burns Harbor Breakwater [USACE 1993]. Calibrating the SRB model (and estimated reliability) was based on successful jetty life-cycle hindcast. The results shown in Table A2- 3 are site specific and applicable *only* for the MCR Jetties. The aspect of jetty resiliency is why a target β range of 0 to 0.5 (for structural performance) is acceptable for MCR jetties, at least until accumulated damage reaches a critical threshold. The limit of cross-section resiliency is reached for jetties when the core stone of a jetty becomes exposed to wave attack (or a critical percentage of the cross section has been removed). At this resilience limit, the remaining jetty can be subject to rapid cross-section loss, and the structure's cross-section may become breached. The MCR jetties are considered to lose function (fail) when the upper cross-section is breached.

Because rubble-mound structures (jetties) can afford a large degree of resiliency before being functionally compromised, less conservative maintenance strategies can be implemented to manage the structure's life-cycle, providing project risk is correctly managed. A less conservative maintenance strategy is essentially a deferred repair condition. The structure is permitted to experience significant degradation before repairs are undertaken. Deferred maintenance can suppress life-cycle expenditures, up to the point at which the structure is on the verge of losing function (failing). When this condition is reached, the damaged structure will require extensive repairs to renew the life-cycle to a point where repairs can once again be deferred.

3. PERFORMANCE FUNCTIONS AND FAILURE MODES

a. Structural Reliability

The estimation of structural reliability within the SRB model is an extension of the method employed for the analysis of a rubble-mound breakwater [USACE 1993; Moritz et al 1994]. The structural reliability of the three jetties at MCR was assessed based on the ability of each jetty's cross-section to resist the environmental loading which occurs along the jetties. Structure reliability is based on the performance of the upper region of the jetty cross-section to remain stable. Structure reliability (jetty stability) examined within the scope of this rehabilitation report is based on the two general performance modes: static stability and dynamic stability.

Static stability affects the lower part of the jetty cross-section, generally below –5 ft MLLW, on the ocean side and channel side of the jetty (Figure A2- 16). Within this analysis, static stability addresses the susceptibility of the jetty toe to be affected by wave-current scour, and resistance of the jetty slope to sliding down grade along a slip-plane. The jetty toe is the interface where the jetty intersects the morphology on which it is founded. Jetty damage motivated by static stability propagates up-slope to affect the upper region of the jetty cross-section, above -5 ft MLLW. Static stability of the lower cross-section region (below -5 ft MLLW) is evaluated stochastically within the SRB model based on jetty slope re-adjustment (creeping failure) in response to toe scour. Static stability performance is indirectly evaluated through the analysis of the upper jetty cross section, which can be affected by both static and dynamic stability performance modes.

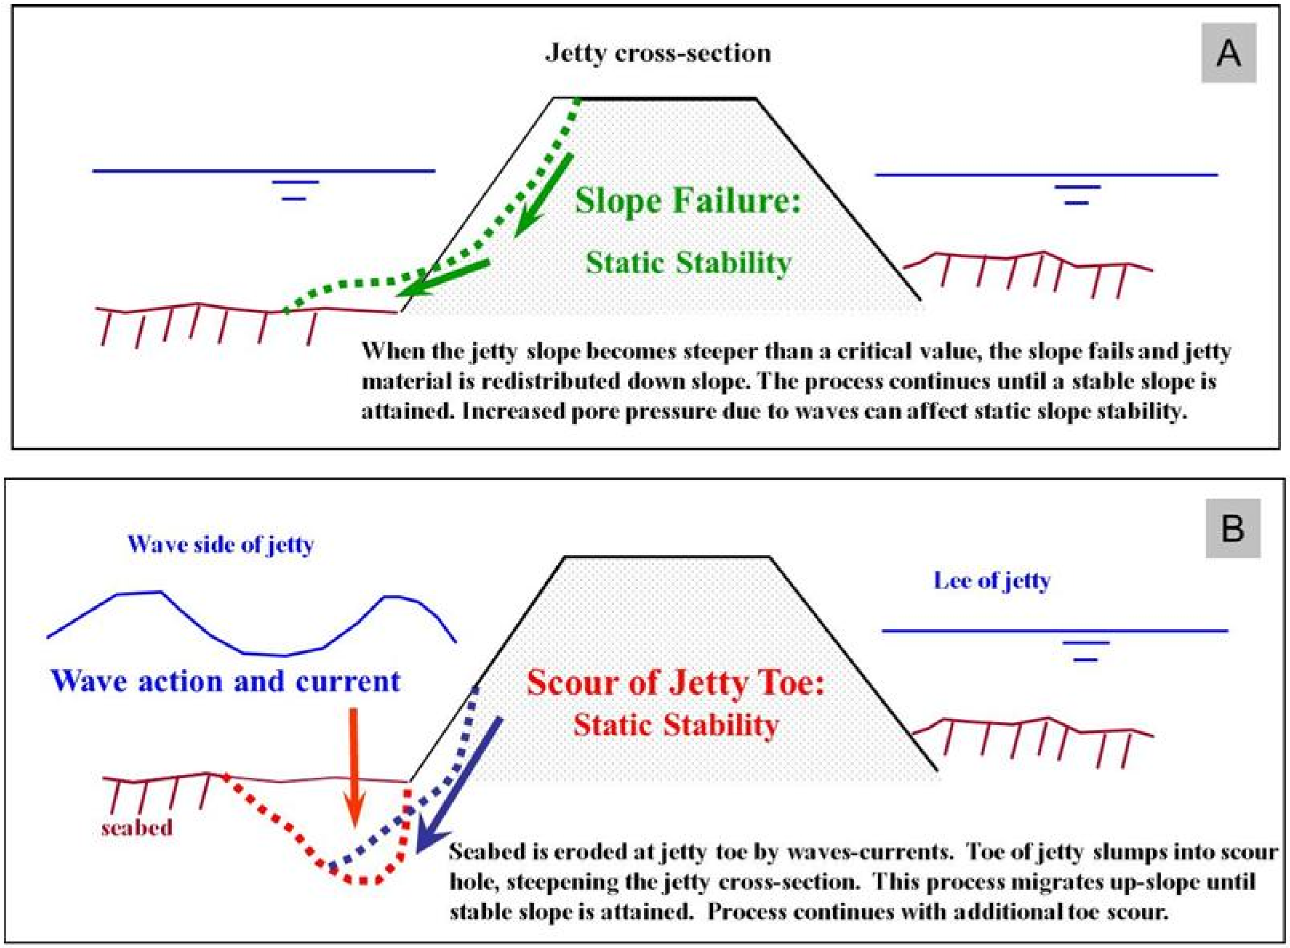

Figure A2- 16. Jetty Performance Modes for Static Stability

Dynamic stability affects the upper part of a jetty cross-section as a result of wave action, generally from –5 ft MLLW up to the jetty crest on the ocean side and channel side of a jetty (Figure A2- 17). On the side of the jetty directly exposed to wave action, dynamic stability is manifest by the direct impact of waves on the jetty and the potential displacement of individual armor units. On the lee side of the jetty, dynamic stability addresses the effect of waves overtopping the jetty crest and displacing armor or down-slope off of the jetty cross-section. There are many locations along the MCR jetties which experience direct wave attack along both sides of each jetty, in which case each side of the jetty experiences direct wave action and overtopping wave action.

The structural reliability and performance of a rubble-mound jetty can be characterized in terms of its ability to: A) resist wave attack (dynamic stability), and B) maintain a stable footprint/slope configuration on the seabed foundation (static stability). If the cross-section of a jetty exhibits chronically poor structural performance and is continually damaged, the upper part of the cross section can be reduced to a level that is less than a minimum functional configuration. The minimum functional configuration for the upper part of a jetty cross-section has been estimated to be 20% of the standard design template. At this point, the jetty cross-section can breach and the jetty will no longer perform its intended function. The function of each jetty is directly attributed to the performance of the upper region of the structure cross-section (above –5 ft MLLW). The consequences of a breached jetty cross-section are dependent upon the location of the jetty breach. Refer to *Functional Reliability* later in this section for additional information concerning functional performance.

1. Static Stability

Within the context of this analysis, static stability was considered to be a long-term performance mode with chronic (creeping) effects that can occur continuously. The long-term accumulation of these effects contributes to the incremental failure (unsatisfactory performance) of the jetty cross-section. There are two modes of performance affecting the static stability of MCR jetties: A) scour of the jetty foundation, and B) slope failure within the jetty cross-section. Static performance modes can interact to contribute to the long-term response and damage of the jetty. This process is described below.

Scour of the Jetty Toe. The MCR jetties were constructed on massive tidal shoals during 1885-1919 and the morphology of the inlet has been changing ever since. The jetties have experienced significant deterioration since construction due, in part, to foundation instability associated with the erosion of tidal shoals on which the jetties were built. This process is manifest as a jetty performance mode - scour of the jetty toe. As the seabed along the jetty toe is eroded by waves-currents, jetty stone along the toe “falls” into the scour trench. The continual loss of stone from the jetty toe can lead to enhanced degradation that migrates upward along the jetty slope, initiating a creeping slope failure within the jetty cross-section (Figure A2- 16b). Scour of marine structure foundations is a function of sediment size, current speed, wave height and period, water depth, and can be enhanced by the interaction of the seabed with structures. Due to the constantly varying interaction of waves and currents with bottom sediment at MCR, explicit specification of a scour performance function for each jetty is problematic. However, based on the rate of change in seabed elevation observed along each jetty during various time periods since jetty construction, average rates and timing for toe scour has been calculated for different locations along each jetty (refer to Table A2- 4 through Table A2- 6 and Appendix A1). The rate of historical scour along the MCR jetties has varied from 0 to 8 ft/yr, depending upon jetty location and exposure to waves and currents. The rate of scour projected for future conditions along the jetties is estimated to vary between 0 and 1 ft/yr. The present and future rate of jetty scour is less than historical values because the inlet has equilibrated to some degree with the jetties. Future jetty scour is projected to migrate inshore along the jetties, as the inlet morphology continues to adjust. It must be noted that although future scour rates are expected to be less than historical rates, toe scour can have a significant long-term effect on jetty stability. The scour rates in Table A2- 4 through Table A2- 6 were used within SRB event tree simulations to estimate jetty damage associated with cumulative scour effects. Refer to Foundation Effects in Section 6 for a discussion of how the toe scour effect is simulated within the SRB model.

Table A2- 4. North Jetty Toe Scour and Morphological Factors for Wave Height

Jetty A morphological factors for modifying wave height along jetty and Scour depth at jetty toe. The toe scour values given for the future life cycle do not include the mitigating effect of constructing additional jetty spurs to reduce toe scour along the jetty foundation.

Slope Stability. The performance mode of slope failure deals with the tendency of a sloping rip-rap surface to seek a more stable horizontal position in response to gravity, environmental loading, and over-steepening of the jetty surface from other failure modes. In a relatively homogeneous stratum, the surface along which slope movement (rotation) is initiated is called a failure surface and is approximated by a circular arc failure surface (Figure A2- 16a). When the rip-rap (stone) mass is on the verge of movement along the failure surface, the forces initiating and resisting the movement are in equilibrium (FS=1.0). The relationship describing this force balance is:

Equilibrium for static slope stability: $W*D = [C' + (P-U)*TAN\phi']*L*R$ where,

W=weight of sliding mass	U=pore water pressure at base of sliding mass
D=moment arm of sliding mass about center of rotation	ϕ'=material stratum friction angle – rock or sediment
C'=material cohesion = 0 for rock	R=radius of moment arm for potential sliding surface
P=normal force @ base of sliding mass	L=arc length of potential sliding surface

The slope stability equation was rearranged to form a performance function which can be used to calculate the reliability of static slope stability along the ocean and channel side slopes of jetties. This performance function is expressed in terms of a factor of safety (FS) and safety margin (SM).

$$FS = \frac{\text{CAPACITY of slope to resist shearing}}{\text{DEMAND imposed by body forces}} = \frac{[C' + (P-U)*TAN\phi']*L*R}{W*D}$$

$$SM = \text{CAPACITY} - \text{DEMAND} = [C' + (P-U)*TAN\phi']*L*R - W*D$$

Several parameters can interact to compromise this performance function. If armor units are poorly interlocked, then “R” and “L” are reduced which can reduce FS. A well interlocked stone mass can increase “R” and “L” by forcing the sliding surface deeper into the structure cross-section, and increasing the failure surface arc length. In a localized sense, “W” (armor stone size as related to armor unit stacking in the slope) can have an adverse effect on jetty slope stability. If “W” is large and the armor units are poorly interlocked with adjacent units, such that an armor elements are protruding from the local jetty slope, then W*D can make FS ≤1. If “U” becomes large, due to transient surcharging by wave or surge action, then the above FS will be reduced.

Because of the irregular geometry, varying strata within a given jetty cross-section, and the complex forcing environment, direct analysis for evaluating the above performance function is not possible. A slope stability model SLOPE-W® (Geo-slope Inc, 2004), was used to investigate the mode static stability performance based on variation analysis of nine parameters (see Appendix B, Geotechnical Studies). Each differing rock material layer contained within the jetty cross-section was described using appropriate constituent values. The evaluation of jetty static slope stability using SLOPE-W, helped to refine the overall analysis of jetty reliability by identifying key factors that affect static slope stability for jetties. Results from the slope stability analysis indicated that the most important factors affecting jetty slope stability are:

Factor 1: Wave action causing adverse pressure transients within the jetty cross-section.
Factor 2: Stone stacking patterns realized during incremental slope damage or jetty repairs.
Factor 3: Toe-scour effect initiating slop instability migrating up the cross-section.

The effect that factors 1 and 2 have on structure reliability is addressed within the SRB model evaluating the reliability if dynamic stability performance functions, as described below. Factor 3 (toe-scour) is addressed stochastically within the SRB model, and its effect on structure reliability is captured by a degradation of several parameters that affect dynamic stability. Refer to Section 5 for a description of how toe-scour can motivate cross-section damage within the SRB model.

Summary – Static Stability. Jetty toe-scour was determined to be the static stability factor which most actively affects MCR jetties. Toe scour is simulated within the SRB model to emanate within the lower region of the jetty cross-section (from the jetty toe to –5 ft MLLW). Unsatisfactory performance effects due to toe scour migrate upward along the jetty face, ultimately affecting the upper region of the jetty cross-section. The displacement (or loss) of stone off the jetty cross-section at the point of toe scour acts to steepen the structure slope above the scour area, resulting in displacement of the entire armor layer up to the jetty crest, exposing core stone within the jetty section to direct wave attack. Jetty repair (placement of armor stone onto the upper region of the cross section) reinstates the jetty to a "new" post-construction condition, in terms of the lower likelihood of slope instability. Yet the opposite may be the case, if the lower region of the cross-section (below -5 ft MLLW) is at the limit of maintaining a stable slope. Adding stone to the upper region of the cross-section may surcharge the lower slope, decreasing the reliability of the overall jetty slope. In this case, jetty repairs could represent a problematical issue if the lower slope of the jetty is at the margin of structural instability.

The SRB model emulates slope stability performance by stochastically simulating the change in jetty cross-section geometry, caused by toe-scour effects. As toe-scour motivates cross-section geometry change through time, attributes that govern dynamic stability of the jetty are affected (reduced). Refer to Foundation Effects in Section 6 for specific details.

2. Dynamic Stability

Dynamic stability is the capacity of the jetty's cross section to remain stable when affected by wave action (Figure A2- 17). Wave-driven processes affecting the dynamic stability are manifest at elevations on the upper part of a jetty's cross-section, typically above -5 ft MLLW. On the windward side of a jetty (direct exposure to ocean waves), dynamic stability is manifest by the direct impact of waves on the jetty and the resultant displacement of individual armor units. On the lee side of the jetty, dynamic stability addresses the effect of waves overtopping the jetty crest and displacing armor unit's down-slope, off of the jetty cross-section. Along many areas of the MCR jetties, dynamic stability is the primary performance mode affecting jetty response in terms of damage. Dynamic stability is a transient performance mode, exhibiting severe effects that occur infrequently as motivated by winter storm waves. In summary, two components of dynamic stability were investigated within the scope of this analysis: A) direct wave attack of the armor layer along the windward side of the jetty, and B) wave overtopping of the jetty crest and attacking the leeward side of the jetty. Both dynamic performance modes are manifested in the upper region of the jetty (from –5 ft MLLW to the crest). Incident wave height (along the jetty) is the dominant parameter affecting both dynamic performance functions.

<u>Direct Wave Attack on Armor Layer</u>. Two formations were utilized to estimate the reliability for jetty armor layer design in response to direct wave attack: the Hudson [1959] and Van der Meer [1988] equations. Comprehensive investigations were made by Hudson and Jackson during 1953-1961 to develop a formula for determining the stability of armor units on rubble-mound structures, in response to direct wave attack. The Hudson equation is based on extensive scaled physical modeling testing and verification by prototype data as presented in the Shore Protection Manual and the Coastal Engineering Manual [USACE 1984, 2003]. The Hudson equation is typically used when the crest of a structure is high enough to prevent significant overtopping by waves and the armor layer slope is not steeper than 1V:1.5H. Armor layer slopes steeper that 1V:1.5H are not recommended [USACE 2006]. A limiting attribute for the Hudson equation is that it does not directly account for wave period or wave steepness. Because the equation was developed from data that included many variations for wave period and steepness, the lack of direct specification for these parameters within the equation is not considered to be significant detriment. The Hudson equation has been successfully used to emulate the reliability of other coastal infrastructure [USACE 1993; Moritz et al., 1994]. The parameters within the Hudson equation are directly associated with the physics of wave action and armor unit stability. Note that four out of the five parameters within this equation are based on physical attributes; only on parameter (K_d, armor unit stability coefficient) is based on empirical derivation. The Hudson equation provides a limit-state or upper-bound estimate for armor stone stability. Using the Hudson equation, a mean armor stone size (weight, W) required for the wave-ward slope of a jetty to resist incident wave action is determined as follows:

Hudson Equation:

$$W = \frac{\gamma r * Hs^3}{K_d * (Sr-1)^3 * Cot\theta}$$

where

$W = W_{50}$ = mean armor unit weight, lb

γr = armor unit density, lb/ft

K_d = stability coefficient

θ = slope of armor layer from horizontal

Hs = incident significant wave height, ft

Sr = specific gravity of armor units

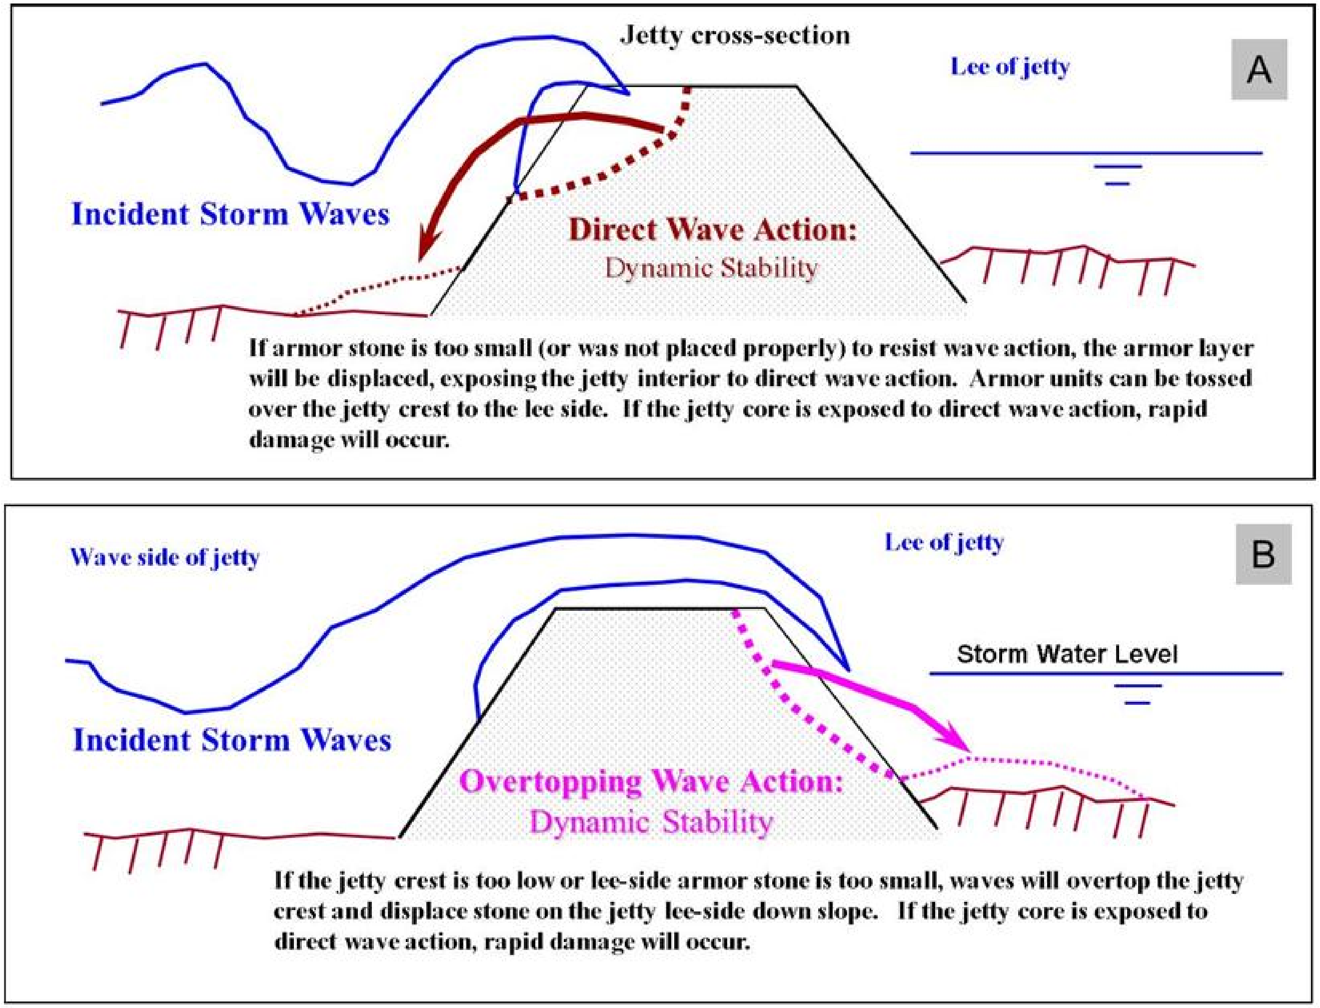

Figure A2- 17. Jetty performance Modes for Dynamic Stability

Other equations describing armor unit stability due to wave attack are documented in literature, the Van der Meer (VDM) equations being a prominent citation. The VDM equations have been used extensively throughout the international engineering community and can produce similar results as the Hudson equation [Kim and Suh 2008]. The VDM equations directly account for wave period and wave steepness within the formulation. It is noted that these equations are based on North Sea and similar prototype data. Storm waves along the U.S. Pacific Coast can have longer wave periods than many of the data sources used to develop the VDM equations. Because of this, the VDM equations may predict smaller armor stone size (W) than what is actually needed to resist a given wave height at U.S. Pacific Coast locations. Despite this potential limitation, the VDM equations offer advantages over the Hudson equation due to numerous structure and wave parameters that are directly emulated within the VDM equations. Separate VDM equations were formulated to account for wave steepness:

Van der Meer Equations:

For *plunging* waves

$$\frac{Hs}{\Delta D_{n50}} = 6.2P^{0.18}\left[\frac{S}{\sqrt{N}}\right]^{0.2} \xi_m^{0.5}$$

For *surging* waves

$$\frac{Hs}{\Delta D_{n50}} = 1.0P^{-0.13}\left[\frac{S}{\sqrt{N}}\right]^{0.2} \sqrt{\cot\alpha}\ \xi_m^{0.5}$$

The transition from *plunging to surging waves* can be calculated using a critical value for the surf similarity parameter (ξmc):

$$\xi_{mc} = [6.2P^{0.31}\sqrt{\tan\alpha}]^{1/P+0.5}$$ Critical surf similarity parameter when Cot α <= 3

The *plunging wave VDM* equation is used when ξm is less that ξmc. The *surging wave VDM* equation is used when ξm is greater that ξmc. If the structure slope is very gentle such that Cot α is greater than 3, then the following equation is to be used for evaluating the critical surf similarity parameter (ξmc).

$$\xi_{mc} = [3.58P^{0.31}]^{1/P+0.5}$$ Critical surf similarity parameter when Cot α > 3

where

Hs = significant wave height, m

Tm = mean wave period, sec

Lo = $gT_m^2/2\pi$

P = notional permeability factor (0.30-0.60)

S = damage level (varies 2-12), within this analysis varies as a function Kd for Hudson equation and structure slope

N = number of storm waves, for a given NW PAC wave event (300-900)

Cot α = structure slope (run:rise)

ξm = surf similarity parameter at structure = $\tan\alpha / \sqrt{Hs/Lo}$

ξmc = Critical surf similarity parameter; transition from plunging to surging waves

Δ = relative specific gravity for armor units = armor density/water density -1
Dn_{50} = median armor size, equivalent diameter, meters

Due to the inherent uncertainty associated with evaluating reliability for rubble-mound structures (in terms of multi-parameter empirical formulas), it was deemed prudent to use both the Hudson equation and VDM equations to evaluate the reliability of a jetty's wave-ward slope when exposed to incident waves (Figure A2- 17a). Reliability from each equation was computed. Both reliability estimates were blended together (by obtaining a mean value) to obtain an objective estimate for wave-ward reliability on each side of a jetty.

The Hudson equation and VDM equations were rearranged to form a performance function (FS=C/D), which was used to calculate the reliability of dynamic stability along the wave-ward slope of the MCR jetties. To increase the confidence of the reliability estimate, the Hudson and VDM equations were also evaluated in terms of a safe margin (SM = C-D). Comparison of the two reliability estimates (FS vs. SM methods) indicated little overall variation, except when C and D became similar in value. Reliability estimates based on FS and SM were blended to produce a confident estimate. Each parameter within the Hudson and VDM equations was treated as a random variable, prescribed by a mean value and standard deviation. The performance functions for Hudson and the VDM equations are expressed below in terms of a FS. Note the degree of sensitivity that the Hudson performance function has with wave height and armor unit density, whereas the VDM equations are linear in terms of wave height and armor size. An advantage of the VDM equations is that they express dynamic performance for jetty armor (size) in terms of a linear relationship vs. the Hudson equation which is non-linear. Linear performance functions tend to produce more stable estimates when the Taylor series FOSM method is used to estimate reliability (for factor of safety and safety margin).

FS = $\dfrac{\text{CAPACITY of armor layer to resist incident wave forces}}{\text{DEMAND imposed on armor layer by incident wave forces}}$

$$= \frac{W * K_d * (Sr-1)^3 * Cot\theta}{\gamma r * H^3} \qquad \textbf{(FS for Hudson Equation)}$$

SM = CAPACITY – DEMAND

$$= (W * K_d * (Sr-1)^3 * Cot\theta) - (\gamma r * H^3) \qquad \textbf{(SM for Hudson Equation)}$$

(VDM for plunging waves)

$$\textbf{FS} = \frac{\Delta D_{n50} 6.2P^{0.18} [S/\sqrt{N}]^{0.2} \xi_m^{0.5}}{H_s}$$

$$\textbf{SM} = \Delta D_{n50} 6.2P^{0.18} [S/\sqrt{N}]^{0.2} \xi_m^{0.5} - H_s$$

(VDM for surging waves)

$$\textbf{FS} = \frac{\Delta D_{n50}\, 1.0P^{-0.13} [S/\sqrt{N}]^{0.2} \sqrt{\cot\alpha}\, \xi_m^{0.5}}{H_s}$$

$$\textbf{SM} = \Delta D_{n50}\, 1.0P^{-0.13} [S/\sqrt{N}]^{0.2} \sqrt{\cot\alpha}\, \xi_m^{0.5} - Hs$$

Reliability for wave attack along the front side of a jetty (using the Hudson and VDM equations) was determined for each 100-ft segment along the jetties, for each year "i" within a given life-cycle simulation. There can be two components for front side dynamic stability in the case where the wave action affects a jetty on both sides of the structure (channel and ocean side). As the jetty cross section becomes damaged, the parameters of K_d, S, and W can change (decrease), further reducing the reliability of the jetty. Recall, that the upper cross-section of a jetty can be damaged by wave action and foundation effects (scour). Evaluation of jetty damage is performed independently of the reliability calculation. In other words, cross-section degradation can affect the reliability estimate of a jetty, but changes in reliability do not affect jetty degradation; as emulated within the SRB model.

Wave Overtopping on the Backslope Armor Layer. During the initial stages of jetty MCR construction (1885-1895), the crest of the South Jetty was constructed to low-mid- tide elevation (about +4 to +12 ft MLLW). The jetty was overtopped by waves resulting in rapid jetty deterioration and significant transport of sand over the jetty root. It was quickly realized that the small jetty section was being destabilized by incident and overtopping wave-action (Figure A2- 17). From the early 1900s onward, the crest elevation of MCR jetties was constructed above high tide elevation (+15 to +30 ft MLLW). A higher crest elevation was required for the jetty to remain stable and fulfill its intended function of shoal control. The performance mode for dynamic stability of a jetty's backslope (leeside) armor layer can be modeled by equations that relate structure freeboard, crest width, incident wave height and period, armor stone density, and ratio of back slope to front slope armor stone sizes. Two types of overtopping stability equations were evaluated within this appendix: the WPD equation and the Van Gent equation. The simpler of the two overtopping equations was developed by Walker et al. [1975], with results cast in terms of a stability threshold. The stability of the leeside armor units are associated with the size of the wave-ward armor units. The WPD equation assumes that the front slope (wave-ward side) armor stone has been correctly sized to be stable for the incident wave environment. The WPD overtopping stability equation is based on extensive small-scale modeling testing and verification by prototype data. Note that the WPD overtopping stability equation is very sensitive to crest elevation (freeboard, h_c), non-linearly. The higher the crest above the water surface, the more stable the leeside of the jetty; even if a smaller armor size is used on the backside of the jetty than on the frontside. Mean armor stone size for the leeside slope (weight, W_b) is determined as follows:

Walker-Palmer-Dunham Equation: $W_b = W_f * C_2 * \exp(-C_1 * h_c/H)$

where

W_b = mean stone weight on backside (lee) slope of jetty, lb
W_f = mean stone weight on frontside slope of jetty, lb
H = incident wave height ft
$C_1 = 2.061$
$C_2 = 4.554$
h_c = jetty freeboard, ft = Crest El. – WSE

The WPD overtopping stability equation does not directly account for structure slope, armor roughness, wave period, or crest width. These parameters embedded within the equation's empiricism The prototype data from which the equation was developed included applications where frontside slope differed from backside slope, in some cases by as much as factor of 3. The WPD equation also assumes that structure maintains a nominal crest width, based on an undamaged configuration. Despite the above assumptions, the WPD equation has been successfully used to emulate the reliability of other coastal infrastructure [USACE 1993; Moritz et al., 1994] and has been used to assess the design of other jetty repairs within Portland District [USACE 1994].

Through extensive prototype and scaled-physical model investigations performed by Van Gent et al, an elaborate overtopping stability equation was developed featuring paramertization similar to the VDM equations [Van Gent 2004]. The Van Gent equation directly accounts for many aspects of a structure's cross-section, and includes effects of wave period and storm duration within the formulation. Although the Van Gent equation is highly empericized, the equation accounts for many of the physics affecting rear-side armor stability. The Van Gent equation can be used to explicitly calculate rear-side armor size, unlike the WPD equation which is a threshold-based formulation dependent on the armor for the front side of the structure. The approach for evaluating rear-side armor size (overtopping) follows a three step process: A) run-up elevations onto the structure are estimated based on wave conditions at the structure toe; B) wave overtopping parameters are calculated based on the run-up estimate from step A; and C) the requisite size of rear-side armor units is calculated based on wave overtopping parameters estimated in step B.

Van Gent Equation: $$D_{n50} = 0.008 \left(\frac{S}{\sqrt{N}}\right)^{-1/6} \left(\frac{u_{1\%}\, T_{m-1,0}}{\Delta^{0.5}}\right) (\cot\varphi)^{-2.5/6}\, (1 + 10 \cdot \exp(-R_{c-rear} / H_s))^{1/6}$$

where

$$z_{1\%} / (\gamma H_s) = c_0\, \xi_{s,-1} \qquad \text{for } \xi_{s,-1} \leq p$$
$$z_{1\%} / (\gamma H_s) = c_1 - c_2 / \xi_{s,-1} \qquad \text{for } \xi_{s,-1} \geq p$$

$$\frac{u_{1\%}}{\sqrt{gH_s}} = 1.7\ (\gamma_{f-c})^{0.5} \left(\frac{z_{1\%} - R_c}{\gamma_f H_s}\right)^{0.5} \Big/ \left(1 + 0.1\frac{B_c}{H_s}\right)$$

$Z_{1\%}$ = 1% exceedance value for wave run-up elevation onto the structure, m
H_s = significant wave height, m
γ = run-up reduction factor, account for oblique wave attach & armor roughness = 0.5
$C_o = 1.45$, $C_1 = 5.1$, $C_2 = (0.25C_1)/C_o$
ξm = surf similarity parameter at structure = $\tan\alpha / \sqrt{Hs/Lo}$
$p = 0.5\ C_1/ C_o$
$U_{1\%}$ = 1% exceedance value for velocity of overtopping onto backside of structure, m/s
R_c = structure crest height above water surface, freeboard, m
B_c = Structure crest width, m

γ_f ,γ_{f-c} = armor unit density, kg/m3
Δ = relative specific gravity for armor units = armor density/water density -1
S = damage level (varies 2-12), within this analysis varies as a function Kd for Hudson equation and structure slope
Tm = mean wave period, sec
Lo = $gT_m^2/2\pi$
N = number of storm waves, for a given NW PAC wave event (300-900)
Cot α = structure slope (run:rise), limiting slope for Van Gent application is 1.5:1

The WPD and Van Gent wave-overtopping equations were rearranged to form performance functions that were used to assess the reliability of dynamic stability along the leeside face of MCR jetties. Each non-constant parameter within the overtopping equations was treated as a random variable, prescribed by a mean value and standard deviation. Recall that a performance function is expressed as a FS in terms of capacity (capacity of armor units to resist movement) and demand (load caused by wave overtopping). To increase the confidence of the reliability estimate, the overtopping performance functions were also evaluated in terms of a SM (SM = C-D). Reliability estimates based on FS and SM were blended to produce a confident estimate. The performance functions (FS and SM) for overtopping dynamic stability are:

$$FS = \frac{\text{CAPACITY of leeside armor to resist overtopping}}{\text{DEMAND imposed by overtopping waves}}$$

$$= \frac{Wb}{W_f * C_2 * \exp(-C_1 * h_c/H)} \qquad \textbf{(FS for Walker-Palmer-Dunham)}$$

$$SM = \text{CAPACITY - DEMAND}$$

$$= Wb - W_f * C_2 * \exp(-C_1 * h_c/H) \qquad \textbf{(SM for Walker-Palmer-Dunham)}$$

$$FS = \frac{D_{n50}}{0.008\left(\frac{S}{\sqrt{N}}\right)^{-1/6}\left(\frac{u_{1\%}\,T_{m-1,0}}{\Delta^{0.5}}\right)(\cot\varphi)^{-2.5/6}\,(1+10\cdot\exp(-R_{c-rear}/H_s))^{1/6}} \qquad \textbf{(SF for Van Gent)}$$

$$SM = D_{n50} - 0.008\left(\frac{S}{\sqrt{N}}\right)^{-1/6}\left(\frac{u_{1\%}\,T_{m-1,0}}{\Delta^{0.5}}\right)(\cot\varphi)^{-2.5/6}\,(1+10\cdot\exp(-R_{c-rear}/H_s))^{1/6}$$

(SM for Van Gent)

Based on peer review recommendation and comparing the reliability results between WPD and Van Gent, it was determined that the Van Gent equation produces superior reliability estimates. Evaluation of armor stability due to wave overtopping was performed exclusively using the Van Gent equation. Time-varying reliability for wave overtopping (using the Van Gent equation) was determined for each 100-ft segment along the jetties. There can be two components for overtopping (leeside dynamic stability) in the case where the wave action affects a jetty on both sides of the structure (channel and ocean side). Recall that reliability indicates the likelihood of a jetty to resist damage (and function satisfactorily) in the presence of wave action; reliability does not define how much jetty degradation would incur if the jetty were damaged.

3. Structure Reliability - Each Segment

Structure reliability is calculated for each 100-ft segment of jetty (j), for each year within a given life-cycle simulation (i). Because a jetty can have wave action affecting both sides of the structure (channel side and ocean side), there can be two components of structure reliability for a given jetty segment. Each component has two modes of dynamic performance: direct wave attack and wave overtopping. When wave action affects the *ocean* side of the jetty, the ocean side is subject to direct wave attack and the channel side of the jetty can be affected by wave overtopping. When wave action affects the *channel* side of the jetty, the channel side is subject to direct wave attack and the ocean side of the jetty can be affected by wave overtopping. Taken together, there can be up to four individual components of structure reliability affecting the upper cross-section region of each 100-ft jetty segment (Figure A2- 18). The individual components are combined, using a series combination of probabilities, to calculate structure reliability for each jetty segment for each year within a given life-cycle. Note that the structure reliability for a given segment is limited by the lowest value of the individual component reliabilities.

Structure reliability at a given jetty *segment-j*, for *each year* in life-cycle-*i*

$$= P_{i,j}(s)_{\text{overtopping wave action}} \times P_{i,j}(s)_{\text{direct wave attack}}$$

where

$$P_{i,j}(s)_{\text{overtopping wave action}} = P_{i,j}(s)_{\text{overtopping – channel side}} \times P_{i,j}(s)_{\text{overtopping – channel side}}$$

$$P_{i,j}(s)_{\text{direct wave attack}} = P_{i,j}(s)_{\text{direct wave attack – channel side}} \times P_{i,j}(s)_{\text{direct wave attack – channel side}}$$

Recall that the process of active toe scour can destabilize the entire side slope of the jetty cross-section, reducing the resiliency and the reliability of the upper cross-section. The above estimate for segment structure reliability incorporates static and dynamic stability performance modes.

Table A2- 7 through Table A2- 9 summarize design parameters and associated reliability at specific locations along each MCR jetty. The design parameters (and reliabilities) are based on the various construction/repair sequences realized during a given jetty's life-cycle. These include initial construction, historical repairs, and future alternative repair/rehab scenarios. Reliability components for each construction sequence are calculated based on an undamaged cross-section exposed to the forcing environment applicable for the time period of interest, and includes the effects of time-varying morphology change.

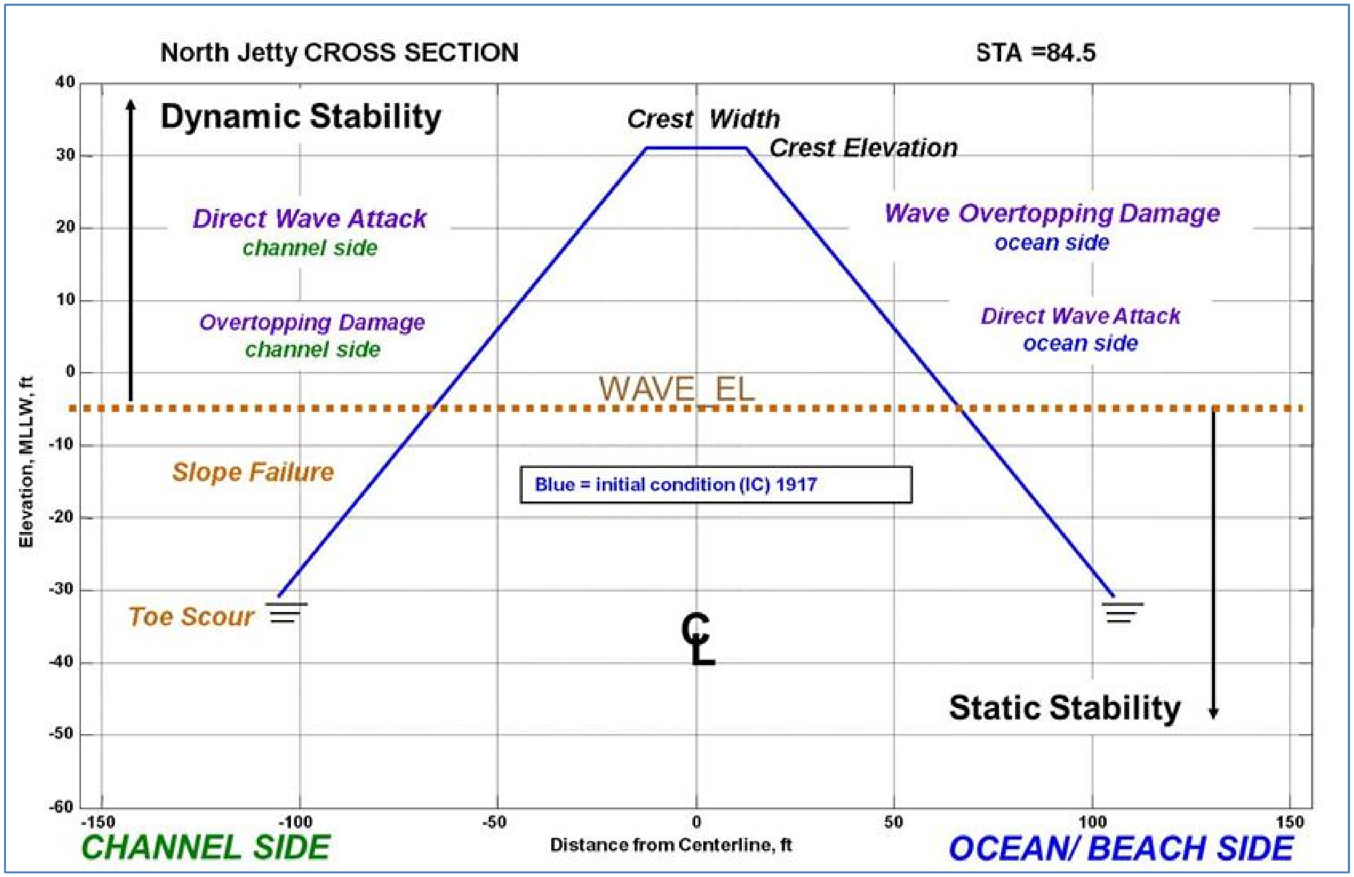

Figure A2- 18. Representation of a Jetty Cross-Section as Emulated by SRB Model

For every 100-ft of jetty. The jetty is bisected horizontally by the centerline (CL) and vertically by the elevation (WAV_EL) at which wave damage becomes the driving process for structure degradation. Below WAV_EL, scour and static slope stability performance modes govern jetty degradation. Jetty degradation is simulated separately for each side of the jetty.

* Jetty Head has a compound slope, 1v:3h from crest to + 10 ft MLLW, and 1v:2.5h down to Toe.
Mean wave height = annual average storm Hsig at time of construction or repair, STD = standard Deviation of annual Hsig Reliability. Reliability is calculated using mean WSE = 5.6 ft NGVD, STD = 1.1 ft
COV = coefficient of variation = mean value / standard deviation. ALL values assumed to have normal distribution about mean value, unless otherwise noted.
W50 = Mean armor stone weight, γ = weight density of armor units, COT(θ) = slope angle of armor layer (1.5 = 1v:1.5H)
CE = X-section crest elevation, CW = X-section crest width
Kd = Hudson Stability Coefficient: values can range from 2.5 (for dumped, random placement armor units) to 6 (for special placemat stone armor units).
Alternative Cross-Section development for this study was based on a Kd value that varied between 4 and 6, for rough armor stone.
W50 was calculated using Kd = 5 for the Repair/Maintenance Template and Kd = 6 for Rehab and Jetty Head templates
Reliability for alternative plans was evaluated using a Kd value of 3 and 4, where noted above; using Hudson equation, Van der Meer equation, and Van Gent equation
Reliability (Ps) was calculated using SM and SF performance functions, solved by Taylor series expansion, FOSM; to obtain Beta factor and P(s). Calculations based on Undamaged Structure

North Jetty: The first row in Table A2- 7 documents the design parameters and associated reliability for the North Jetty initial construction template. In 1917, the structure reliability at Station 85 was 0.59 and was affected by the modest performance of the ocean side of the jetty to resist direct wave action. During 1917 to the mid 1930s, significant accretion occurred along the ocean side of the North Jetty resulting in the formation of Benson Beach. The accretion prevented wave action from affecting much of the ocean side of the jetty, acting to improve the reliability for most of segments along the North Jetty. As Peacock Spit receded (1939-present), wave action increased along the ocean side of the North Jetty, acting to reduce reliability of exposed jetty areas. This is the reason for the low structure reliability for North Jetty repairs conducted after 1939.

South Jetty: The South Jetty was initially constructed using a relatively small cross-section allowing significant overtopping of the jetty. The first row in Table A2- 8 documents the design parameters and associated reliability for the South Jetty initial construction template. Upon full completion in 1910, the extremely low reliability for the South Jetty at Station 230 (0.020) was affected by poor reliability for overtopping performance modes. As the jetty was repaired during the 1930s and 1960s, a larger (higher and wider) cross-section was used which significantly improved the jetty's overtopping reliability. The 1982 repair featured a less robust cross-section (steeper side slopes) and lower rock density than previous repairs, which lowered the reliability for this repair action.

Jetty A: Jetty A was initially constructed to function more as a revetment and breakwater than as a jetty. Initially, only the outer 1/5 of the jetty (~1,000 ft) functioned as a true jetty. The first row in Table A2- 9 documents the design parameters and associated reliability for Jetty A's initial construction template. The low reliability for the initially constructed Jetty A was due to the small sized size armor stone used along most of its length and low crest elevation. The initial meager cross-section was quickly damaged by wave action and scour, and was repaired using cross-section and construction materials that were not resilient (1940s and 1950s). Consequently, the first series of repairs for Jetty A had very low initial reliability. The third series of repairs (1960s) was performed using a more robust cross-section and larger armor stone size, resulting in improved structure reliability.

Structure Reliability for the Entire Jetty

For each year (i) in a given life-cycle, the overall structure reliability (PS-i) for the *entire* jetty is calculated as the mean value of the structure reliability over all active segments. For hindcast simulations, the overall structure reliability for each year is calculated using all jetty segments extending to the initial jetty head location. In forecast *simulations*, the overall structural reliability, for each year (i), is based on jetty segments that extend to the location of the current jetty head.

4. Structure Reliability and Jetty Cross-Section Damage

Structure reliability indicates the likelihood for a given jetty segment to incur damage. The structural reliability for each jetty (segment) is calculated based on the spatial variation of the forcing environment affecting the jetty and the condition of a structure, at a given point in time. Structure reliability does not define the extent of structure damage.

If the jetty cross-section continues to degrade over time, the parameters affecting structure reliability (crest elevation, armor stone size, armor stone stability number) will change, resulting in reliability reduction. Within the SRB model, degradation of jetty cross-section can be motivated by two processes:

1. Slope instability of the lower cross-section of the jetty, induced by toe scour – static stability performance (affects lower and upper cross-section region).
2. Wave induced damage to the upper cross section of the jetty – dynamic stability performance (affects upper cross-section region).

The cross-section of the jetty is modified in response to incident (and overtopping) wave action by a prescribed set of damage functions. Physical model studies were conducted by ERDC [Ward and Melby 2007] to define damage functions for various jetty cross-section configurations. These damage functions were used within the SRB life-cycle model to emulate jetty damage when the simulated wave height incident to the jetty exceeded the threshold condition for initiating damage (zero-damage wave height, $H_{D=0}$). When the armor layer for a given jetty segment is damaged, the value for $H_{D=0}$ is reduced to account for the presence of smaller and less stable stone exposed to wave forcing. As the armor layer and side slope of a jetty is progressively damaged, the geometry of the jetty's upper cross-section is reduced; eventually lowering the crest elevation of the jetty. As the crest elevation is reduced, the leeward slope becomes increasingly susceptible to damage from wave overtopping. The reliability of a jetty segment is cast in terms of the upper cross-section region (and physical attributes) being reduced as the segment becomes progressively more damaged. Damages sustained by the upper region of a jetty are expressed as a percent reduction in terms of the total upper cross-section area. As the parameters that describe dynamic performance (of the jetty upper region) are reduced, jetty reliability is also reduced.

The concept of jetty degradation affecting reliability is illustrated in Figure A2- 15, which shows how the change in jetty cross-section area can drive structure and functional reliability at a given jetty segment. The result shown in Figure A2- 15 is based on one realization from a SRB model hindcast simulation, for the MCR North Jetty at station 84+50. Based on the hindcast realization, the cross-section at station 84+50 was repaired 2 times during 1917-2006; note how the reliability is reduced as the cross-section area is reduced and how the reliability is restored as the cross-section is repaired. The relationship between upper cross-section change (above -5 ft MLLW) and total cross-section change is affected by wave action and jetty toe scour. When the jetty damage is primarily due to wave action, the structural response is manifested in terms of upper cross-section degradation.

Excessive erosion of the morphology, on which a jetty is founded, causes downward displacement of the jetty toe (toe scour). Continual toe scour leads to slope re-adjustment, which affects of the entire jetty cross-section. Refer to Structural Reliability below for additional details. If the jetty is affected by toe scour, the structural reliability of the entire structure will be compromised regardless of the dynamic reliability of the upper cross-section region. If the likelihood exists for significant toe scour, its abatement must be addressed when considering repairs or improvements for the upper cross-section.

b. Functional Reliability & Satisfactory Project Performance

All three rubble-mound MCR jetties perform in different ways to provide the same basic function: secure and maintain the configuration of the authorized channel through the coastal inlet. Without the present function of each jetty, year-round deep-draft navigation would not be possible at the MCR inlet. An essential objective for each jetty is to prevent rapid shoaling within the MCR navigation channel. The prevention of pronounced channel shoaling during winter is especially important, when large ocean waves can significantly degrade navigability within a shoaled channel due to the under-keel clearance requirements of MCR deep-draft navigation. The northerly 2,000 ft of the MCR channel is maintained at -55 ft MLLW (plus 5 ft for over-dredging to -60 ft), and the southerly 640 ft of the channel to be maintained at -48 ft MLLW (plus 5 ft for over-dredging to -53 ft).

If the upper region of the cross-section of a jetty is damaged beyond a minimum configuration, it will no longer perform its intended function; the jetty will experience unacceptable performance (the segment fails, functional reliability = 0). The minimum configuration that a Pacific Northwest seacoast jetty can remain functional was estimated to be 15% of a standard design template (Table A2- 10). At this point, the jetty section can be breached allowing for a separate flowpath to be established through the jetty, motivating sediment transported into the inlet and possibly into the navigation channel. Depending upon the condition of the jetty, and location along a given jetty, the consequences of functional failure can range from: A) a minor increase in the annual maintenance dredging requirement, to B) aggressive or emergency actions required to prevent rapid and significant shoaling within the MCR navigation channel. If the northern 1/2 of the channel experienced shoaling above -50 ft MLLW, deep-draft navigation would be significantly impaired during the fall-winter-spring time frame. Refer to Section 4 for a description of jetty breach scenarios associated with each MCR jetty.

Table A2- 10. Target Reliability for Functional Performance, Reliability = 1-P(u)

Jetty is assumed to have two more layers of armor units protecting core material. Values and corresponding consequences are applicable for MCR jetties ONLY.

Expected Performance Level Rubble-mound Structures @ MCR	Probability of Unsatisfactory *Functional* Performance P(u)	Potential Functional Consequences to MCR Jetties and Channel Shoaling [1/]
Excellent	0.005	Essentially no likelihood of jetty breach.[1] No sustained structure degradation.
Very High	0.02	Very little likelihood of jetty breach.[1] Minor sustained structure degradation.
High	0.05	Very little likelihood of jetty breach.[1/] Nominal sustained structure degradation.
Good	0.10	Little likelihood of jetty breach. Notable sustained structure degradation. Active structure monitoring required.
Average	0.15	Low likelihood for jetty breaching;[1] breaching potential exists for an extreme storm year. Notable sustained structure degradation. Active structure monitoring required.
Below Average	0.20	Potential for jetty breaching,[1] in response to severe storm activity. High level of structure degradation. Jetty repairs should be in active state of planning.
Poor	0.30	Elevated Likelihood for jetty breach,[1] in response to severe storm activity. Excessive structure degradation. Jetty should be in process of being repaired.
Unsatisfactory	0.40 to 0.50	High likelihood for jetty breach,[1] in response to severe storm activity. Significant structure degradation. Expedited jetty repairs are needed to avert a jetty breach. Moderate potential for priority dredging, if sediment is available for transport into channel.
Hazardous	>0.50	Jetty breach is likely. High degree of structure sustained degradation. Immediate action needed to prevent jetty breach. High likelihood for priority dredging to avert significant channel shoaling, if sediment is available for transport into channel.

1 = In the case of a jetty breach, likely to occur in winter when wave loading is highest: "Priority dredging" refers to dredging that would be needed to maintain MCR navigation channel during winter at authorized depth (-55 ft) due to significant channel shoaling due to the jetty breach. If a jetty breach event does not have the capacity to mobile more than 250,000 cy into the MCR channel during the winter season, then dredging is deferred until the following summer.

1. Calculation of Functional Reliability

The time-varying functional reliability for each jetty segment is estimated for each year (i) by combining the segment's upper cross-section with the four components of structure (dynamic) reliability to obtain weighted estimate for functional reliability for each year in the simulation. The weighting parameters are based on the fraction of cross-section remaining at year (i). The weighting function is modified to give more influence to segments having a higher or lower than average percentage of remaining cross-section. The "average remaining cross-section" is expressed in terms of an upper cross-section template that has been reduced to 57% of its full template area. For a given segment to have unsatisfactory function reliability, the cross-sectional area must be highly degraded and the structural reliability must be poor. In this sense, functional reliability is indicative of jetty resilience.

Figure A2- 15 shows how the functional reliability can change over time with respect to the cross-section area for a specific jetty location. Recall that structure reliability can be affected by the degree of damage a given segment has sustained, as can functional reliability. However, functional reliability displays less irregularity than structural reliability due to the buffering effect of the cross-sectional area. The sensitivity of functional reliability to changes in cross-section area (and structural reliability) can be observed in Figure A2- 15. If the cross-section area for a given reach of a jetty becomes diminished, the functional reliability may be affected more by cross-section area change than by the change in structure reliability. The complex interaction between cross-section area change, structure reliability, and the averaging of the two parameters along the entire jetty (when discrete areas of the jetty are being "repaired") can lead to instances when average structural reliability (for the entire jetty) is improving while the functional reliability is neutral or decreases. This means that the effect of the jetty being damaged (loss of cross-section) is greater than the effort to repair the jetty, in an overall average-jetty sense. In this case, the effort of repairing a jetty (restoring the cross-section) has less influence on affecting the functional reliability, than does the structure reliability. The jetty cross-section is being restored, but it has low reliability to resist damage.

Table A2- 10 gives the expected performance level and potential functional consequence for a range of unsatisfactory functional performance probability, p(u). A low value for functional performance p(u) indicates that a jetty segment has high resilience and can accept a finite amount of structure degradation and still have a high likelihood of functional performance.

4. MOTIVATION AND CONSEQUENCES OF JETTY FUNCTION FAILURE

Each jetty at MCR functions in a unique way to maintain the present inlet and navigation channel configuration. Jetty components include the head, trunk, and root. The morphology on which a given jetty is founded can also be considered a jetty component, and is included with the life-cycle analysis. In the vertical sense, a given jetty is composed of a lower section which re-directs subsurface currents and provides a foundation to support the upper part of the jetty. The upper part of the jetty re-directs surface currents, intercepts wave action, stabilizes the morphology adjacent to the jetty, and controls the (re)formation of shoals within the channel. Each MCR jetty is now acting to stabilize 10's of millions cy of sediment at the MCR inlet. Figure A2- 19 describes the functional components of a jetty and the related consequence for a given jetty component to lose its function (fail, functional reliability = 0). The MCR jetties and adjacent morphology have evolved to function together as s system. In this sense, each jetty can be thought of as a system of components working together to provide an overall jetty function.

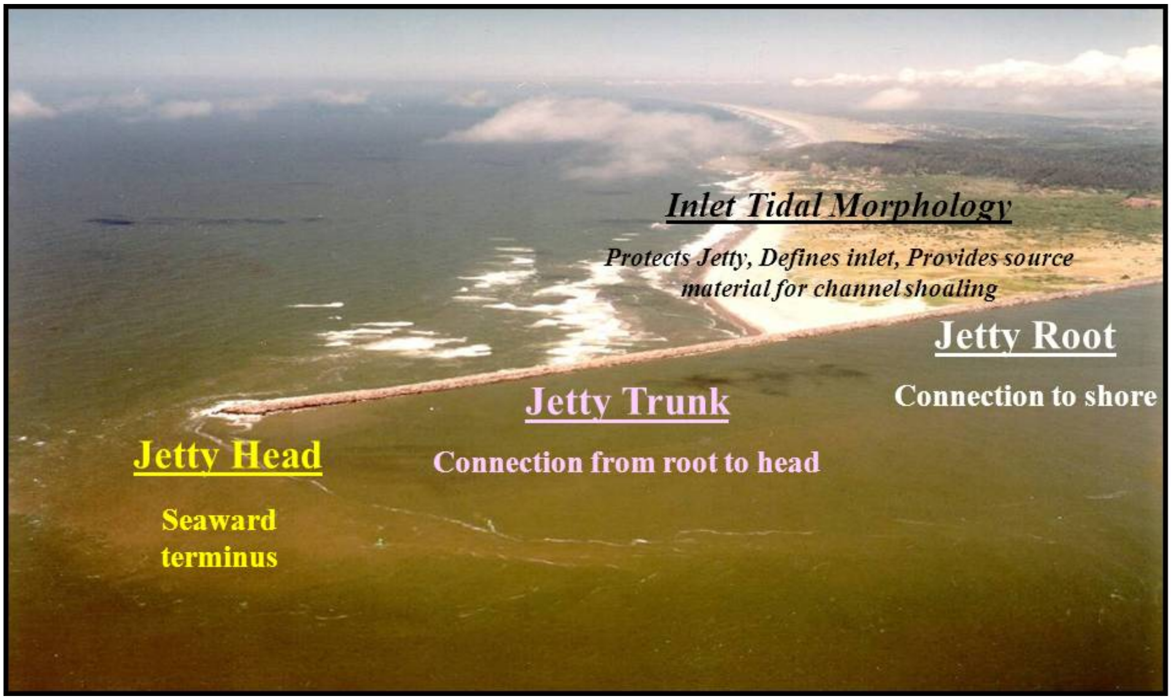

Figure A2- 19. General Components of a Coastal Jetty and Damage Consequences

MCR North jetty, view to the north. Jetty Head recession leads to progressive loss of jetty function and release of inlet morphology, which can impact inlet dredging requirements and stability of other jetty areas. Cumulative jetty Trunk damage can result in a trunk breach which can have functional consequences on the inlet. Cumulative jetty root damage can result in a root breach which can have serious functional consequences on the inlet. Note plume of suspended sediment transported past the jetty head and into the MCR inlet. Tide stage is at peak of flood tide.

Due to the complexities of the MCR jetty system, it is problematic to analyze life-cycle performance of all three jetties collectively. Rather, each jetty was analyzed independently using the SRB model and it was important to account for the primary and secondary processes, which affect future life-cycle performance and consequences on the MCR navigation project, and to discount the other process and related consequences that do not govern the life-cycle performance of the MCR jetty system. It is crucial to understand how each jetty presently functions, how each is affected by the forcing environment, how each jetty can fail, and the consequences of jetty failure.

North Jetty Function. Construction of the North Jetty was motivated by the northward evolution of the inlet in response to South Jetty construction. The North Jetty was the second to be constructed at MCR, to stabilize a series of ebb tidal shoals along the northern half of the inlet that were disrupted by the South Jetty. North Jetty construction constricted the center area of the inlet, resulting in the seaward displacement of ebb tidal shoals and establishment of a secured jetty inlet. Much of the shoals displaced by the North Jetty reformed along the north side of the inlet adjacent to and offshore of the North Jetty to form the modern day configuration of Peacock Spit. The North Jetty now anchors Peacock Spit along the northern flank of the MCR inlet. Without the functional aspect of the North Jetty, Peacock Spit would re-enter the inlet, devolving into a large flood tidal shoal spread across the inlet. The inlet would cease to support deep-draft navigation. Incremental loss of North Jetty function can produce consequences that have a moderate to high level of immediate impact intensity for a given location, and could accrue over time to have significant affect over the inlet.

<u>South Jetty Function</u>. The South Jetty was the first to be constructed at MCR. It is the longest of all three jetties and has had the largest effect on reforming the MCR inlet to the present condition. The South Jetty's present ocean exposure is three miles. The jetty continues to have a profound effect on the inlet; protecting the inlet and Clatsop Spit from destabilizing wave action and currents associated with regional-scale near shore circulation and coastal tidal flow. Clatsop Spit functions in conjunction with the South Jetty with refract wave energy within the inlet away from the navigation channel. Without the functional aspect of the South Jetty, Clatsop Spit would be dispersed within the inlet, devolving into a large flood tidal shoal spread across the inlet. The inlet would cease to support deep-draft navigation. Incremental loss of South Jetty function can produce consequences that have a low to moderate level of immediate impact intensity for a given location, but could accrue over time to have large affect over the inlet.

<u>Jetty A Function</u>. Construction of Jetty A was in part motivated by the breaching of South Jetty during the late 1920s. Jetty A was the last to be constructed at MCR, to minimize northward encroachment of Clatsop Spit, reduce the scour effect on North Jetty, stabilize the inlet's thalweg along the northing margin of the inlet, and to stabilize the morphology of Sand Island and Baker Bay. Jetty A anchors the interior (eastern) side of the inlet. Without the functional aspect of the Jetty A, Clatsop Spit would migrate northward into the inlet thalweg destabilizing Sand Island and the foundation of the North Jetty. The entrance into Baker Bay, through the Ilwaco channel, would not be passable without Jetty A. The inlet would cease to support deep-draft navigation at its current level. Incremental loss of Jetty A function can produce consequences that have a low to moderate level of immediate impact intensity for a given location, and could accrue over time to have large affect over the inlet.

This section of Appendix A2 describes the consequences that can arise when the MCR jetties fail due to breaching, head recession, or foundation scour-root erosion. The SRB model implements jetty response on similar basis (as described below) for life cycle simulations. SRB simulations for future conditions *do* account for consequences related to jetty repair and incremental dredging caused by jetty function loss. Recall that the SRB model assesses only jetty repair costs for hindcast simulations; incremental dredging costs associated with jetty deterioration are *not* included in hindcast simulations.

a. Jetty Head Recession

Figure A2- 20 identifies eight areas of MCR where the morphology is affected by landward recession of the jetty head. Figure A2- 21 shows schematically how jetty head recession can affect the inlet's morphology. As the jetties recede landward, the adjacent morphology is destabilized and the inlet and jetties become increasingly exposed to wave and current action. Sediment mobilized from the destabilized morphology can increase the MCR O&M dredging requirement. Figure A2- 19 and Figure A2- 22 describe how jetty head recession and adjacent morphology change are related. The SRB model incorporates these values into future life-cycle simulations. The incremental and long-term reduction of the inlet's morphology (and related increase in O&M dredging) due to jetty head recession is a complex process; one which defies definitive quantification. The SRB accounts for the first order jetty recession/morphology change processes, which can be estimated. As represented within the SRB model, the jetty recession/morphology change process is based solely on the incremental lateral reduction (cut) of the present tidal shoals (over a finite length), in relation to the incremental recession of the jetty heads. There are other morphological change processes that likely occur, but estimating these are problematic, refer to Jetty Head Recession Impacts Not Represented within the SRB Model. Implementation of engineering features such as jetty head "caps" at the terminus of a given jetty can arrest the landward migration of the jetty head. Refer to Jetty Rehabilitation and Engineering Features for a description of how Jetty head cap engineering features are emulated within the SRB model.

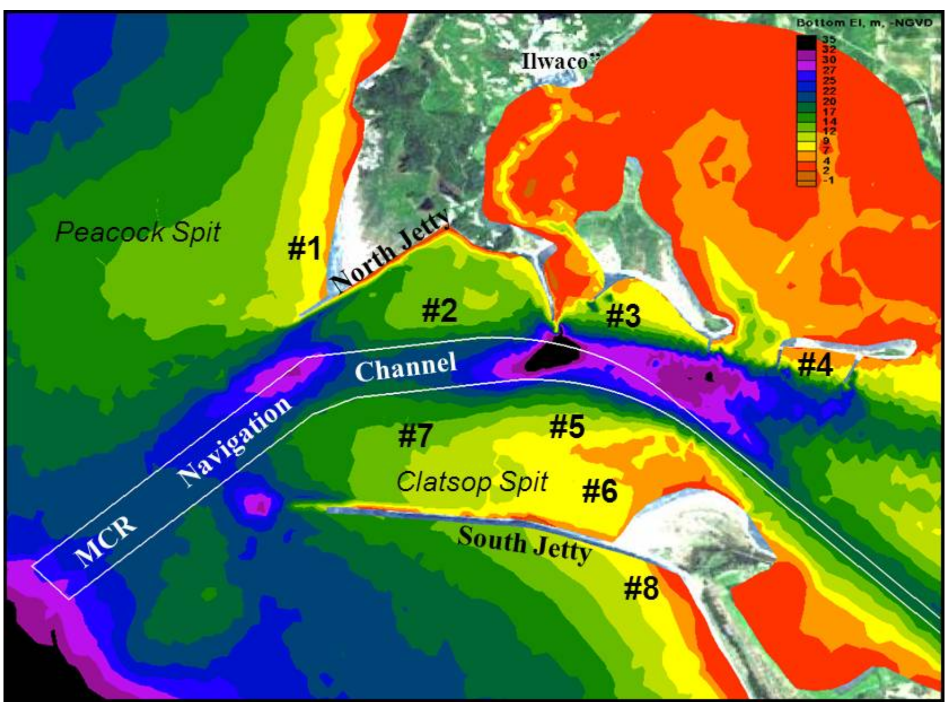

Figure A2- 20. Areas of MCR Morphology (1-8) Affected by Jetty Deterioration

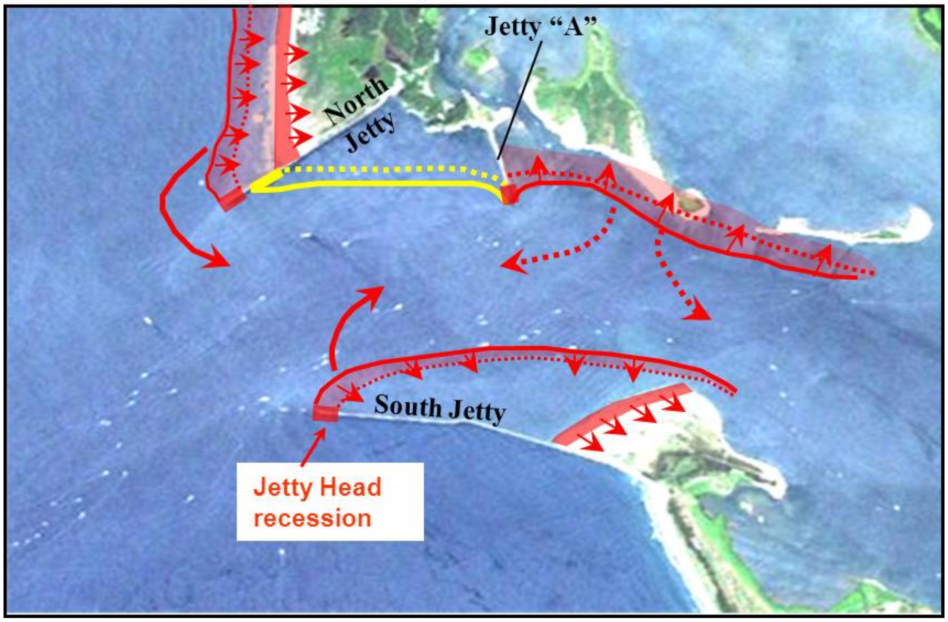

Figure A2- 21. Schematic of Jetty Head Recession Impacts

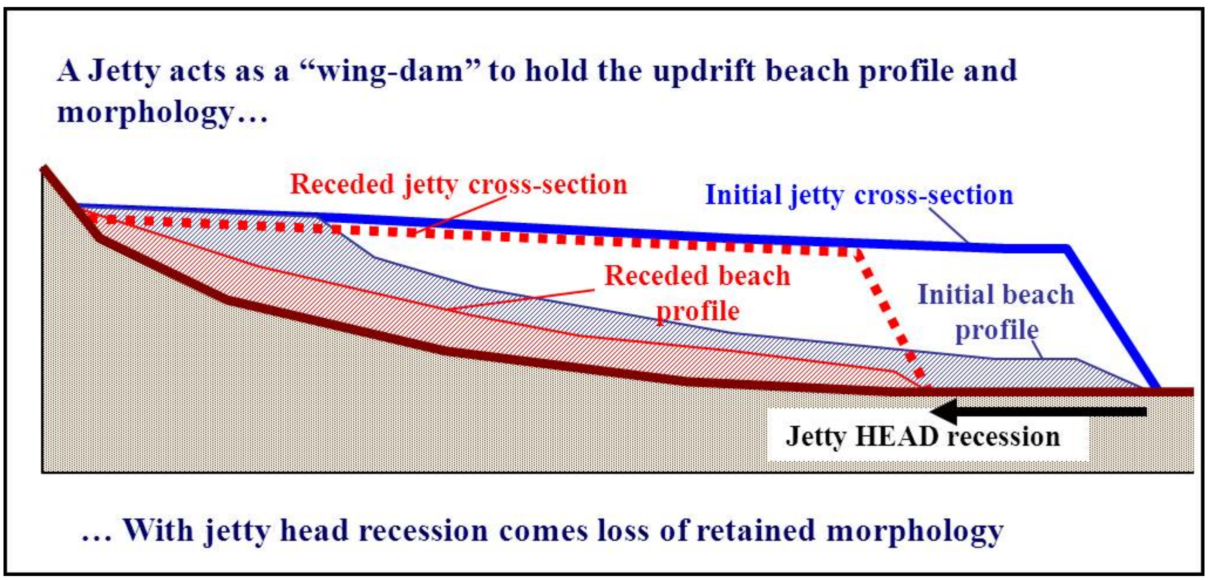

Figure A2- 22. Schematic Showing Profile of a Jetty as the Jetty Head Recedes Landward

1. **North Jetty – Head Recession**

North Jetty essentially acts as a wing dam to hold the morphology of Peacock Spit and prevent the spit from migrating into the MCR inlet (see Figure A2- 3 and Figure A2- 21). As the North Jetty head recedes landward, sand from Peacock Spit and the adjacent ocean shore is transported past the receding jetty and deposits within the MCR channel. When sediment is lost from Peacock Spit, the bathymetry deepens and the ocean shoreline recedes, exposing North Jetty to increased wave action. The ocean shoreline adjacent to North Jetty is controlled by the position of the North Jetty head. The morphology identified by area 1 (Figure A2- 21 and Table A2- 11) is affected by North Jetty head recession. The incremental increase in shoaling within the MCR channel (due to North Jetty head recession) would add to the volume of dredging routinely performed under the present O&M dredging program. As the North Jetty head recedes landward, the combined recession effect of Peacock Spit and North Jetty modifies the wave climate along the North Jetty such that the waves attacking the present head of the North Jetty remain constant while the waves along the inshore reaches of the North Jetty increase with respect to the changing distance to the North Jetty head. As the North Jetty head recedes landward from its 2007 position, the wave environment shoreward of the receding jetty head will increase. This wave climate vs. head recession effect is emulated within the SRB model only for areas along the North Jetty. Modification of the wave climate beyond the North Jetty for other inlet areas (due to North Jetty head recession), is not emulated with the SRB model.\

2. South Jetty - Head Recession

South Jetty stabilizes Clatsop Spit, preventing its northward and landward encroachment on the MCR navigation channel (Figure A2- 4). As the head of the South Jetty recedes landward, sand from the northern flank of Clatsop Spit is exposed to increased wave and current action. Sediment mobilized from Clatsop Spit is deposited within the MCR channel; similar to encroachment of a cut-bank shoal. The morphology identified by areas 5-8 (Figure A2- 22 and Table A2- 11) is affected by South Jetty head recession. The incremental increase in shoaling within the MCR channel (due to South Jetty head recession) would add to the volume of dredging routinely performed under the present O&M dredging program.

3. Jetty A - Head Recession

Jetty A protects the North Jetty from erosive ebb current and prevents northward migration of the MCR inlet (see Figure A2- 5). Jetty A also protects Sand Island from ocean waves and flood current. As Jetty A recedes, the North Jetty is exposed to an increased ebb current acting to destabilize the foundation of the North Jetty. The MCR inlet will translate northward as Jetty A recedes, destabilizing and increasing the erosion of Sand Island. The navigation entrance into Baker Bay through Ilwaco Channel would experience increased O&M dredging requirements. Sediment eroded from Sand Island would be deposited within the MCR channel. The morphology identified by areas 5-8 (Figure A2- 21) is affected by Jetty A head recession. The incremental increase in shoaling within the MCR or Ilwaco Channel (due to Jetty A head recession) would add to the volume of dredging routinely performed under the present O&M dredging program.

Table A2- 11. Effect of Jetty Head Ersion on Mobilizing Sediment Transport

Morphological Area	1 ft of Receding Jetty Head	Morphologcal Expression Affected by 1 ft of Jetty Head Recesion	VOLUME of Sediment Eroded from Morphology Area for Every 1 ft of Jetty Head Recession		Corresponding Volume of Eroded Sediment Transported into Navigation Channel	
		Elevation Extent of recession cut X Shore parallel extent of morphology recession	Erosion Below intertidal, CY	Erosion Above intertidal, CY	From Erosion Below intertidal, CY	From Erosion Above intertidal, CY
1	North Jetty	morpholgy recession from -30 to -20 ft along shore reach of 10,000 ft, 75% into inlet	3,700		2,700	
		morpholgy recession from -20 to 7 ft along shore reach of 9,000 ft, 75% into inlet	6,700	2,300	5,000	1,800
		morpholgy recession from 7 ft 13 along shore reach of 6,000 ft, 75% into inlet		1,300		900

North Jetty Degradation	Jetty "A"	60 Tons				

b. Jetty Head Recession Impacts Not Represented in SRB Model – Residual Risk

Vertical Deflation of Morphology. As represented in the SRB model, the jetty recession/ morphology change process is based solely on the incremental lateral reduction (cut) of the present tidal shoals (over a finite length), in relation to the incremental recession of the jetty heads. The vertical deflation of the inlet's shoals in response to jetty head recession is not included in the SRB model. There is a likelihood that this process actually occurs in response to jetty head recession. The added volume of sediment lost from the inlet's shoals due to vertical deflation of the shoals (incremental increase in O&M dredging) could approach the volume of sediment lost from the shoals by lateral reduction. The SRB model did not account for the vertical deflation of the inlet's shoals (due to jetty head recession) because there was a high degree of uncertainty as to if this effect would occur or how to best estimate the areal extent of the process.

Littoral Sediment Inflow. It is likely that as the heads of the MCR North and South Jetties recede landward, the volume of littoral sediment entering the inlet from the adjacent coastal areas will increase (along with O&M dredging). This process was not emulated within the SRB model. Combining the omission of this littoral shoaling process with the omission of the vertical component of morphology deflation within the inlet, it is likely that the SRB model is not accounting for a significant contribution of additional channel infilling (or omission of added O&M dredging cost) associated with jetty head recession. It was deemed more prudent to error on underestimating increased channel O&M dredging (and related cost) by omitting the above speculative effects, as opposed to overestimating O&M dredging costs by including the aforementioned effects. This rationale introduces residual risk of understating the O&M dredging costs (lost benefit) for not stabilizing the jetty heads. Alternatives that do not include head stabilization (head cap engineering feature) will have residual risk as described above.

Impacts to Inlet Stability. Without stabilization of the jetty heads at MCR, the morphology within and adjacent to the inlet will recede at a significantly higher rate as compared to the case where the jetty heads were stabilized. Long-term reduction (erosion) of morphology within a coastal-estuarine inlet such as MCR will act to increase wave action and modify current patterns within the inlet. Without the present function of MCR jetties, these changes would occur because the inlet would be preferentially deepened along its shallow flanks due to morphology erosion. Thalweg depth will remain approximately the same as the present condition. With depths increased along the inlet's interior margins, larger ocean waves can penetrate further into the inlet and current action becomes less aligned with the thalweg. The occurrence of such changes within the interior margins of the MCR inlet are likely to adversely affect sensitive ecology that normally resides within the inlet flanks or passes through the inlet. The SRB model does not account for the potential changes in environmental (ecological) conditions that would occur due to morphological deflation within the inlet.

Impacts to Navigation. As larger waves propagate further through the inlet (due to jetty head recession), under-keel clearance for ships can be reduced and the persistence of strong cross-currents will reduce ship handling through the MCR channel. The end result of an increased incremental rate of morphology loss within the MCR will be an incremental loss of deep-draft navigability through the inlet. Ship handing and keel clearance will be reduced through the more confined areas of the inlet due to increased wave and cross-current action, specifically along RM 1 to 4. The realized effect on navigability will be an increased occurrence of conditions at MCR when ship maneuverability is reduced, such that the frequency and duration of delay periods will increase for ships passing through the MCR. Bar pilots will have a harder time controlling the vessels during what are now deemed as nominal storm wave and tidal conditions, and the threshold for closing the bar (based on offshore storm wave height and tidal window) will be reduced. The end result will be more frequent inbound/outbound delays due to adverse wave action and tidal conditions, increasing the days per year when the MCR bar is closed to shipping. The cause and effect process between morphology loss and reduction of deep-draft navigability has been confirmed by the MCR Bar Pilots based on observed changes in ship handling characteristics correlated to bathymetry change during 1997-2007 [Jordan 2007]. The SRB model does not account for the reduction in deep-draft navigability that would occur due to morphological deflation within the inlet.

In summary, if the jetty heads are not stabilized (capped), the functional performance of the MCR inlet will be compromised by the residual risk of morphology deflation.

c. Jetty Rip Currents - Toe Scour and Root Erosion

Waves and currents constantly churn along the base of jetties and at the shoreface where the jetty root interfaces with adjacent topography, acting to create secondary circulation (eddies and counter currents). The secondary circulation along the jetties produces rip currents which erode sediment away from the jetty foundation (toe scour). Jetty toe-scour is a localized process that affects a finite volume of sediment along the seabed interface with the jetty. The toe scour zone along a jetty typically extends less than 200 ft away from the jetty toe-seabed interface. The volume of sediment directly affected by the toe scour process (within the scour zone) is relatively small, yet the degree to which toe-scour can affect jetty stability is large. Secondary circulation, motivated by jetties interacting with regional circulation, can mobilize sediment along the shore face adjacent to the jetties, resulting in shoreface recession. In many cases, the shore edge recession effect can extend for a considerable distance away from a given jetty and produce a large quantity of mobilized sediment.

Once mobilized and injected into the jetty rip current system, much of this shore edge sediment (50% to 80%, depending on jetty location) is transported by rip-currents that flow along each jetty, and deposited into the MCR channel. In general, annual O&M dredging at MCR is affected by 10% to 20% by the processes that govern shoreline retreat and rip-currents formation along the North and South Jetties. Figure A2- 23 shows schematically how jetty toe scour and shore recession are related and contribute to shoaling with the MCR channel. Implementation of engineering features such as spur-groins along a given jetty can mitigate the scour of the jetty toe and reduce shoreface recession along the root of a jetty, reducing the rip currents that form along a jetty. Jetty rip currents are responsible for both promoting jetty toe scour and for transporting eroded shoreface sediment into the navigation channel. Refer to Jetty Rehabilitation and Engineering Features and Table A2- 12) for a description of how jetty spur-groin engineering features are emulated within the SRB model.

Table A2- 12. Channel Shoaling Volume Attributed to the Processes of Shore Recession and Jetty Head Retreat on Morphology

1. North Jetty - Toe Scour and Root Erosion

As the ocean shoreline adjacent to the North Jetty recedes, the North Jetty root is exposed to increased wave action. Since the 1930s (after Peacock Spit attained its largest subareal extent), the shoreface along the North Jetty has been receding landward by 4-8 ft per year, not including the effect of jetty head recession. Much of the eroded sediment is transported into the MCR inlet by rip-currents forming along the jetty, adding to the O&M dredging required to maintain the channel. Table A2- 12 gives the estimated volume of sediment entering the MCR channel for every 100-ft of shore edge recession that occurs along the ocean side (Peacock Spit) of the North Jetty. The compounding effect of rip currents is to erode sand away from the submerged part of the jetty. Table A2- 13 gives values for scour along the North Jetty. Storm wave and surge/run-up action can destabilize the jetty slope and toe along the beach side of the North Jetty leading to degradation of the jetty root area.

2. South Jetty- Toe Scour and Root Erosion

The channel side shoreline along the (north side) root of the jetty is receding landward at 2-5 ft per year, not including the effect of jetty head recession. Currently, the eroded sediment is transported into the MCR channel and the channel side of the South Jetty is exposed to increased wave action. Table A2- 12 gives the estimated volume of sediment entering the MCR channel for every 100-ft of shore edge recession that occurs along the channel side (Clatsop Spit) of the South Jetty. As the ocean shoreline south of South Jetty recedes landward (2-5 ft per year), the ocean side root of the South Jetty is exposed to increased wave action. The sediment eroded away from the ocean side of the South Jetty root is not considered to enter the MCR channel. Table A2- 14 gives values for scour along the South Jetty. Storm wave and surge/run-up action can destabilize the jetty slope and toe along both sides of the South Jetty, where the jetty connects to shore, leading to degradation of the jetty root area.

Table A2- 14. SOUTH Jetty Morphological Factors for Modifying Wave Height

3. Jetty A - Toe Scour and Root Erosion

The present condition of the shoreface along each side along the root of Jetty A is highly resistant to erosion (stable) due to armoring from previous jetty repairs. Consequently, there is no sediment estimated to enter either the MCR or Ilwaco Channel due to the ambient recession of the shoreline on either side of Jetty A, not including the effect of jetty head recession. The jetty toe along the most of the outer half of Jetty A (ocean and estuary side) continues to experience scour due to rip currents that form along the jetty due to enhanced circulation motivated by flood and ebb tide action. Future scour along the outer-most part of Jetty A (> sta. 95) is expected to stabilize, while scour along areas between sta. 65-95 will continue. Table A2- 15 gives values for scour along Jetty A.

Table A2- 15. JETTY A Morphological Factors for Modifying Wave Height

Jetty Station	Side of Jetty	PAST Life-Cycle 1939 - 2006 Estimated	Observed	Present Seabed Elevation	FUTURE Life-Cycle 2006-2070 Estimated	Estimated

d. Jetty Breaching

The function of each MCR jetty has evolved through time. When initially constructed, the jetties functioned to diffuse (or flush) the inlet's shallow broad tidal shoals which had significantly restricted navigation across the bar at the MCR. Once the inlet's tidal shoals were re-oriented by the flushing action of the MCR jetties, the function for the jetties was to maintain a stable deep thalweg through the inlet. Through time, the function of the MCR jetties has evolved to include an additional objective - to hold sediment (morphology) in place along the inlet's interior and exterior margins. Each MCR jetty now acts to retain 10's of millions of cy of tidal shoal sediment.

The most efficient way to release sediment back into the MCR inlet is to "punch a hole" (breach) through the jetty along an area where waves and currents can quickly mobilize a large volume of sediment. The likelihood of a jetty breach is low, but can increase with decreasing jetty resilience. If the jetties are not maintained, then unchecked degradation of the cross-section will lead to reduced jetty resilience and the rate of jetty deterioration will increase. Jetty resilience can also decrease if the loading conditions increase, if the regional wave environment becomes more severe (non-stationary climate), or the inlet's morphology is reduced (non-stationary morphology). See Section 5 and Figure A2- 24 for additional discussion regarding jetty cross-section deterioration rates as a function of maintenance strategy and other life-cycle considerations. Figure A2- 25 shows schematically how a jetty breach can contribute to shoaling with the MCR channel.

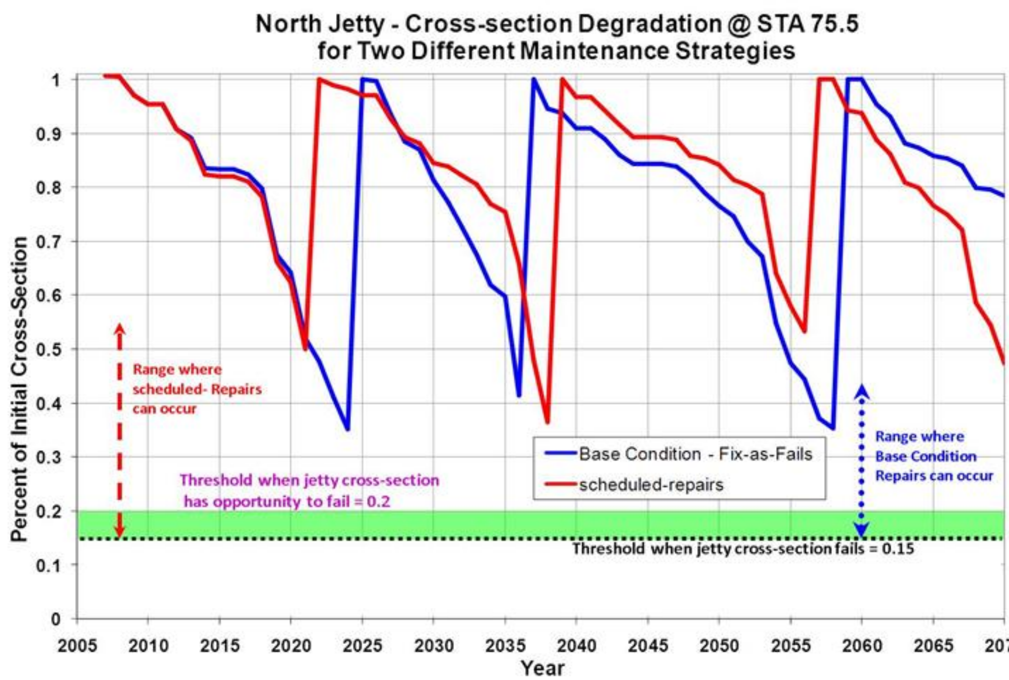

Figure A2- 24. Jetty Cross-Section Degradation Rate and Repair Timing

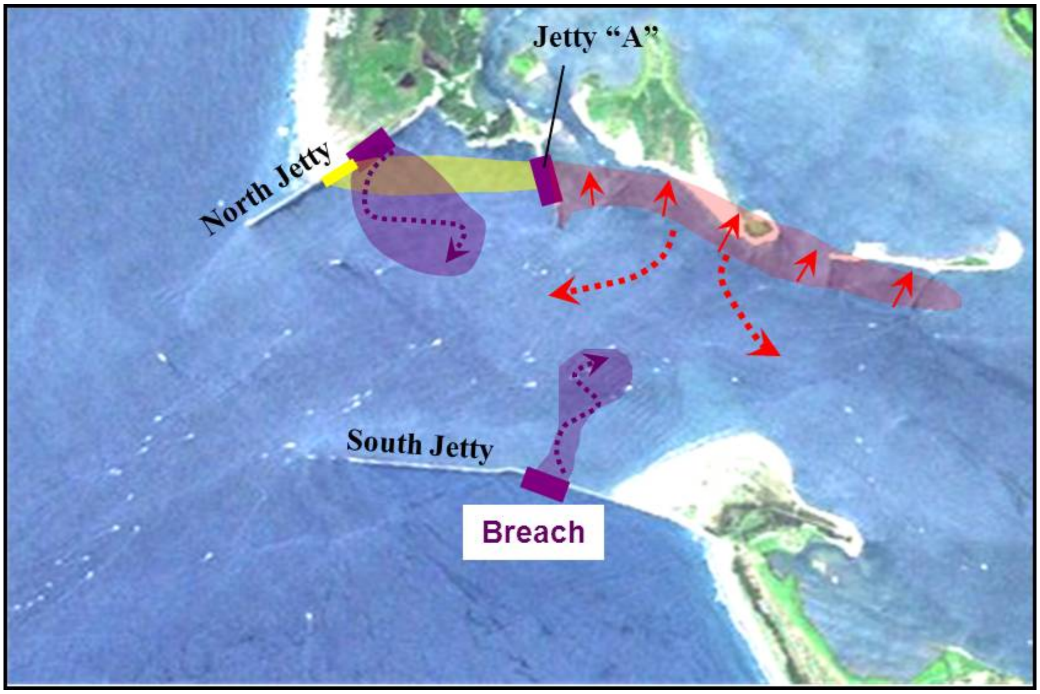

Figure A2- 25. Effects of Jetty Breaching at MCR Inlet for Shoaling and Jetty Stability

e. Tsunami

The specter of a tsunami is a reality for the coastal margin along the Pacific Northwest of North America. The last Cascadia Subduction Zone (CSZ) earthquake to affect the northwest coast of North America occurred in 1700 (8-9 magnitude, 50-150 miles offshore). It is estimated that the re-occurrence interval for these events is approximately 400 years. The USGS has speculated that there is a 1:6 chance that such an event will occur within the next 50 years. The tsunami generated from an 8-9 magnitude Cascadia earthquake could range from 5 ft to 30 ft high along the present shoreface. Co-seismic subsidence (due to strain release of the earth's tectonics) may induce immediate lowering of the coastal margin by 2-8 ft [Atwater and Hemphill-Haley 1997]. The effect of a 5-30 ft tsunami on the MCR jetties would be significant and transient, likely to destabilize the roots of all the jetties due to overland flow eroding the morphology along the jetty roots. The jetty roots may be flanked. Immediate repairs would be needed to re-secure the jetty roots. The seaward ends of the jetties could be affected by significant scour due to the volume of water transported into and out of the inlet in response to tsunami passage. A significant volume of sediment may be mobilized and deposited within the MCR inlet. Violent shaking of the jetties would likely destabilize many areas having a side slope steeper than 1V:2H. Liquefaction of the jetty foundation may occur and initiate jetty settlement and toe failure. If vertical co-subsidence occurred with the CSZ temblor, the long-term effects on the jetties and existing land margin being lowered by 2-8 ft may be more profound than the earthquake and tsunami. Jetty freeboard could be significantly reduced and depth-limited wave height would be significantly increased. This effect would significantly increase the rate of jetty degradation and expose the landward areas of each jetty to increased wave loading and overtopping. Jetties that were in a good state of repair (or recently rehabbed) would be more resistant to earthquake-related damages as opposed to jetties that were in a condition of deferred repair. The effect of a tsunami is presently not addressed within the SRB model.

5. COMPONENTS AND PROCESSES OF SRB LIFE-CYCLE MODEL

The SRB model is a computer simulation which integrates many simple interacting considerations governing jetty response and performance. The modeling objective is to simulate time varying condition of the jetty and estimate costs associated with the functional performance of the jetty. A key limitation that must be understood is that the SRB model simulates outcomes based on many assumed input conditions; most are cast in terms of uncertainty. Models provide insight, not answers. The SRB model produces bounded estimates. By using Monte Carlo simulation within the SRB model, these estimates can be given a specified level of certainty (or uncertainty).

a. SRB Model Structure

The SRB model uses a project event tree (Figure A2- 9 through Figure A2- 11) as the basis for conditional logic, decision making, and consequence evaluation for assessing jetty life-cycle performance. The SRB model was developed within Portland District based on a similar approach used to evaluate rehabilitation of Burns Harbor breakwater at Portage Indiana [USACE 1993]. The SRB model simulates a jetty life-cycle in a series of one year increments. A model year begins June of calendar year 1 and ends May of year 2. This timing captures the storm climate during fall-spring within the same year and repair structure damages the following year (during summer construction season). The coding structure and organization of the SRB model is schematically shown in Figure A2- 9 through Figure A2- 11. The primary actions undertaken during SRB model development were to:

1) Adequately describe the forcing environment affecting the jetty cross-section,
2) Simulate jetty cross-section response to environmental forcing,
3) Estimate consequence of jetty breaching, should it occur, and
4) Emulate jetty maintenance intervention.

The SRB model was written in MATLAB and is composed of a number of script (.mat) files and modules (functions), each to perform specialized tasks. The modules independently deal with generating realizations of life-cycle wave and water level environment, interpolating the realized wave environment continuously along the jetty, calculating reliability, performing cross-section geometry calculations due to damages, and other tasks. A more detailed description of the model structure is provided in the *User's Manual*.

The SRB model considerations include: (1) existing condition of structure; (2) previous repairs of structure; (3) foundation conditions; (4) failure modes; (5) structure function; (6) exposure to changing wave conditions; and (7) coupling between jetty function and morphology evolution of the tidal shoal(s) directly adjacent to each jetty. Physical and numerical modeling was conducted to evaluate the forcing environment (waves and currents) along each jetty and the response characteristics of various jetty design sections.

Each SRB model assumes a pre-specified nominal evolution in environmental forcing as related to the expected long-term morphological change of the MCR inlet (refer to Foundation Effects in Section 6). Localized changes in environmental forcing along each jetty, attributed to progressive specific changes in function of a given jetty, are also included in each SRB model. The SRB model for Jetty A accounts for subsequent effects on the inlet, should the function of Jetty A be compromised. Recall that Jetty A is functionally linked to the North Jetty by reducing the ebb current (scour) that would affect the North Jetty, in the absence of Jetty A. Jetty A also stabilizes the morphology along the north side, and to a lesser extent, the south side of the inlet thalweg. The Jetty A SRB model accounts for the one-way localized interaction of Jetty A with the North Jetty, and for localized interaction of Jetty A with Clatsop Spit. The SRB models for the North and South Jetties do not account for interaction with Jetty A, nor do the models interact with each other.

In general, the SRB jetty models do not simulate the consequences of interaction between the jetties. If the SRB model for the South Jetty predicts severe jetty degradation (head recession or jetty breach) such that Clatsop Spit would devolve significantly over time, there is no inlet-wide effect implemented within the SRB model to account for related impacts that may be realized by the North Jetty, Jetty A, or within the inlet itself. Additionally, if all three MCR jetties were (independently) predicted to significantly degrade over time such that the respective morphology affected by each jetty devolved, it is likely that the regional wave and current environment in the MCR inlet would be modified to adversely affect: A) navigation passing though the inlet; and B) each jetty by more vigorous regional environmental loading than estimated in the SRB models. These regional effects are not simulated in the SRB models due to the uncertainty involved in attempting to evaluate such large-scale effects within the complex MCR system. The above scenarios demonstrate the level of residual risk not captured by the models and is further discussed in *Engineering Feature Analysis*.

b. Input and Output Data Definition

Parameters utilized within the SRB model include: time-varying shoreline evolution along each side of the jetty, time- and spatially-varying scour rates along each side of the jetty, time- and spatially-varying wave conditions along each side of the jetty, time-varying water levels, variable jetty root degradation rates, spatially-variable and time-varying jetty cross-section attributes (for each side of the jetty).

Two stand-alone scripts are used to convert Excel-based data into MATLAB (.mat) files for input to the SRB model. The input data conversion process (from Excel to MATLAB) deals with data that defines the present physical condition of the jetty, STWAVE model output, wave damage functions, and rehabilitation and engineering feature costs per jetty segment. The data file conversion is performed only one time; after which the SRB model automatically reads the input data from the MATLAB (.mat) data file every time the SRB model is run. Other data types and SRB model control parameters are specified directly within the model script. Most of the model control parameters are located within the first 175 lines of the SRB model. All parameters (model control and data definition) are described within the SRB model through commenting of the code.

When executing a hindcast SRB simulation, the initial condition geometry, jetty armor/core stone attributes, and jetty foundation scour rates are defined for the entire jetty, on a segment by segment basis. A jetty segment is 100-ft long. The historical repair sequence is defined within the model to define the number of times segments can be rebuilt, repair cross-section attributes, and the applicable threshold to initiate repairs. Future life-cycle simulations use the ending jetty condition from the hindcast to describe the initial jetty condition (geometry and armor stone characteristics) in the forecast. This means that a calibrated hindcast simulation must be completed (with hindcast MATLAB [.mat] output files saved), prior to initiating a future life-cycle simulation.

The SRB model does allow for the use of observed geometry data (present jetty survey) to override the simulated end-state jetty geometry obtained from model hindcast. In this case, the SRB model would use "observed" survey data to define the initial forecast condition when conducting future simulations. The "observed" geometry option was used to define the initial condition for jetty geometry for all SRB life-cycle forecasts conducted in this study. Because there is no objective way to estimate the armor layer characteristics for the forecast initial (present day) condition along each jetty, the calibrated SRB hindcast solution was utilized to define initial conditions for armor stone characteristics along each jetty, when forecasts where conducted. For additional information on hindcasting performed to support this study, refer to Section 7.

Various types of SRB model output can be saved to files, depending upon SRB parameters set within the model. Output produced by the SRB model includes ACSII text-based data files (for life-cycle repair tonnage and incremental dredging volume) expressed in a mean value and standard deviation. Multiple graphical summaries are produced for pertinent model metrics describing the spatial and time-varying conditions of a given jetty. The entire MATLAB simulation environment, containing all variables accessed or created by the SRB model, can be saved as a .mat file.

1. Future Life-cycle Simulations

Future Jetty Repairs. Jetty repairs may be enacted at three different levels of response, depending on the urgency for repairs. In a normal O&M level, jetty repair areas are identified and executed in a methodical manner (multi-year planning effort). In an expedited level, jetty repairs are fast-tracked and made within one year of problem identification. Expedited repairs may be made to prevent the onset of a breach, when the jetty is in an advance state of degradation. Expedited repairs are enacted for the South Jetty and Jetty A in response to a jetty breach. In an emergency level, jetty repairs are executed within 2-6 months, in response to a serious breach along the North Jetty. Within the SRB model, jetty repair costs associated with normal O&M and expedited repair efforts are tracked separately from emergency repairs, which are associated with significant breach events.

Rehabilitation and Engineering Features. Within the SRB model, tonnage for jetty rehab elements or engineering features was pre-determined based on design template cut and fill volume computations. A design template (cross-section and profile) was developed for each alternative, and the existing jetty surface or seabed grade elevation was subtracted from the template surface to determine the volume of "new" work. This volume was converted to jetty stone tonnage per jetty segment (100 ft). Rehab cost per jetty segment was determined by multiplying tonnage/segment by the unit cost for the rehab alternative ($/ton). Unit costs (including mob-demob, mitigation, and other cost factors) for various rehabilitation alternatives were estimated by the NWD regional cost estimating team within the MII framework. The material tonnage and cost for engineering features was determined in a similar manner. Within the SRB model, rehab alternatives and engineering features are sequentially implemented along a jetty according to a pre-specified schedule. This process emulates the "real life" implementation schedule. If degradation of the jetty cross-section occurs before a given rehab alternative is implemented, then the tonnage for the rehab alternative is increased to account for additional cross-section replacement. If future jetty repairs occur at a given location before a rehab alternative is implemented (due to cross-section degradation), then the tonnage of the rehab alternative is reduced to account for cross-section being supplemented through the repair action. Within the SRB model, costs associated with implementing jetty rehabilitation and engineering features are tracked separately from jetty repair costs.

Incremental Dredging Costs. The SRB model can estimate the volume associated with increased channel dredging (due to loss of jetty function) that are incrementally within the normal O&M program, or that exceed normal O&M outlays. Incremental O&M dredging volume can occur through: A) landward retreat of the jetty head; B) landward recession of shoreface along the ocean side or channel side of the jetty; and C) scour of the tidal shoal along the jetty toe. Dredging costs that exceed the normal O&M outlay are the occurrence of a jetty breach allowing the progressive migration of tidal shoal sediment into the estuary and navigation channel. At some locations along the North Jetty, a jetty breach can result in the rapid release of sediment into the navigation channel. In this case, emergency dredging may be required to mitigate shoaling within the MCR navigation channel. Within the SRB model, dredging associated with incremental impairment of jetty function (head recession and local scour effects) are tracked as O&M dredging volume. Dredging motivated by jetty breach events are tracked separately from O&M dredging volume.

c. Jetty Segmentation

Within the SRB model, a jetty is divided into 100-ft long semi-independent responding segments. Segmentation allows for the jetty to be modeled as a system of interacting components, the response of each being described by a specific performance mode relating to head recession, foundation erosion, slope stability, and wave-induced damage. The SRB model uses these performance modes to simulate jetty response over a specified period of time (a given life-cycle), by evaluating the cumulative structural response of the jetty cross-section in 1-year time steps. Jetty damage is simulated to occur in winter (damage being motivated by storm wave action) and, if needed, jetty repairs are simulated to occur the following summer (when construction activities are normally executed). If a jetty fails during winter, before normally programmed repairs can be activated the following summer, the jetty response is described as "breached." A breached jetty may require implementation of an emergency or expedited repair action, depending upon the impending severity of the breaching consequences. Expedited repairs are more costly to execute (cost per ton of placed jetty stone) than normal repairs, and emergency repairs are more costly than expedited repairs.

For this study, application of the SRB life-cycle model is initiated by first simulating the structure's previous life cycle history (hindcast). Correct simulation of the jetty's previous life-cycle produces a calibrated model that can be used to evaluate structure performance in the project environment. The calibrated SRB model is then used to project the existing jetty condition into the future. Future life-cycle simulations were performed for variable maintenance strategies and a range of graduated rehabilitation alternatives.

d. Lateral Subdivision of Jetty Cross Sections

Recall that within the SRB model, the entire jetty is segmented into 100-ft long semi-independent responding segments. The initial condition for each segment is described by specific cross-section geometry and armor-core stone attributes, which can vary along segments and on each side of the jetty (oceanside vs. channel side). The centerline of the present jetty crest serves as the boundary to split the segment cross-section into channel vs. ocean side. Refer to Figure A2- 18 for jetty cross-section element definition. Segment attributes include toe elevation, crest elevation, crest width, jetty side slope, armor stone characteristics (size-tons, stability number, density), and core stone presence. All segment attributes are described in terms of a mean value and standard deviation to enable segment-based reliability calculations.

e. Vertical Subdivision of Jetty Cross Sections

Each segment is divided into two vertical areas (upper section and lower section) based on an elevation of -5 ft MLLW. Above this elevation (WAV_EL) wave damage generally controls jetty cross-section evolution; below WAV_EL the cross-section evolution is generally controlled by scour or static slope instability issues. If the jetty toe elevation is higher than -7 ft MLLW, then the demarcation between upper and lower sections is set at jetty toe elevation, plus 2 ft. This allows for the vertical subdivision of a jetty cross-section in shallow water regions, where the jetty toe may be higher than -5 ft MLLW. The 2-ft offset is the minimum vertical distance required to represent geometric changes in the lower section of a jetty (within the SRB model) as motivated by slope/foundation adjustment processes associated with jetty toe scour.

f. Cross-Section Damage Process – Lower Section

The lower cross-section of each jetty segment can be affected by foundation (toe) scour which motivates slope stability issues (static failure modes). The initial condition for the lower slope along the jetty is assumed to be constructed to a statically stable configuration (slope is equal to or flatter than 1.5H:1V). The degree of damage sustained by the lower cross-section each year of the simulation is based on how much jetty toe can be lowered due to scour, before the lower slope is steepened beyond a limiting value (slope steeper than 1.3H:1V). The limiting value (of 1.3H:1V) for the lower slope was based on results from a slope stability analysis reported in Appendix B, *Geotechnical Studies*. If the limiting slope value is exceeded, the lower slope "fails" at the new toe elevation (hinge point) and the steepened slope rotates into the jetty cross-section until a stable slope is attained (1.4H:1V). This process emulates a creeping failure of the lower section slope where the jetty toe incrementally follows the vertical progression of foundation scour. This creeping slope adjustment, due to jetty toe scour, is what has been observed to occur along jetties subjected to foundation scour. Adjustment of the lower cross-section can affect the upper slope if geometry conditions allow (Figure A2- 18). The displaced jetty section (stone) falls downslope leaving non inter-locked and unstable stone behind. The displaced stone provides little function to the jetty. The area of damage associated with the toe elevation and slope re-adjustment is calculated based on geometry change for the upper and lower cross-section. The damage areas are then subtracted from the area remaining within the segment (upper and lower sections).

g. Cross-Section Damage Process – Upper Section

Reliable simulation of jetty performance requires accurate and consistent accounting of cross-section damage. Considerable effort was invested in SRB model development to ensure continuity in cross-section area change, with respect to changes in jetty crest width and crest elevation. Accurate tracking of damages sustain by the jetty cross-section and related changes in structure configuration are crucial for several reasons:

- Jetty crest width reduction indicates the degree to which the armor layer is disturbed and indicates the extent to which core material is exposed to wave action. Reducing the crest width on a given side of the structure lowers the threshold for wave damage and decreases the reliability of the jetty segment by lowering the stability number (Kd) for the disturbed armor stone remaining on the cross-section. If sufficient armor stone is displaced off the jetty cross-section such that core stone is subjected to direct wave action, then the effective size (W) of the "armor" stone is decreased in proportion to the relative amount of true armor stone remaining on the jetty slope.
- Jetty crest elevation reduction decreases the jetty freeboard, increases the potential for wave damage on the lee of the jetty due to wave overtopping, and decreases the reliability of the jetty segment.
- As the area of the jetty cross-section is reduced, the resilience of the jetty segment decreases, affecting the jetty reliability and increasing the likelihood for segment function failure (breaching).

The upper cross-section of each jetty segment is affected by wave-related loading (dynamic failure modes) when wave action exceeds the capacity of the jetty armor units (or exposed interior material) to resist being displaced off the upper cross section. The upper section can also be affected by static stability modes migrating upward from the lower cross-section.

Wave damage can be caused by waves impinging on the area of the jetty facing the waves or by waves overtopping the jetty and attacking the crest or lee side of the jetty. Wave overtopping can be considerable when the jetty freeboard is reduced by either high water levels or by a low crest elevation (low by design or through accumulated damage). Many areas of the North and South Jetties are subjected to heavy wave action on both sides of each jetty. This means that the jetty can be directly attacked and overtopped from both sides of the jetty (Figure A2- 26). If armor units or core stone are displaced by wave action, they can be toppled off of the cross section or redistributed in a chaotic and unstable manner. In either case, the damaged jetty section is considered to have experienced reduction of cross-section area and loss of stability.

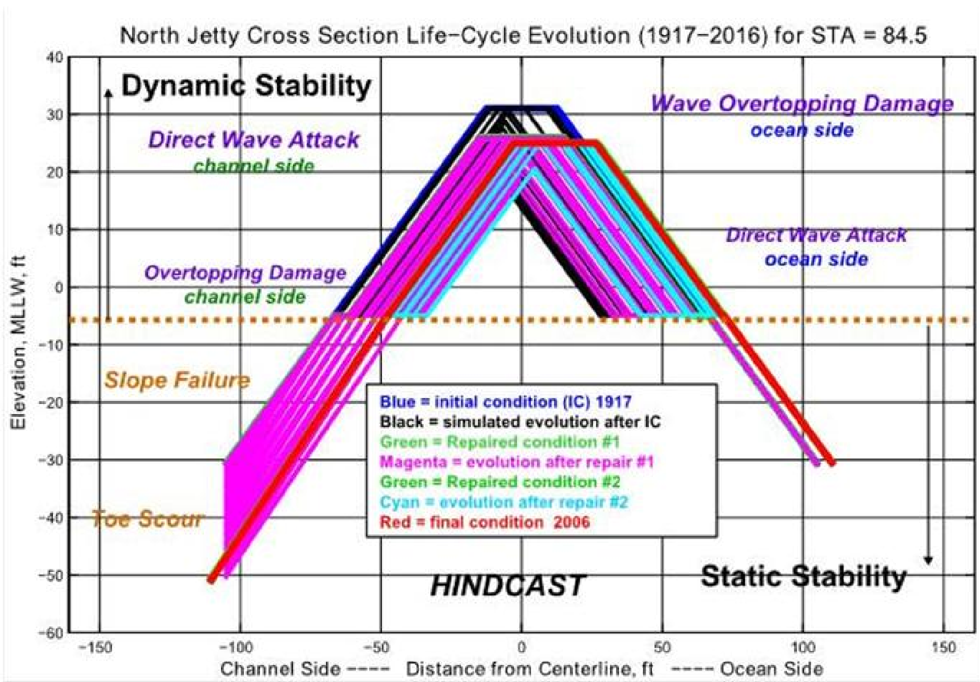

Figure A2- 26. Evolution of Jetty Cross-Section within SRB Model

Evolution of jetty cross-section at station 84+50 based on one realization for hindcast simulation for the MCR North Jetty. The cross-section at this location of the jetty was repaired 2 times during 1917-2006.

Within the SRB model, damage sustained by each jetty segment is accumulated through time. The jetty cross-section is repaired to the full standard template area after the jetty cross-section has been reduced below a prescribed maintenance threshold. If a given jetty segment sustains a very high rate of damage, the segment can fail (breach) before normally planned repairs can be executed. A sizable percentage of the displaced stone armor units and core stone can be "re-used" within the jetty repair template. Figure A2- 15 shows the change in cross-section area for one segment along the North Jetty (at sta. 84+50), during 1917-2006 and is based on one realization for a hindcast simulation. The jetty cross-section degrades and is rebuilt based on the resiliency of the jetty cross-section and its exposure to the forcing environment. The results shown in Figure A2- 15 are performed for each 100-ft segment along the entire jetty.

h. Jetty Damage Functions – Wave Action

Extensive physical model testing was conducted by USACE-ERDC to develop damage functions for the MCR jetties [Ward et al., 2007]. Refer to Appendix A1 for a detailed description of the ERDC physical model setup, testing procedure, jetty cross-section plan development, and testing results. Jetty cross-section configurations evaluated included the existing damaged jetty, restored standard jetty template (interim repair), and 2-8 rehab plans per jetty. Model tests were performed for both stone armor and concrete armor units. The "pool" of best candidate rehab cross-section configurations was narrowed to three plans for the North Jetty, four plans for the South Jetty, and one plan for Jetty A.

The damage functions express wave damage (reduction in cross-section area) vs. incident wave height at the jetty. Figure A2- 27 through Figure A2- 31 describe wave damage functions developed for specific jetty cross-section configurations, for both the North and South Jetties. North Jetty damage functions were used to simulate Jetty A cross-section response. The wave height ordinate values expressed in the damage functions are equivalent to the significant wave height averaged during the peak 2 hours of prototype storm duration. Peak wave height for Pacific Northwest maritime storms, affecting coastal zone, varies from 1 to 4 hours in duration. Physical model tests were conducted incrementally for progressively increasing wave height. A given wave condition was run for 2-hour prototype duration with subsequent incremental cross-section damage being measured.

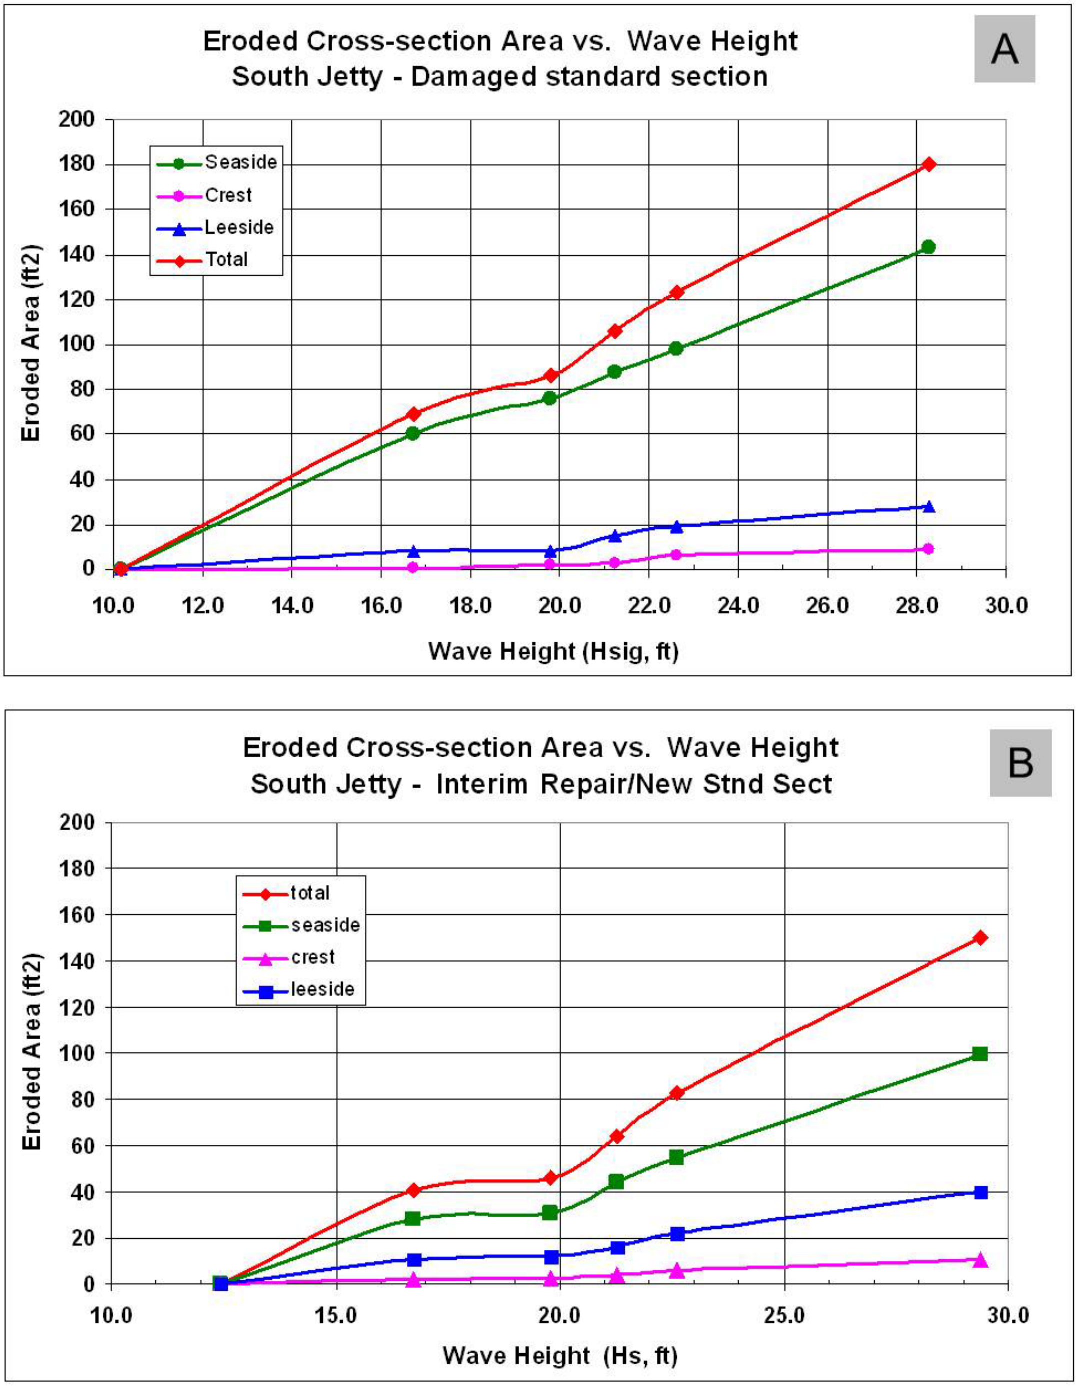

Figure A2- 27. Damage Functions for MCR South Jetty Damaged and Standard Template

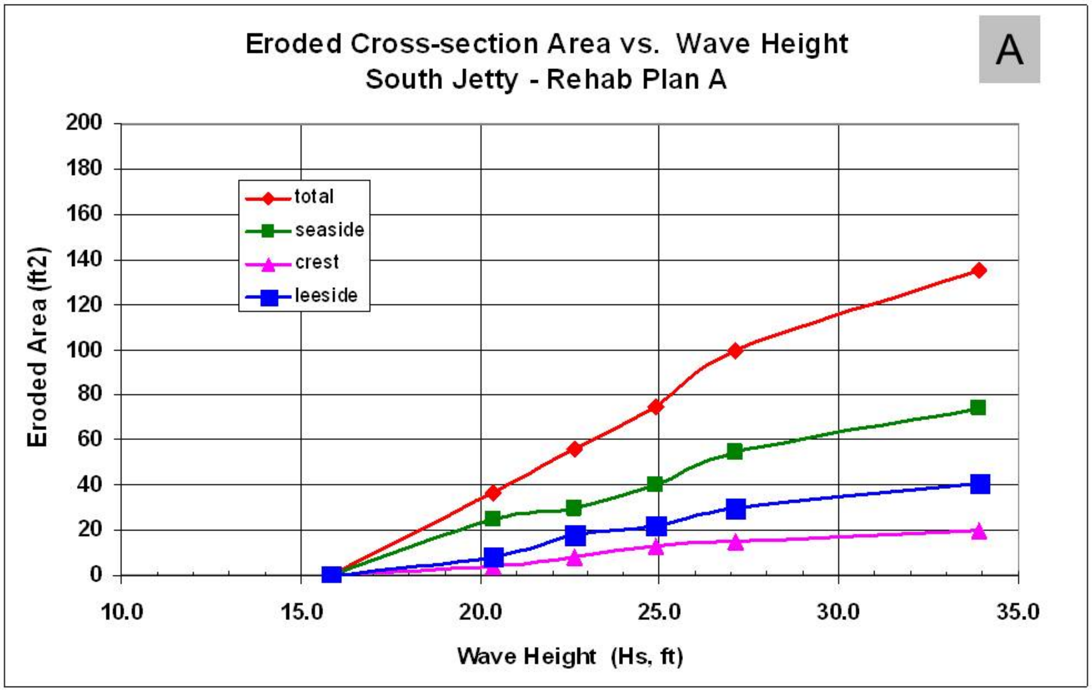
Damage functions for MCR south jetty. A) Applies to jetty segments where a standard cross-section has been used and has become damaged. B) Applies to jetty segments based on a standard template that has not been damaged. Damage functions developed at ERDC physical model study [Melby and Ward 2006]. Above damage functions apply to historical jetty cross-sections.



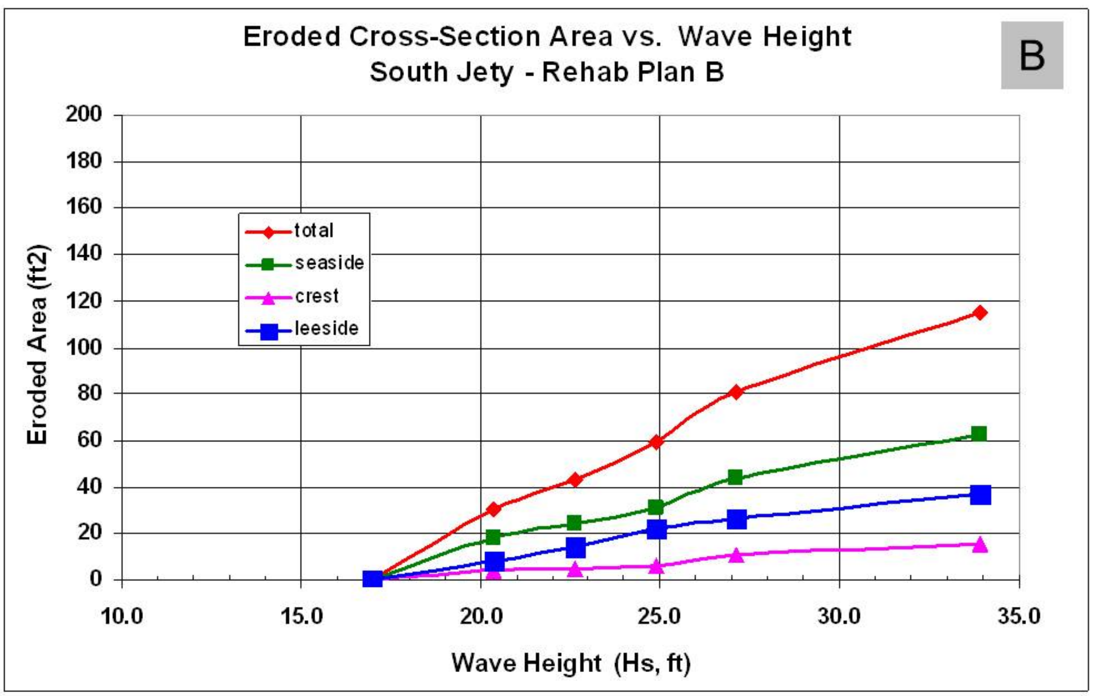


Figure A2- 28. Damage Functions for South Jetty Rehab Plans A and B

Damage functions for MCR South Jetty. A) Applies to South Jetty rehab Plan A. B) Applies to South Jetty rehab Plan B. See Appendix A1 for a description rehab plan cross-sections and design attributes. Damage functions developed at ERDC physical model study [Melby and Ward 2006]. Above damage functions apply to inshore jetty locations (Sta 230).

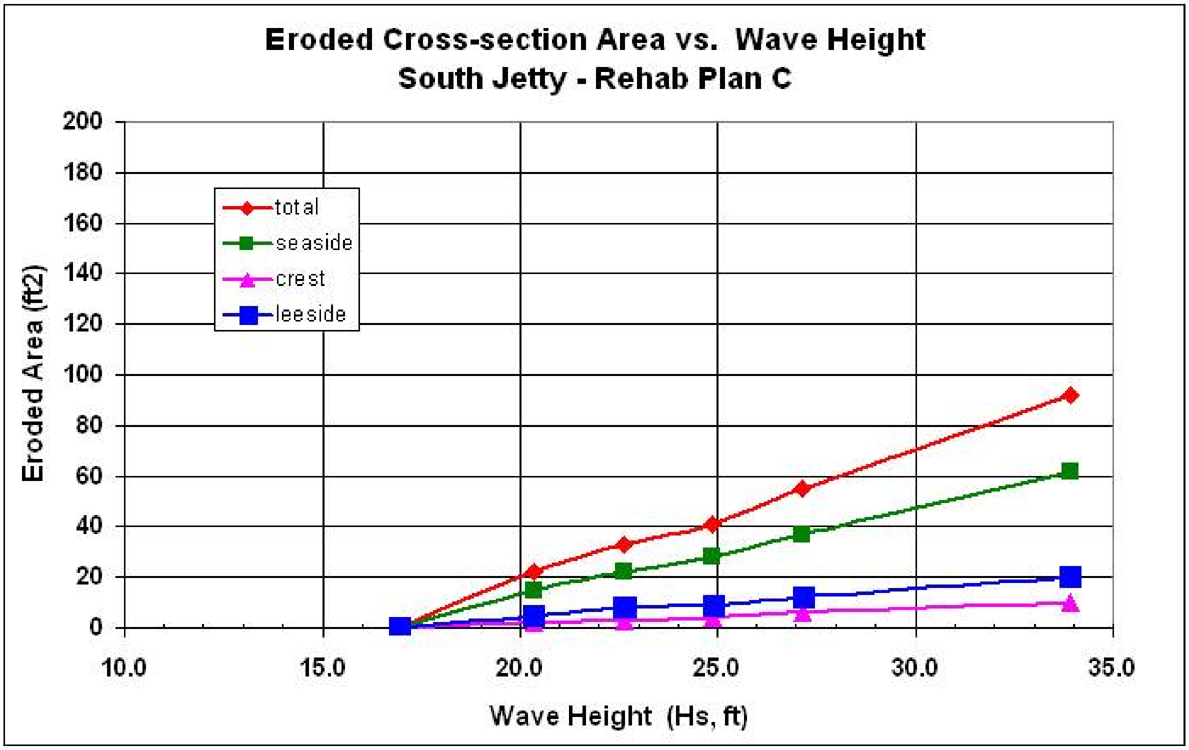

Figure A2- 29. Damage Functions for South Jetty Rehab Plan C

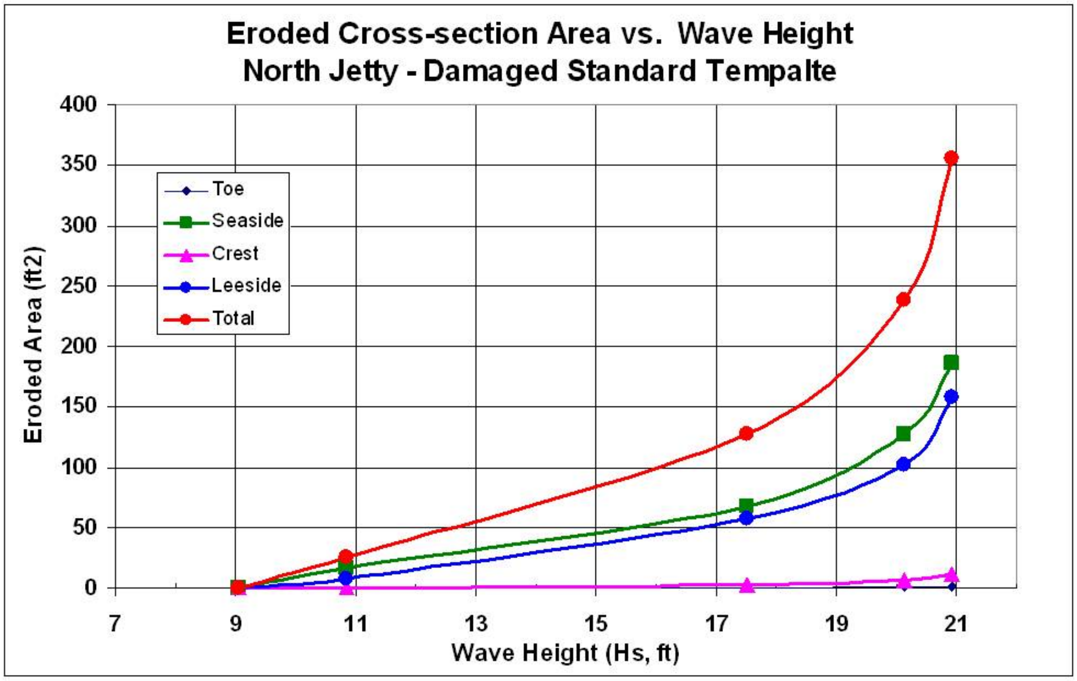
Damage function for MCR South Jetty rehab Plan C. See Appendix A1 for a description rehab plan cross-sections and design attributes. Damage functions developed at ERDC physical model study [Melby and Ward 2006]. Above damage functions apply to inshore jetty locations (Sta 230).



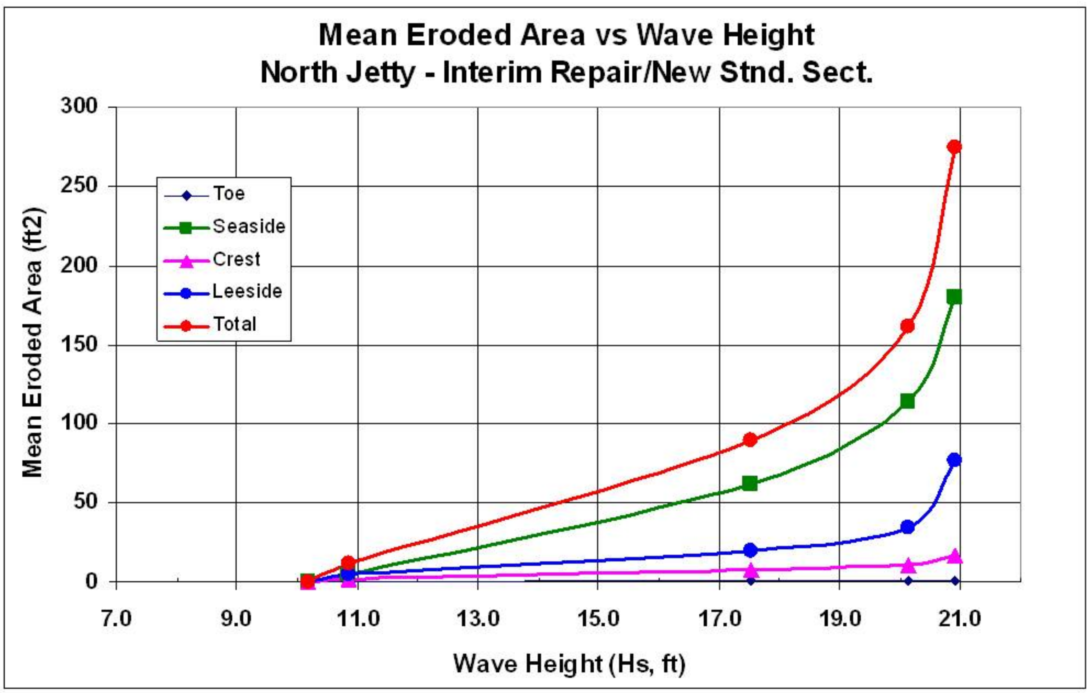


Figure A2- 30. Damage Functions for North Jetty and Jetty A Damaged and Standard Template

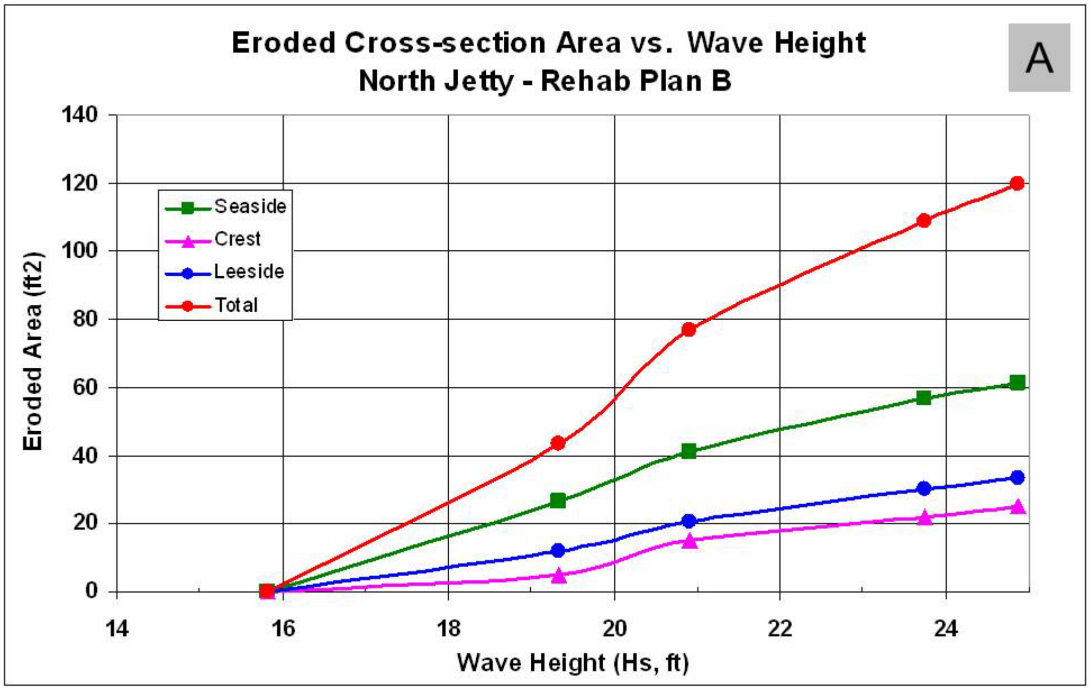
Damage functions for MCR North Jetty and Jetty A. A) Applies to jetty segments where a standard cross-section has been used and has become damaged. B) Applies to jetty segments based on a standard template that has not been damaged. Damage functions developed at ERDC physical model study [Melby and Ward 2006]. Above damage functions apply to historical jetty cross-sections.



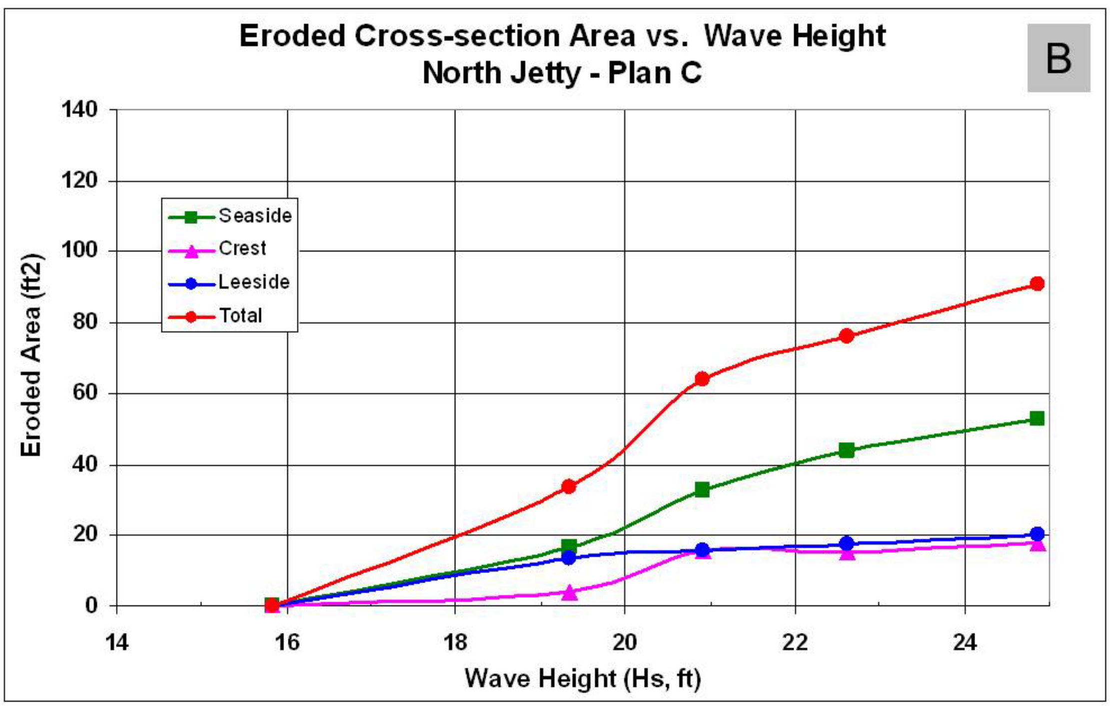


Figure A2- 31. Damage Functions for North Jetty Rehab Plans B and C

Damage functions for MCR North Jetty. A) Applies to North Jetty rehab Plan B. B) Applies to North Jetty rehab Plan C. Plan A was not used for this analysis. See Appendix A1 for a description rehab plan cross-sections and design attributes. Damage functions developed at ERDC physical model study [Melby and Ward 2006]. Above damage functions apply to inshore jetty locations (Sta 230).

Specific jetty cross-section configurations were used to emulate existing damaged jetty sections, repaired "standard repair template" sections, and rehabilitation alternatives. The threshold value for the onset of wave damage, as described by specific damage function, was adjusted depending upon the level of progressive deterioration for the jetty cross-section of interest. The wave damage threshold was also adjusted to account for the robustness of various jetty maintenance scenarios.

The threshold values for jetty head cross-sections were adjusted to account for increased or decreased resilience for a given jetty head configuration. Figure A2- 24 shows how the maintenance threshold for enacting repairs can vary based on the type of maintenance strategy assigned to a given jetty. The scheduled repair strategy is more proactive than the base condition by allowing jetty repairs to occur earlier in the degradation phase to reduce the chance of segment failure (before repairs can be initiated). Scheduled repairs also employ a more resilience (better built cross-section) than the base condition, so the degradation rate for scheduled repairs is usually less than for the base condition. Threshold adjustment (for value of wave height initiating jetty damage) was implemented based on stability equations indicating when: A) a given armor unit size (W_{50}); B) stability number (Kd or equivalent); and C) cross-section configuration would be damaged by wave action. The process of life-cycle hind-casting provided the opportunity to calibrate the SRB model for each jetty. The calibration process focuses on resolving the threshold values for applicable wave damage functions. The calibrated models (for each jetty) were then used to conduct life-cycle forecasting.

i. Wave Action, Cross-Section Area Change, and Repair Tonnage

For each year within a life-cycle simulation, there can be 1 to 11 storms that can affect the individual segments along a given MCR jetty. If the incident wave height for a given storm event exceeds a specified damage threshold value, the jetty segment cross-section is damaged according to applicable damage functions. Wave damage is expressed in terms of cross-section loss. Each side of the jetty is evaluated for a given storm, and wave damage is rendered onto each side of a segment's upper cross-section based on whether the waves are incident to or overtopping the jetty. Annual wave damage imparted onto a given jetty segment results in variable cross-section reduction, per year. The cumulative effect of wave damage reduces the upper cross-section of the jetty over time (for each segment). When the area of the upper cross-section is reduced to a specified maintenance level, the upper cross-section is repaired to restore the cross-section to a specific design template area. The amount of armor stone (repair tonnage) needed to restore the damaged jetty segment is based on the difference between the design template area and the cross-section just prior to repairs. Repair tonnage for a given jetty segment is calculated assuming that the void ratio for placed armor is 0.7:

Repair Tonnage per 100-ft Jetty Segment (for the upper cross-section) =
= 0.7 x gamma x 100 x (Initial Template Area – Area Immediately Prior to Repair) / 2000

As an example, based on a typical North Jetty segment repair, the repair tonnage would be
= 0.7 x 167 lb/ft^3 x 100 ft/segment x (2250 ft^2/segment – 800 ft^2/segment) / 2000 lb/ton
= 8,475 tons

The damage trends and repair scenarios emulated in the SRB model are intended to follow closely with prototype conditions. As the upper cross-section becomes significantly damaged (>1/2 of the crest width is missing on a given side of the jetty), the wave height threshold for initiating damage is reduced and rate of damage sustained by the "damaged" section increases. At this point, the armor layer has been highly disturbed (Kd has decreased) with much of the armor layer being displaced off of the upper cross-section. If sufficient armor stone has been displaced off the jetty cross-section such that core stone is subjected to direct wave action, then the effective size of the "armor" stone is decreased in proportion to the relative amount of true armor stone remaining on the jetty slope.

Recall that a jetty's structural performance is characterized by the capacity of the cross section to resist imposed environmental loading. If the loading exceeds capacity, then the segment incurs damage at specific areas of the cross-section, as governed by applicable failure modes (described by damage functions for upper and lower cross-sections). The functional performance of a jetty is defined by its ability to perform the intended function, within context of sustained structural damage. A given cross-section may be able sustain significant degradation (exhibit poor structural response) yet still provide adequate functional performance, providing that the cross-section has resiliency. At the limit at which the cross-section becomes too small to prevent wave action from breaking through the jetty, the jetty becomes breached, it fails and jetty function is lost at the segment. Segments are considered to be semi-independent because each segment incurs damage independently, yet as one segment fails (looses function), the failed segment can cause neighboring segments to also fail if the neighboring segments have incurred upper section damage beyond a specified threshold (40% of initial section area).

j. SRB Model Simulation of Jetty Repairs – Maintenance Threshold

As is the case of the prototype condition, an active jetty segment located within the body of the jetty is normally repaired before a breach is allowed to occur. Breaching of a jetty segment may occur when the upper cross section area is reduced to a range of 15%-20% of the standard template area (Table A2- 16). At this point, only a fraction of the jetty will be functioning to resist wave action and surface currents. The highly damaged jetty cross-section would be composed of smaller core stone having crest elevation less than 5 ft MLLW. All armor stone is likely to be displaced off the upper cross-section (from jetty crest to -5 ft MLLW). If there is armor stone remaining on the upper section, it will be disjointed and posses little stability. The threshold range for jetty cross-section breaching is based on field experience at other jetty entrances to coastal inlets (Coos Bay, Tillamook Bay, and MCR). The longer the segment remains un-repaired once its cross-section area falls below 20%, the higher the likelihood that the segment will breach. If the cross-section area is reduced to less than 15% of the standard template, the jetty segment is forced to breach within the SRB model.

Table A2- 16. Standard Cross-section Template used to Assess When Jetty Repair or Breaching Occurs for MCR Jetties (recent past and future conditions)

Jetty	Template Area* ft², above WAV_EL = -5 ft	WAV_EL, ft MLLW	Crest Elevation, ft MLLW	Crest Width, ft	Side slope (rise,v : run,h) Channel / Ocean
North Jetty	2250	max(-5 , TE+2)	25	30	1:1.5 / 1:1.5
South Jetty	2475	max(-5 , TE+2)	25	30	1:2 / 1:1.5
Jetty A	1687	max(-5 , TE+2)	20	30	1:1.5 / 1:1.5

**= Template area shown is based on WAV_EL at -5 ft MLLW*
TE = Jetty Toe Elevation

The objective of a responsive maintenance strategy is to monitor structure degradation. When the jetty cross-section degrades to a prescribed threshold, planning for repair is initiated. Funding is procured and jetty repairs are implemented before the jetty is breached. This process requires a certain amount of lead time, which is affected by the prescribed maintenance strategy.

When a jetty segment becomes damaged to the point of requiring repair, the amount of stone needed to repair the jetty segment (replace the rock missing from the cross-section) is reduced to account for partial re-use of the displaced remnant relic stone. The amount of relic stone re-use within a damaged segment can vary from 25%-50% of the displaced cross-section, depending on the water depth at the jetty toe, exposure to extreme wave action, number of previous repairs, and degree of repair deferral. Appropriate values for relic stone re-use within the SRB model are defined through model calibration (hindcasting).

k. Maintenance Strategy and Threshold for Implementing Jetty Repairs

Various jetty repair strategies (options) have been implemented within the SRB model to activate repair of damaged segments within the jetty before they fail and reduce the risk of a jetty breach. The repair scenarios are based on various damage threshold and timing considerations. Maintenance strategies, in order of lowest to highest intervention, include fix-as-fails, interim repairs, and programmed repairs. The ability to evaluate various jetty maintenance strategies allows one to rationally adopt a prescribed approach for managing life-cycle risk for vulnerable infrastructure. Recall that within the SRB model, each segment is repaired as the upper cross-section area becomes less than the imposed maintenance threshold. Depending upon the selected maintenance strategy, repair threshold can range between 15%-72% of upper cross-section area (based on the standard jetty cross section template). The actual threshold used to trigger repairs within a specified maintenance strategy is affected by a degree of random variation. Table A2- 17 summarizes jetty repair threshold values for various maintenance strategies; repair thresholds are cast in terms of the breaching threshold (BT). Threshold values are expressed as a fraction of the standard template (upper jetty cross section); 0.05 = 5% of the standard template. Table A2- 16 lists standard template cross-section for each MCR jetty. Scheduled (or programmed) jetty maintenance initiates repairs 4 years after the upper cross-section area is reduced to a value less than the UPPER threshold. If the jetty is breached (upper section falls below 15%-20% of standard template area), expedited/expressed repairs undertaken to repair the breached segment can be two times more costly than if repairs were conducted under normal conditions.

Table A2- 17. Thresholds used to Activate Jetty Repair or Breach Events for Various Jetty Maintenance Scenarios. Part-A lists thresholds in terms of random variable and BT.

Scenarios are listed in order of potential for breach occurrence; fix-as-fails has a higher likelihood for breaching than scheduled. Percentage (%) is the fraction of standard jetty template area remaining within the upper cross-section. Table A2- 16 lists the standard template area for each jetty.

Jetty Maintenance Scenario- A	Jetty Segment REPAIR			Jetty Segment Hardship	
	UPPER Threshold to Enact Repair	Repair Planning Period	LOWER Threshold to Enact Repair	EXPEDITED Repair Threshold	BREACH THRESHOLD (BT)
Fix-as-Fails	BT + 10%	N/A	BT + 5%	BT + 5%	15% + rand(5%)
Scheduled -V	Variable*	4 yrs	N/A	BT+ 5%	15% + rand(5%)
Historical Repairs	40% – BT +rand(BT)	N/A	BT + 5%	BT+ 5%	15% + rand(5%)
Scheduled - F	67% ± rand(5%)	4 yrs	N/A	BT+ 5%	15% + rand(5%)

Jetty Maintenance Scenario - B	Jetty Segment REPAIR			Jetty Segment Hardship	
	UPPER Threshold to Enact Repair	Repair Planning Period	LOWER Threshold to Enact Repair	EXPEDITED Repair Threshold	BREACH THRESHOLD (BT)
Just-in-Time	25 - 30%	N/A	20 - 25%	20 - 25%	15 - 20%
Scheduled –V	Variable (25 – 65%)	4 yrs	N/A	20 - 25%	15 - 20%
Historical Repairs	25 - 40%	N/A	20 – 25%	20 - 25%	15 - 20%
Scheduled – F	62 - 72%	4 yrs	N/A	20 - 25%	15 - 20%

Scheduled-F = programmed repairs using a **Fixed** UPPER threshold value for initiating the repair planning period.
Scheduled-V = programmed repairs using a **Variable** UPPER threshold value for initiating the repair planning period.
Variable value for UPPER threshold is independently set for each segment (for a given design cross section) by running the SRB model in fix-as-fails to calculate the 85^{th} percentile value of repair or breach initiation.

If the frequency of repairs for a given jetty segment becomes too high (repairs are made within 15 years of previous repair event), the jetty segment is repaired using a repair template having more robust characteristics. In this case, the enhanced template includes larger armor stone which is placed more carefully to achieve improved stability (W50 and Kd are increased by 50%), and the repair unit cost ($/ton) increases by 30% for the affected jetty segment.

1. Fix-as-Fails Jetty Maintenance

To defer jetty maintenance for a long as possible, the jetty is maintained close to the margin of functional loss. The fix-as-fails option attempts to minimize maintenance costs by deferring them into the future for as long as possible. When the jetty repairs are implemented under a fix-as-fails condition, they are not as resilient (reliable) as other, more proactive maintenance scenarios due to a shortened time period to plan and execute the construction. The design armor stone size is smaller and placement standards are less stringent than higher-order maintenance or rehab plans. The threshold for fix-as-fails maintenance was set at a level approximately 10% below the upper threshold for interim repair maintenance strategy. Under a fix-as-fails maintenance strategy, repairs for a given segment can be initiated when the upper cross-section area falls below 30% of the standard template. If repairs are initiated for a cross-section that has been reduced to less than 25%, then the repairs are considered to be expedited to prevent an imminent jetty breach. Expedited repairs carry an elevated cost. Keep in mind that a jetty segment can be breached if the cross-section falls below 15%-20% of the standard template area. The fix-as-fails maintenance option carries an elevated risk for incurring added costs, for having to expedite repairs (to prevent functional loss of a jetty), or responding to a breached jetty. Consequently, there is an elevated likelihood that jetty repairs may be more expensive (cost/ton of repair stone placed) when they do occur, and that the jetty may lose function before repairs are initiated. The present- and future-base condition maintenance strategy for the MCR South Jetty and Jetty A conforms most closely with the fix-as-fails strategy.

2. Interim (Historical and Base Case) Repair Jetty Maintenance

Historical maintenance efforts for MCR jetties are best described by an interim repair strategy. In this scenario, a given jetty is maintained at what is deemed to be a reasonable, yet variable level of degradation to defer jetty maintenance and reduce the risk of realizing jetty function loss. Repair activation under interim repair strategy is based on a monitoring program, resulting in a jetty that is maintained at a higher level than the fix-as-fails strategy. In this case, jetty degradation is sporadically monitored such that repairs may be implemented whenever the jetty cross-section area falls in the range of 20%-40% of the standard template area. The interim repair strategy allows for a wide margin of uncertainty for undertaking repairs. As is the case of fix-as-fails, thresholds (and costs) for implementing expedited repairs or incurring a jetty breach also apply to the interim repair strategy. Because there were periods when the jetties were not well maintained during the previous life-cycle, the interim repair strategy was used to perform hindcast simulations for the MCR jetties. If interim repairs are consistently deferred such that repairs are implemented just in time to prevent a jetty breach, then the repair strategy could be considered as a fix-as-fails condition. Implementation of an interim repair strategy activates jetty repairs, which are more resilient (reliable) than the fix-as-fails option; interim repairs use larger stone and the stone is placed to improve stability. Interim repair cost ($/ton) can be slightly higher than fix-as-fails. The present- and future-base condition maintenance strategy for the MCR North Jetty conforms most closely with the interim repair strategy.

3. Scheduled Repair Jetty Maintenance

The jetty is maintained at a prescribe level of degradation, to manage the risk of jetty breaching and other functional impacts. The scheduled repair strategy emulates an enforced protocol of structure monitoring, repair forecasting, and funds programming to ensure that a structure is maintained to a prescribed condition. The scheduled repair strategy implements structure repairs before the rate degradation accelerates past an acceptable level. Repairs for a given jetty segment are implemented 4 years after the segment has been damaged beyond a specific threshold. The 4-year period emulates a typical method for programming funds needed for navigation structure maintenance. Implementation of a scheduled repair strategy activates jetty repairs which are more resilient (reliable) than either the interim repair or fix-as-fails options; scheduled repairs use larger stone and the stone is placed to improve stability. Scheduled repair cost ($/ton) is higher than interim repairs. There are two options for the scheduled repair scenario:

1. A fixed(F) option prescribes a constant threshold for each segment; each segment is maintained with respect to a constant cross-section threshold. The constant value threshold is set at a fairly low level of degradation, so it is highly likely that repairs will be enacted before the jetty becomes threatened by a breach. Under a fixed scheduled repair option, the jetty is maintained to a consistently higher standard than the interim repair condition, to emulate a risk-adverse posture with respect to jetty breaching.

2. A variable(V) option applies a unique maintenance threshold for each jetty segment; one which is less conservative than the fixed option. To set the segment-specific maintenance threshold, the SRB model is first run in fix-as-fails mode (for a given structure design) to define the 85^{th} percentile value of repair or breach initiation. These values are saved to a database to be used when invoking the schedule repair-variable option. Under a variable scheduled repair option, maintenance of the jetty is optimized to prevent degradation beyond a point which incurs excessive risk of jetty breach yet minimizes the likelihood of over-maintaining the jetty. This is the option adopted to emulate the scheduled repair option in the MCR rehabilitation evaluation report.

I. Challenges for Long-Term Jetty Maintenance

The life-cycle outcome for infrastructure is a function of balancing the resilience of the structure's initial construction with a long-term repair strategy. The paradigm is to manage the trade-off between initial investment vs. maintenance costs. When renewing a structure's life-cycle, the same consideration applies to rehabilitation vs. repairs. Once a specific maintenance strategy is justified and implemented, it must be embraced through the entire life-cycle of the structure. Figure A2- 24 shows how jetty cross-section deterioration rates can vary based on maintenance strategy.

When choosing a specific strategy for maintaining the future life-cycle of a jetty, consideration must be given to the entire time frame under consideration, 50 to 60 years in this case. If a fix-as-fails viewpoint is embraced for jetty maintenance to reduce or eliminate near-term expenditures, then the need for future repairs (as early as 20 years out in time) may escalate to a very high level. Unless future cost outlays are allocated to address the deferred repair costs, the reliability of the jetty will fall below the justified target level.

A scheduled repair maintenance strategy may be enacted to reduce the scope or eliminate the need for jetty rehabilitation. Implementing this type of aggressive long-term maintenance could be more cost effective than expending a large initial re-investment. If the scheduled repair strategy is suspended 10 years into the future life-cycle, then the assumption to proactively maintain the jetty instead of rehabilitating it becomes void. In this case, the initial economic justification to repair rather than rehabilitate is not valid. USACE guidance for life-cycle analysis (ER 1110-2-859) acknowledges the risk of assuming that the requisite funding stream for a given maintenance strategy will remain uninterrupted: "Funding constraints may result in the deferral of critical project repairs, resulting in reduced project reliability." Funding constraints may also result in a lack of funding for construction of other alternatives as well, again resulting in reduced project reliability.

m. Jetty Rehabilitation and Engineering Features

If future maintenance requirements are expected to become unfavorable for a given structure, the option of rehabilitating the structure may offer the opportunity to reduce life-cycle costs and increase reliability. Elements of jetty rehabilitation include jetty cross-section/armor layer enhancement and the addition of engineering features. Engineering features include specific structural elements to stabilize the jetty head, reduce jetty-toe scour, and mitigate jetty root degradation. Several designs for cross-section enhancement have been developed to optimize jetty rehabilitation along each jetty at MCR (see Appendix A1 for design details). The jetty cross-section alternative types that were considered for rehabilitation and implemented as various options within the SRB model are summarized below:

- North Jetty Rehab Cross-Section Alternatives: Minimum, Moderate, and Large
- South Jetty Rehab Cross-Section Alternatives: Minimum, Small, Moderate, and Large
- Jetty A Rehab Cross-Section Alternatives: Low-Profile and Full-Profile

The SRB model includes options to accommodate variations in cross-section configuration for implementing jetty rehabilitation for both a single cross-section (constant along a given jetty) and composite cross-section (spatially variable) alternatives. The SRB model was used to optimize the scheduling of jetty rehabilitation by matching the timing of rehab implementation along various reaches of each jetty to when the jetty is expected to require repair.

Three types of engineering features can be emulated within the SRB model to reduce the effect for a specific process affecting a jetty. Aspects of engineering features are summarized below with design details presented in Appendix A1.

1. A jetty head "cap" consists of a robust 200-ft long bull-nose head geometry featuring very large armor units placed on a wide crest and compound slope cross-section. A jetty head cap has very high reliability and damage threshold. The jetty head engineering feature (head capping) can also be activated within the SRB model in

terms of extending the jetty head beyond the present location, if needed. The benefit for adding a jetty cap is to prevent (or significantly reduce) loss of the jetty head, which reduces shoaling into the MCR inlet. Stabilizing the jetty head can also prevent wave action from increasing along the jetty or within the inlet. Extending the jetty head beyond the present location can further reduce shoaling within the MCR inlet.

2. Jetty spur groins are small, low-profile appendage structures that can reduce the rip-current that locally affects scour along the jetty toe (foundation). Spur groins can be implemented within the SRB model at specific jetty locations and at specific times during the jetty life-cycle.
3. A graded back-fill (lagoon-fill) option can be activated within the SRB model to emulate stabilization of the landside North Jetty root which is presently being de-stabilized by storm wave and tidal surge action propagating through the jetty. If the lagoon fill feature is enabled, then degradation along the North Jetty root due to surge action is eliminated.

Other smaller-scale engineering features are not included within the SRB model. These include measures to protect the backshore along each jetty by augmenting the foredune along the oceanside of the North and South Jetties (North Jetty berm and South Jetty dune augmentation, respectively).

n. Combined Maintenance Strategy for Jetty Rehabilitation

It may be advantageous to employ a given repair strategy at the start of a structure's life-cycle and then change to another type of repair strategy later in the life-cycle. Such could be the case for jetty rehabilitation. Before a given segment is rehabbed, it is assigned an interim repair strategy and, after jetty rehab, the segment is assigned a scheduled repair strategy. In this scenario, the jetty is maintained at a reasonable level of degradation before a planned rehab condition to reduce the likelihood of a jetty breach while rehab construction is being planned or ongoing. After the jetty rehab is completed, the jetty is maintained at a slightly higher level to minimize the risk of functional loss for the newly restored cross-section. The above scenario is employed within the SRB model for evaluating rehabilitation alternatives for the MCR jetties.

o. Standard Upper Cross-Section Template

Recall that each jetty segment is repaired independently of each other. The repaired segment's upper section is restored to the geometry imposed by a "standard" repair template with attendant armor/core stone attributes. A standard repair template (upper area of a cross-section) is specified in terms of standardized parameters for jetty side slope, crest elevation, crest width, and the elevation at which wave damage diminishes (WAV_EL). Life-cycle results based on a segment-by-segment repair scenario can produce highly variable estimates for time-varying cost from one year to the next and one life-cycle realization to the next. Monte Carlo simulation is used to estimate expected values of life-cycle metrics within context of a highly variable outcome. Table A2- 16 summarizes the present repair template values for the three MCR jetties. For hindcast conditions, the standard template for the upper cross-section is based on the design section respective to the time of jetty performance. Refer to Appendix A1 for definition of the design and repair template configurations used for each jetty during the previous life-cycle.

p. Unit Repair Length

A unit repair length (reach) was developed for each jetty based on the previous life-cycle to portray the average reach length for a given repair campaign. Unit repair length is a metric reported by the SRB model and can be used to assess jetty life-cycle performance in terms of jetty maintenance requirements. The unit repair reach for the MCR jetties are specified below in terms of a mean value and standard deviation:

- North Jetty standard repair length = 3,100 ft ± 1,100
- South Jetty standard repair length = 5,000 ft ± 2,400 ft
- Jetty A standard repair length = 1,900 ft ± 1,500 ft

q. Jetty Segment Failure Consequences

The longer a damaged jetty segment goes without repair, the higher the rate of cross-section degradation due to wave action, and the more likely that the jetty segment could breach before repairs are made. In rare instances, a jetty segment may be damaged at such a high rate as to fail (loose function) before timely repair can be implemented. A given jetty segment has the *potential* to lose function when the upper cross-section area has been reduced to less than 20% of the standard upper cross-section. Within the SRB model, a jetty segment is assumed to fail when the upper cross-section is reduced to less than 15% of the standard upper cross-section. If the jetty segment fails, the segment has functional reliability = 0. If a jetty segment adjacent to a breached segment has less than 40% of its cross-section remaining, the adjacent segment can be induced to breach. This process is intended to account for the destabilizing effect that a breached jetty has on adjacent areas of the jetty. Within the SRB model, the maximum length for a given breach event location is 3 segments. Table A2- 17 summarizes threshold values used within the SRB model for enacting jetty repair and for initiating segment failure, expressed as a percentage of a standard upper cross-section template.

1. Jetty Head Recession

The default condition within the SRB model is to allow the jetty to recede landward as degradation affects the jetty head. This means that if a jetty segment fails at the seaward terminus of the jetty, the subareal jetty head will recede landward. The SRB model will simulate jetty head repairs if the appropriate model parameter has been set to rebuild the receding head. In most Pacific Northwest prototype cases, jetty heads are allowed to recede landward without repair due to the difficulty and high cost associated with jetty head repair. Resilient jetty head repair alternatives are generally not considered to be within the “normal” maintenance budget. In some cases, jetty head recession will cause accelerated recession of the shore profile along the jetty root and adjoining shoreline areas exposing the jetty to increased wave action and increasing the requirement for maintenance dredging. This process is replicated in the SRB. Although the option is available within the SRB model to force the jetty head to be maintained at its initial condition, it was not used to assess MCR future jetty life-cycle performance, as it was deemed impracticable for the MCR jetties. In hindcast mode, the frequency of jetty repairs is specified for each segment and, in some cases, the jetty head was repaired multiple times. The SRB model will rebuild the jetty head if historical conditions dictate.

r. Monte Carlo Approach

Employing the Monte Carlo method within the SRB model enhances interpretation of the inter-annual cost stream by stabilizing the variation due to the many random factors employed, and stabilizes expected value estimates for annualized cost. Monte Carlo enhancement to the SRB life-cycle simulations involves running multiple life-cycle iterations and generating statistical estimates of the life-cycle ensemble. The SRB model uses Monte Carlo method to increase the confidence of life-cycle estimates and allow for the evaluation of variance.

6. DEFINITION OF VARIABLES USED IN SRB SIMULATION

a. Environmental Loading

The MCR jetties are subjected to the vigorous loading associated with storm waves, tidal action, and morphological change. Each jetty is uniquely affected by the forcing environment at MCR due to structure orientation, location, and the sequence of project development. As the inlet continues to evolve, the loading affecting each jetty has been, and will continue to be, variable in time and space. The two primary environmental loading factors affecting jetty stability are incident wave action and jetty toe scour. Contributing factors include long-term morphological change and the variation of water level. The following sections describe how environmental loading was implemented within the SRB model to emulate both the actual conditions historically experienced and the expected range in future conditions at the MCR inlet.

Wave action, produced by winter storms, motivates much of the damage sustained by each jetty. Within the SRB life-cycle model, water levels and incident wave heights produced by winter storm events drive the damage functions that are used to evaluate cross-section evolution for each segment along a jetty. Figure A2- 32 shows the distribution of data points along each jetty at the MCR which are used to impose the annual wave loading environment to each jetty segment. Figure A2- 33 (and the following paragraphs) describes how the near shore wave environment is assigned to each of the points shown in Figure A2- 32.

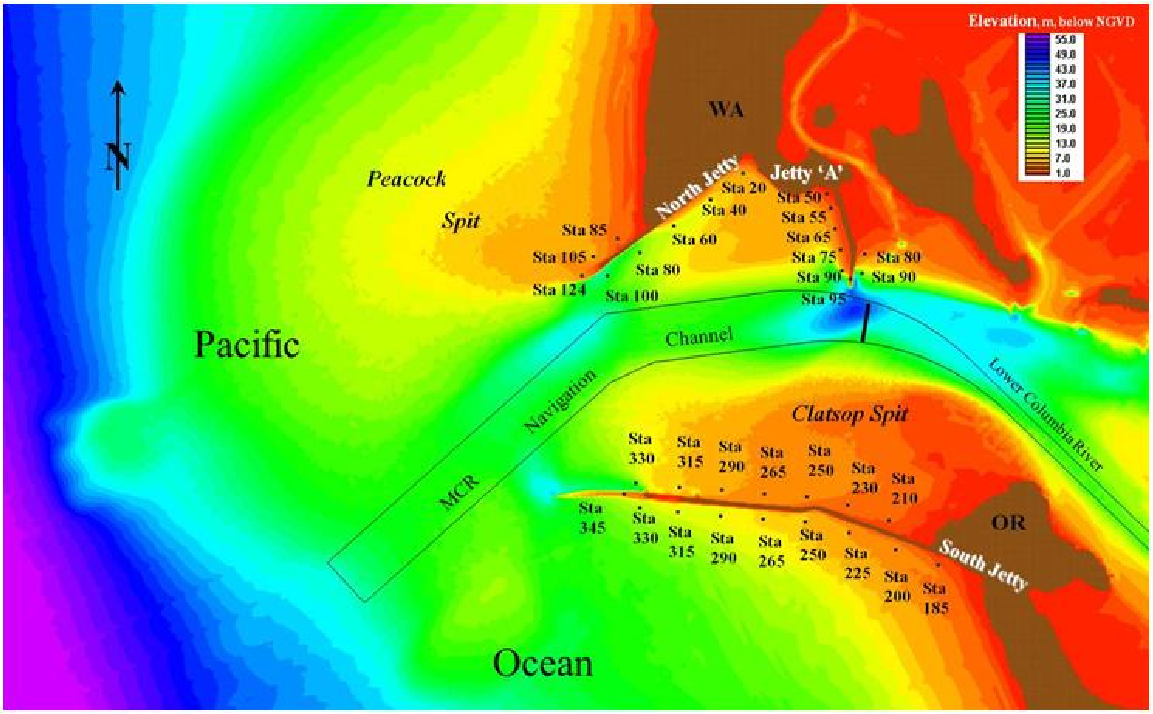

Figure A2- 32. Close-Up View of MCR Bathymetry as Described in STWAVE Model

Area shown is 10 km (north-south) x 15 km (east-west). Distance between North and South Jetties is 3 km. Survey data is a composite from 2003-2007. Note the variability in water depth along each jetty; waves at inshore jetty locations become depth-limited. Refer to Appendix A1 for additional details. Labels along each jetty refer to jetty station location at which STWAVE output was obtained for using in the SRB model.

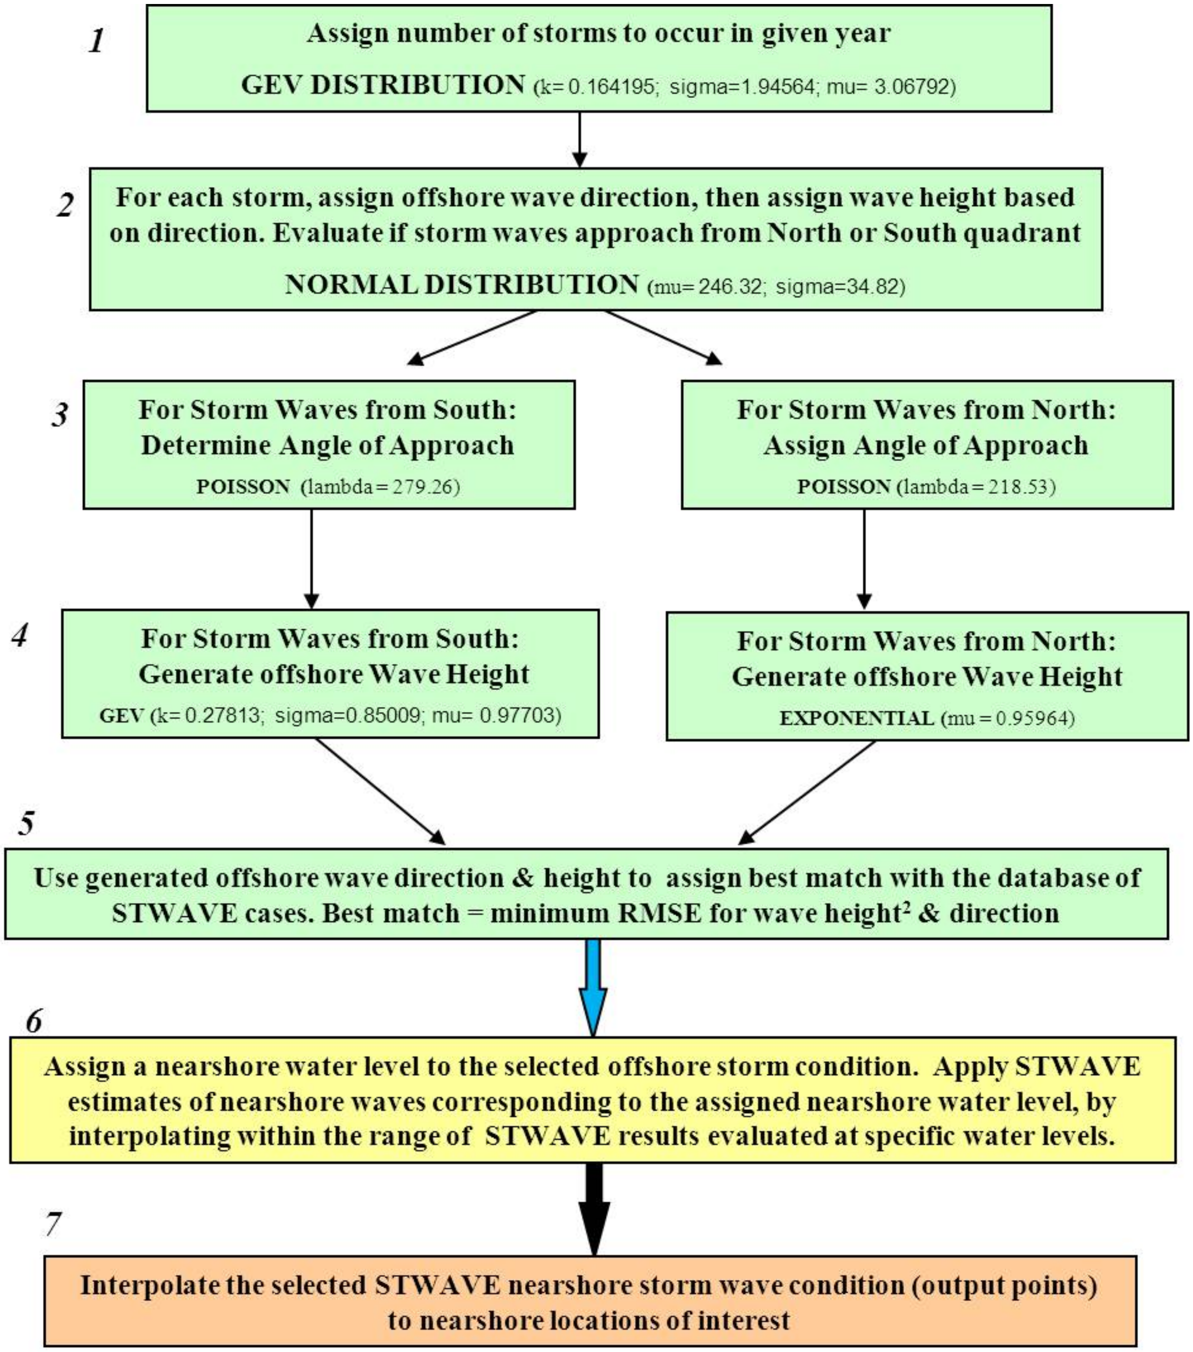

Figure A2- 33. Flowchart for Assigning Nearshore Wave Conditions

Assign Number of Storms per Year (step 1): A peak over threshold analysis (POT, for Hsig >= 7 m) was performed using wave data measured offshore of MCR during 1987-1998. A total of 89 storms were identified. Figure A2- 34 through Figure A2- 37 show results in terms of a histogram and define the median and maximum number of storm events per year is 4 and 11, respectively. A generalized extreme value (GEV) distribution was determined to provide the best approximation for the POT histogram. Within the SRB model, a random number is generated using the GEV distribution to estimate the N-storms that can occur during any given year. Figure A2- 38 shows that although the GEV distribution is bounded at n-storms = 11, less than 3% of the randomly generated events exceed the upper bound.

<u>Generate Candidate Offshore Wave Direction and Height (steps 2-4):</u> From the POT analysis for Hsig >= 7 m, a total of 59 peak wave heights had associated mean wave directions on record. Results are shown in Figure A2- 35 in terms of a histogram for mean offshore wave direction. By closer inspection of the mean wave directions from the 59 storm events, the histogram appears to be bimodal, with data separation between 245º and 255º. Using the separation point of 250º, a random number is generated within the SRB model using a NORMAL distribution to determine if the storm event wave direction is from the north (250º - 320º) or south (180º - 250º). No storm events with Hsig $\geq$ 22 ft have been observed to have approach direction greater than 320º or less than 180º. For storm waves approaching the MCR from the north, the mean wave direction is estimated with a POISSON distribution and the wave height is estimated with an EXPONENTIAL distribution (Figure A2- 36 and Figure A2- 37, Right). For a storm approaching from the south, the mean wave direction is estimated with a POISSON distribution and the wave height is estimated with a GEV distribution (Figure A2- 36 and Figure A2- 37, Left). Step 4 is completed (for each candidate storm event) after an offshore wave height and associated direction has been assigned.

Of the 59 peak wave events having statistics for associated mean wave direction, 52 events were found to have reliable directional spectral data as measured at NDBC buoys 46029 and 46089 during 1998-2008. Each of the 52 offshore wave events was transformed to the near shore region of MCR, for a given storm water level, using the numerical wave model STWAVE [Smith et al., 2001]. The STWAVE model used the directional spectra observed for each of the 52 storm events as offshore boundary conditions. The transference of offshore wave conditions to the MCR jetties is problematic without using observed directional wave spectra as an offshore boundary condition (BC). The offshore wave environment in the Pacific Northwest is too complex to be described by parameterized spectra. Directional offshore wave data (spectra) for the MCR is available from 1998 onward. This is why the ensemble of 52 offshore wave events is pooled from 1998-2008. This ensemble included the three largest observed wave events on record for the MCR offshore region (1987-2008). The STWAVE modeling was performed a priori and externally from the SRB model to develop a database of storm wave conditions along each jetty (Figure A2- 32) for various water levels. Recurrence intervals for the 52 events span a range of: 5 times per year to once in 25 years (Figure A1- 71 and A1- 73). Table A2-24d (left hand side of table) lists summary statistics for each of the 52 offshore storm wave events simulated using STWAVE. Refer to Appendix A1 for added details.

<u>Assign Offshore Wave Direction and Height (step 5):</u> After the values for offshore wave height and direction values have been generated in step 4, a best-match STWAVE storm wave solution is selected. The best-match event is selected by minimizing RMSE between: A) The values of height^2 and mean wave direction for the generated offshore wave event (step 4) <u>vs.</u> B) The values of height^2 and mean wave direction conforming to the ensemble of 52 events simulated using STWAVE.

Note that the above procedure applies a database of storm wave conditions along each jetty, applicable to the *present morphological condition* of the MCR inlet. Because gravity (wind generated) waves are modified by water depth and the water depth varies along each jetty, the storm wave environment along each jetty is highly variable. During minor storm events, waves along the inshore area of the jetties can be depth-limited. For a given water level, the waves are the same height regardless of the height of offshore storm waves. During severe near shore wave conditions, waves along many areas of each jetty become depth-limited, regardless of the height of waves offshore. In areas where the storm waves are depth-limited, the storm water level plays a larger role in defining near shore wave height than does offshore storm intensity. For these near shore areas, a 1-year offshore wave height occurring on a 10-year near shore water level will produce a larger wave height at a given jetty than a 25 year offshore wave height super occurring on a 1-year near shore water level.

<u>Assign a Storm-induced Water level and Select the STWAVE Solution (step 6):</u> Figure A2-39 through Figure A2- 42 describe the best-fit distributions that were used to stochastically simulate individual components for near shore water level. The observed data is shown in figure A1-78. Each water level component (for MCR) was simulated using a GEV distribution and was bounded by the extreme values of the observed data. The PDFs capture 100% of the total possible variation for each water level component. The PDFs are clipped at the upper and lower bounds, affecting less than 1% of the simulated result. Figure A2- 42 shows the result of combining each of the simulated water level components (PDF realizations) to estimate a total water level per storm event. The SRB model applies appropriate water level component PDFs to generate a randomized total near shore water level associated with a realized storm event. The effect of sea level rise is added to the storm-induced water level to produce a total event water level. The event-based water level generated in step 6 is used to interpolate from within the range of STWAVE solutions, based on the three water levels associated with a given candidate storm.

<u>Interpolate the Selected STWAVE Nearshore Wave Field onto All Jetty Segments (step 7):</u> The SRB model spatially interpolates the above derived STWAVE wave solution along the solution points shown in Figure A2- 32 to develop a continuous description of the wave field along each jetty for each storm wave event. The storm wave environment along the jetty is further modified based upon the present morphological stage within the jetty life-cycle being simulated. This series of steps produces the combined wave and water level environment along the jetty for a given storm event. The realized wave event is used to estimate jetty damage by accessing the appropriate damage function.

The above process is repeated for each storm event within a given year. Wave induced damage is calculated for each storm event realized within each year of the SRB simulation, using wave-damage functions developed by ERDC [Ward and Melby 2007]. Reliability is calculated using the mean value and standard deviation for the annual storm wave and mean value and standard deviation for water level environment realized each year. The above stochastic approach accounts for variation of: A) annual storm climate-numbers of storms per year; B) individual storm wave parameters-height, direction, period; C) the superposition of water level components-tide, storm surge, and infra-gravity transients; and D) the evolving morphological stage of the inlet. Values of wave and water level were applied along each jetty segment for each storm within each year of a given SRB simulation.

Emulation of past and future bathymetry conditions (and related wave environment) for the MCR inlet is handled indirectly through the application of morphological factors, as described in *Foundation Effects*.

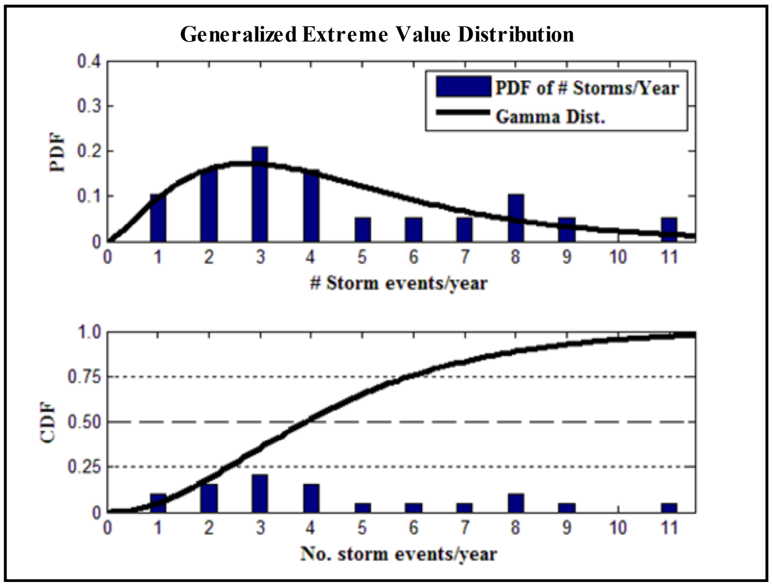

Figure A2- 34. Generation of Random Wave Parameters: Generalized Extreme Value Distribution

Within the SRB model, a random number is generated using a GEV distribution to estimate the number of storms that can occur during any given year.

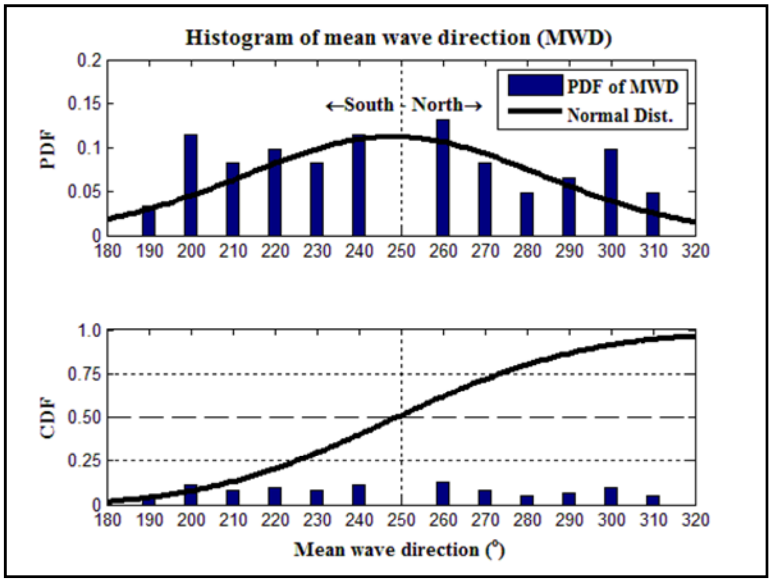

Figure A2- 35: Generation of Random Wave Parameters: Histogram of Mean Wave Direction

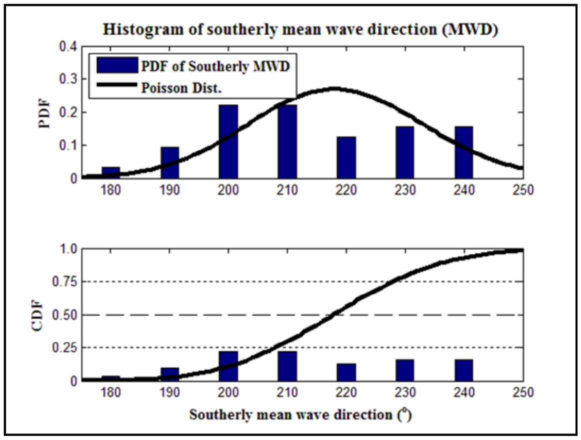
Within the SRB model, a random number is generated using a NORMAL distribution to determine if the storm event (offshore) wave direction is north or south of 250 degrees azimuth. If wave direction is south of 250 deg, storm wave direction and height is further resolved in Figure A2- 36 and Figure A2- 37 *at bottom LEFT. If wave direction is north of 250 deg, storm wave direction and height is further resolved in* Figure A2- 36 *and* Figure A2- 37 *at bottom RIGHT.*



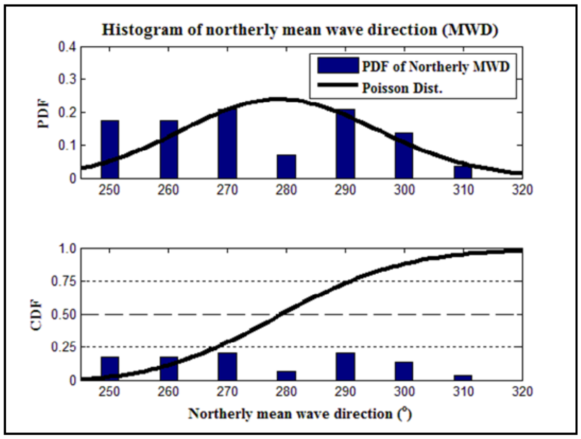


Figure A2- 36. Generation of Random Wave Parameters: Histogram of Southerly/Northerly Mean Wave Direction

For a storm approaching from the SOUTH the mean wave direction is estimated with a POISSON distribution (LEFT).For a storm approaching from the NORTH, the mean wave direction is estimated with a POISSON (RIGHT).

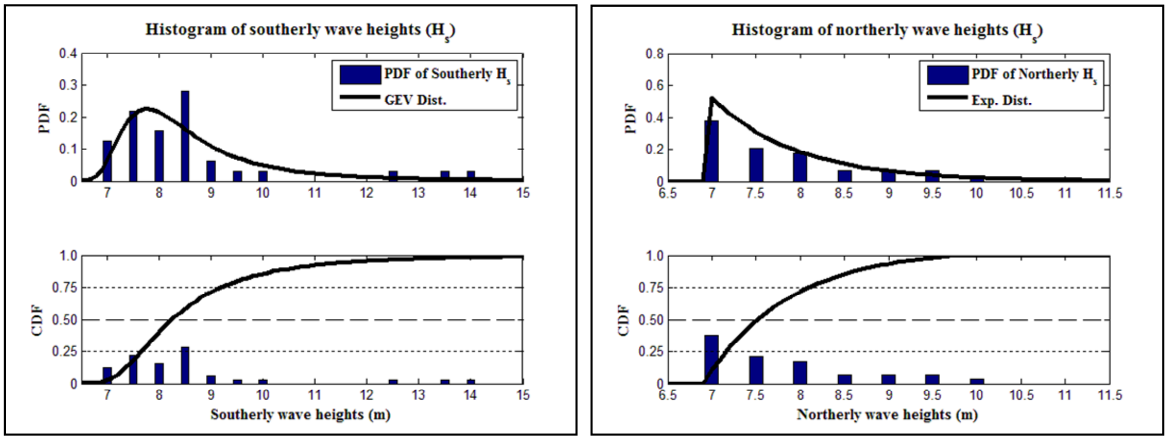

Figure A2- 37. Generation of Random Wave Parameters: Histogram of Southerly/Northerly Wave Heights

For a storm approaching from the SOUTH the wave height is estimated with a GEV distribution (LEFT).For a storm approaching from the NORTH, the wave height is estimated with an EXPONENTIAL distribution (RIGHT).

1. Offshore Wave Climate

The offshore storm wave climate affecting the MCR was established a priori outside of the SRB model by synthesizing the observed range of winter storm wave conditions during

1987-2008. Synthesized parameters include offshore wave height, wave period, wave direction, and number of storms per year. The SRB model proceeds sequentially year by year through a given life-cycle simulation. For each year in the simulation, an offshore storm climate is generated through a series of probability density functions (PDFs) to define the number of offshore storms, associated wave characteristics, and nearshore water level associated with each storm. There can be 1 to 11 storm events affecting the MCR inlet per year, having offshore significant wave height (Hsig) ≥ 22 ft. The maximum offshore Hsig observed during 1987-2008 was 46.3 ft. An extremal analysis of the wave data observed during 1987-2008 produced the following return intervals for offshore Hsig (Appendix A1):

- 1-year storm event = 29 ft (observed)
- 4-year storm event = 36 ft (observed)
- 25-year storm event = 46 ft.(observed)
- 50-year storm event = 51 ft (projected based on extremal analysis)
- 100-year storm event = 55 ft (projected based on extremal analysis)

Based on the observations made to date, the largest offshore waves (> 4-year event) approach the MCR from the south-southwest. This is consistent with the configuration and transit path of cyclonic storm systems approaching the Pacific Northwest Coast. Figure A2- 33 outlines a procedure used within the SRB model to simulate the offshore storm wave environment annually affecting MCR (steps 1-5). The procedure is based solely on observed wave event data, and does not include data extrapolated from the extremal analysis. The largest observed event is equivalent to the 25-year offshore wave. Figure A2- 34 through Figure A2- 37 describe the best-fit distributions that were used to stochastically simulate offshore wave parameters based on observed wave events. Consequently, the storm events emulated within the SRB life-cycle model can produce offshore Hsig ranging from 22 ft to 46 ft. Steps 6-7 (Figure A2- 33) summarize how the generated offshore storm wave condition is interrogated to select a nearshore wave condition for each MCR jetty.

2. Water Levels

To account for the effect that water level can have on nearshore wave height, STWAVE simulations were performed for each of the 52 offshore wave events using three different nearshore storm water levels: a low value conforming to a sub-annual occurrence (1.3 ft MLLW); a median value conforming to the annual 1-year event (8.5 ft MLLW); and extreme high water level conforming to a 20-year event (15.8 ft MLLW). MLLW is approximately equal to -3.5 ft NGVD. The nearshore storm-induced water level was developed from a superposition of variably-correlated random components featuring: A) astronomical tide; B) quasi-static storm surge; and C) infra-gravity transient due to storm wave grouping. Refer to Appendix A1 for detailed description of the MCR water level environment.

3. Sea Level Rise

The effect of sea level rise was included for assessments of *future* jetty performance at the MCR. Future sea level rise estimated within the SRB model is outlined in EC-165-2-211

[USACE 2009]. The EC prescribes a method for defining three future projection curves which are used to bound the estimate for sea level rise over time. The sea level projections (curves) are site-specific and are derived based on the historical sea level trend blended with the huestatic effect. EC curve #1 defines the lowest expected bound for sea level rise, EC curve #2 defines a prudent expected trend, and EC curve #3 defines the highest expected bound. The sea level projections that were used within the SRB model were based on the NOS station at Astoria, Oregon. Within the SRB model, each jetty life-cycle realization (extending 50 years beyond the base year 2011) was assigned a randomly generated sea level rise trend, which is bounded by EC curve #1 (-0.2 ft) and EC curve #3 (1.8 ft). Figure A1-79 shows a subset of 9 randomly generated sea level trends superimposed on the three EC curves. A total nearshore water level is estimated for each storm (k) by adding the estimated sea level rise (for a given year, i) to the nearshore storm-induce water level, described above. Sea level rise effects were not included within the historical assessment of jetty performance (hindcast).

4. Nearshore Wave Climate and Water Levels

As noted above, 52 offshore storm wave events were transformed to the jetties a priori to estimate the nearshore wave field for a range in water levels. Each candidate offshore storm was evaluated (using STWAVE) for three water levels, producing a data-base of 156 nearshore storm wave conditions.

5. Return Period for Extreme Nearshore Waves

The largest event within the data base of 52 storms is equivalent to the 25-year offshore wave. To investigate how an extreme offshore wave events (greater than the 25-year) would equate along the MCR jetties, two offshore wave events (50-year and 100-year) were simulated using the STWAVE model for the moderate and extreme water level. The BC (directional wave spectra) for these extreme events was estimated by increasing the spectral energy of the observed 25-year wave event to achieve the associated extremal analysis wave heights (figure A1-73). The results of transforming the 50-year and 100-year wave events to the jetties, using STWAVE, indicate that the nearshore wave height at the jetties increases less than 0.1 meters as compared to the 25-year observed offshore storm condition. The reason for the above result is that the largest offshore waves approach the Pacific Northwest Coast obliquely from the south-southwest, expending much energy through refraction as the waves shoal and refract into the nearshore. By the time these waves reach the MCR jetties, the wave height is reduced much more (on a relative basis) than smaller offshore waves that approach the coast from a more direct angle (southwest to northwest).

In consideration of the above, the estimated return period for events affecting the MCR jetties is based on storm events less than the 4-year return period, combined with water level events spanning sub-annual to a 20-year occurrence. These lesser offshore events produce waves that approach the coast from southwest – northwest (which are not reduced as much by shoaling and refraction as waves from extreme events) and can affect nearshore infrastructure to a greater degree. Based on the above considerations, the return interval for the largest nearshore events affecting the jetties (as emulated by the 52 offhshore wave conditions and 3 water levels) is estimated to range from the sub-annual event (5 times per year) to a 40-year event. The 40-year nearshore wave event is based on a 2-year offshore event occurring on a 20-year water level. Regardless of the severity of an offshore wave event, the largest waves that the jetties will "see" are nearshore equivalent to the 2-year offshore wave event. The morphology of the MCR inlet protects the jetties from the severity of extreme offshore wave events and nearshore water level modulates the effect of offshore waves.

b. Foundation Effects

1. Morphological Change

The actual wave environment affecting a given jetty can be modified over time based upon the water depth at the structure, as controlled by the evolution of the shoal (morphology) on which the structure was built. If waves are depth-limited along a given jetty location and the water depth along the structure increases over time (shoal recession), then the wave environment at the structure will also increase over time. If the shoal on which a jetty was founded accreted such that water depth along the jetty was to decrease, then the wave environment would decrease over time. The effect that morphological change has on wave conditions at MCR has been estimated for past and future jetty life-cycle simulations, with respect to the present condition (Table A2- 13 through Table A2- 15).

Bathymetry data describing the MCR inlet conditions for periods of time in the distant past (more than 30 years ago) were incomplete in areal coverage. The absence of a complete historical bathymetry data set of the MCR inlet precluded accurate wave modeling for the MCR inlet in the historical setting. There is no data set yet observed to describe the future condition of the MCR inlet. Attempting to accurately reproduce the entire bathymetric condition at the MCR inlet for past or future conditions, to a resolution necessary for detailed wave modeling, was deemed impossible. The morphological factors given in Table A2- 13 through Table A2- 15are used to modify the wave environment along each jetty for the life-cycle time period of interest with respect to the present condition. These factors were estimated based on assessing the evolving morphological stage of the inlet using historical bathymetry data (for hindcast simulations) and extrapolation of recent observed bathymetry change (for future life-cycle simulations). In summary, morphological factors were used to adjust the present bathymetry-wave condition of the MCR inlet to enable estimation of past or future wave conditions along each jetty. The morphological factors were used of as a surrogate method to emulate past and future MCR wave conditions in the absence of detailed bathymetry data.

2. Jetty Toe Scour

The waves and currents can interact along the transition between jetty side slope and the seabed to form an organized rip-current system. These local rip currents run along the interface of the jetty and seabed and can erode and transport sediment away from the jetty's foundation. The resultant scour that forms along the jetty's base and adjacent shoreline can be more pronounced and localized than the large-scale processes which drive morphological change affecting tidal shoals. At some jetty locations, the jetty toe (interface between jetty and seabed) has been eroded by more than 40-ft vertical, resulting in the progressive collapse of the jetty cross-section. Scour of the jetty toe is typically limited to the seaward half of the jetty and sometimes the jetty root. However, jetty toe scour can affect the jetty anywhere if the channel thalweg migrates toward the jetty or secondary circulation (caused by an eddy or wave action) sets up an enhanced rip current along the jetty. These scour effects have occurred along the MCR jetties at various times and locations during the present life-cycle.

As the inlet continues to evolve, the location and nature of jetty toe scour will change along each jetty. Historical rates of jetty toe scour have been calculated by comparing the elevation of the structure toe along the jetty alignment (immediately prior to construction) to various periods after jetty construction. Future scour rates were estimated based on extrapolating present scour rates combined with the effect of estimated future morphology change at the inlet. Table A2- 13 Table A2- 15list the historical (observed) and future (estimated) scour rates along each side of the MCR jetties. These values were used within the SRB model. Scour rates for each side of a given jetty were evaluated on a 500-ft reach basis, and these values are adapted to each jetty segment (100 ft) using interpolation within the SRB model. Jetty toe scour for each segment accumulates through time (for each simulation year) within the SRB model. As discussed previously in this appendix, excessive jetty toe scour can lead to destabilization of the jetty foundation; this effect is cumulative and can affect the entire structure side slope.

Implementation of spur-groin engineering features can interact with the rip-current system along a given jetty to reduce the rate of scour affecting the jetty toe. If the option for implementing spur-groins is activated within SRB model for future life-cycle simulations, the estimated rates for jetty toe scour are reduced, as described in Table A2- 12 (Part II-1).

c. Jetty Cross-Section Attributes

Within the SRB model, jetty stability is related to the time-varying resilience of the jetty's cross-section in terms of an upper and lower region for each segment. Multiple attributes are tracked within the SRB model to describe the time-varying geometry of the jetty cross-section. Attributes for a given jetty segment are recorded in terms of the upper and lower region. To assess the time-varying condition of a jetty segment, the present cross-section attributes are compared to the jetty's initial condition or a set of threshold conditions. Initial conditions and associated jetty cross-section thresholds are specified within the SRB model script or by external data (.mat) files. When a given jetty segment is repaired or rehabilitated, the cross-section attributes are reset to the appropriate initial conditions and related threshold values.

1. Lower Cross-Section Attributes

The geometry of the jetty's lower cross-section is affected by slope instability, as motivated by the lowering of the jetty toe through scour, which can occur independently on either side of the jetty. Recall that the response of the lower region of a jetty cross-section can affect the upper region. Active SRB model parameters which describe the time-varying condition of the lower cross-section include:

- Lower Region Structure Side Slope (θ_L) – variable for each side of the jetty.
- Lower Region Crest Width (CW_L) – variable for each side of jetty, with respect to centerline.
- Toe Elevation (TE) – variable for each side of the jetty.
- Lower Region Cross-section Area – a function of θ_L, CW_L, and TE.

The initial condition side slope for the lower cross-section is set at 1.5H:1V. If a given side of the jetty is subjected to scour, the jetty toe is lowered and the side slope is adjusted to meet the geometry constraints. The side slope can be reduced to a limiting slope of 1.3H:1V, at which point the slope is re-adjusted to a stable slope of 1.4:1V. Unless the jetty segment is repaired or rehabilitated, the lower slope will vary between 1.4H:1V to 1.3H:1V as the toe is lowered by scour. The crest width of the lower region serves as the bench on which the upper cross-section rests (see Figure A2- 18 and Figure A2- 26). The crest elevation of the lower region is located at WAV_EL. The area of the lower cross-section is calculated in terms of the lower region crest width, side slope, and toe elevation.

2. Upper Cross-Section Attributes

The upper section of a jetty can be directly damaged by wave action or indirectly damaged by the lower region's response to toe scour and slope instability. As the upper cross-section of a jetty is damaged, the resiliency of the upper cross-section can be reduced in two ways.

Cross-section Geometry Reduction. Less area remaining within the upper section of a jetty means less area remaining to resist a jetty breach (loss of jetty function). As the cross-section becomes more damaged, the damage rate can increase. If the cross-section is damaged to a point such that the crest elevation becomes reduced, the wave overtopping effects can promote added rates of damage on the lee side of the jetty. The following parameters are used to modify the geometry of the upper section of a jetty as it is damaged by wave action or effects induced by lower section instability.

- Upper Region Structure Side Slope (θ_U) – constant value, each side of the jetty.
- Upper Region Crest Width (CW_U) – variable on each side of jetty, with respect to centerline.
- Upper Region Jetty Crest Elevation (CE_U) – variable elevation of the jetty's crest.
- Upper Region Cross-Section Area – a function of θ_U, CW_U, CW_L, and CE_U.

Reduction in Armor Layer Stability. As the upper cross section is damaged, the stability of the jetty's armor layer becomes compromised. The degree of armor layer stability loss is related to the reduction in jetty crest width with respect to the initial (or repaired) condition. Regardless of how the upper jetty cross-section is damaged, *crest width* is the geometric parameter used to actively modify the performance aspects of the cross-section. The total crest width of the jetty is bisected into a channel side and ocean side component. Damage sustained by the upper region of a jetty is expressed in terms of an equivalent crest width reduction, which is a function of the damaged area and structure side slope. The slope of the upper cross-section is set and held at a constant value of 1.5V:1H, as sustained damage causes the jetty crest to translate inward toward the centerline.

The following armor layer characteristics are modified as the crest width (on each side of the jetty) is reduced:

Median armor unit size (W_{50}). As the crest width of the jetty is reduced, less of the armor layer remains to protect the interior of the jetty and the jetty interior becomes exposed to wave action. At this point, much of the armor layer has been displaced off of the upper cross-section such that core stone is subjected to direct wave action. The effective size of the armor stone is decreased in proportion to the relative amount of true armor stone remaining on the jetty slope (core stone becomes more prevalent along the disturbed slope face). When the crest width on a given side of the jetty has been reduced to less than 1-ft wide, the mean armor stone size of the upper jetty slope is reduced to 70% of the initial condition. The standard deviation of armor stone size is adjusted accordingly.

Armor Unit Stability Coefficient (K_d). When armor units are displaced from their set position within the armor layer of a jetty, the armor units lose the aspect of interlocking, which affords an added degree of stability for the armor layer en mass. As the jetty incurs damage, crest width of a jetty is reduced, and the armor unit stability coefficient (or equivalent stability parameter) is reduced to reflect the disruption of the armor layer. If the crest width on a given side of the jetty has been reduced to 10-30% of its initial width, then Kd is re-set to max (0.9* initial value, 2.5). If crest width on a given side of the jetty has been reduced to less than 10% but greater than 1 ft in width, then Kd is re-set to max (0.8* initial value, 2.2). If crest width on a given side of the jetty has been reduced to less than 1 ft in width, then Kd is re-set to max (0.7* initial value, 1.8). The reduction in Kd is based on an equivalency of Kd and values of $H/H_{d=0}$, for 0 to 50% cross-section damage, as expressed by the Hudson equation in the SPM [USACE 1984].

The initial condition for jetty cross-section geometry and armor layer characteristics are set within the SRB model according to the design parameters implemented at the time of jetty construction. In some cases, there can be considerable variation in jetty cross-section attributes along the structure length, and from one side of the jetty to the other. If a given jetty segment is repaired or rehabilitated, the jetty cross-section attributes are reset according to the specific plan implemented (specified within the SRB model). Appendix A1 describes jetty parameters applicable for the initial condition, historical repairs, rehabilitation plans, and future repairs for each MCR jetty.

7. MCR JETTY LIFE-CYCLE HINDCAST – SRB MODEL CALIBRATION

Before performing hindcast simulations for a given structure, it is essential that a structure's as-built condition be established to match the actual post-construction condition of the prototype. Fortunately, the historical record for the MCR jetties is good and data was available to define the initial conditions for jetty toe elevation, jetty cross-section geometry, armor/core stone attributes, and historical scour rates for MCR jetties. Refer to Appendix A1 for historical jetty repair details. Repair history for each jetty is summarized in terms of the location and type of jetty stone placed, and construction methods. The SRB model hindcast jetty maintenance strategy was set at "interim repair" to emulate the maintenance conditions actually undertaken during the historical life-cycle of each jetty.

When executing a hindcast SRB simulation, the initial condition geometry, jetty armor/core stone attributes, and jetty foundation scour rates are defined for the entire jetty, on a segment-by-segment basis. Table A2- 13 through Table A2- 15 summarize observed scour rates along the MCR jetties as employed in the SRB model. The historical repair sequence is defined within the model to assign the number of times segments can be rebuilt, applicable thresholds to initiate wave-induced damage, and stone "re-use" parameters. The storm wave and water level climate is generated for a given life-cycle iteration (89 years for North Jetty, 97 years for South Jetty, and 67 years for Jetty A), and then jetty life-cycle calculations are performed sequentially for each year, for all jetty segments. Monte Carlo simulations are performed by running multiple life-cycle iterations and generated statistical estimates of the life-cycle ensemble. Output produced by the SRB model includes text-based data files (cost data), the entire MATLAB simulation environment, and multiple graphic summaries. The model skill of each jetty hindcast was assessed by comparing the simulated hindcast result to actual metrics based on time-varying repair cost, sequence of repairs, number of repairs made per jetty segment, and crest elevation of jetty at the end of historical performance period. Other informative metrics discussed included time varying reliability, cross-section area, and cost expended per segment.

a. Hindcast Calibration Parameters

Several calibration parameters with the SRB model require adjustment to become fully resolved within the context of a specific jetty, or reaches within a given jetty. Calibration parameters that affect jetty degradation include "wave-damage thresholds" for: A) initial state jetty cross-section; B) damaged initial state cross-section; C) repair cross-section; and D) damaged repair cross-section. The parameter that affects unit repair costs is "armor stone re-use factor," which defines how much of the damaged-displaced armor stone is re-used in the subsequent repair and can be different for each observed repair event. Within the framework of hindcast simulations, the above calibration parameters are held constant after being adjusted through model calibration. For future life-cycle simulations, the above parameters are allowed to randomly vary about the mean value (achieved through calibration).

Calibration of jetty damage thresholds is achieved by converging simulations from the SRB model with the observed life-cycle history in terms of the occurrence and frequency when the jetty was actually repaired though its historical life-cycle. The model was considered to be calibrated when the simulated jetty profile for the end-state condition was equivalent to the observed end-state condition. The observed end-state condition for each jetty was defined by detailed topographic/bathymetric surveys conducted during 2006-2007.

b. North Jetty Simulated Historical Performance, 1917-2006

To avoid redundancy in reporting hindcast results for all three jetties, a detailed description is given here for the North Jetty results and summary descriptions given for the South Jetty and Jetty A. Much of the North Jetty descriptive results can be applied to the other jetties when interpreting the graphical results summarized within this appendix.

Upon completion of the North Jetty in 1917, the entire ocean side of the jetty was exposed to wave action due to the inlet's morphological condition. Soon after completion of the North Jetty, the presence of the jetty radically reformed Peacock Spit producing subareal deposition along the north side of the North Jetty. The SRB model simulated the time-varying condition of Peacock Spit as its rapid accretion first acted to protect the ocean side of the North Jetty from wave and currents and then re-exposed the jetty to the elements during gradual recession of the Spit. The intensity of wave action along exposed areas of the North Jetty in 1917 was estimated to be less than the present condition due to the orientation and geometry of the underwater shoals. Because of this, the initial condition wave environment along the ocean side of the North Jetty was reduced from present average conditions using a morphological factor varying from 0.7 near the landward end of the jetty (station 25), to 0.75 at 4/5 of total jetty length (station 100), to 0.65 at the jetty head (station 124). For similar reasons, the initial condition for wave environment along the channel side of the North Jetty was reduced (from present day value) using a morphological factor ranging from 0.6 at the landward end (station 20), to 0.8 at 3/5 of total jetty length (station 80), to 0.65 at the jetty head. Morphological factors for the North Jetty are shown in Table A2- 13. The morphology factors changed through time, from the initial condition values to 1.0 for the present condition. Wave events realized within the SRB model are modified "at the jetty" using the time-varying morphology factors (Table A2- 13 through Table A2- 15). A key assumption in the SRB model is that the average long-term *offshore* wave (deepwater) climate, at time of jetty construction, was similar to present.

Figure A2- 43 shows the center line profile for "as-built" initial condition, observed condition in 2006, and simulated condition in 2006. There is good agreement between observed and simulated end-state. Note the extent of jetty head recession, which is being aggravated by severe toe scour. As Peacock Spit continues to recede landward into the future, the toe scour effect will translate landward. Figure A2- 44 shows the progression of damage to the cross-section at station 97.5and subsequent repairs for the last Monte Carlo iteration, and complements the information shown in Figure A2- 26. Figure A2- 45 through Figure A2- 47 show the timing, number, and location of repairs historically made to the North Jetty. Areas further seaward from station 70 require additional repair due to the increased exposure to wave action and toe scour. There is good agreement between actual repairs made and the simulated condition. Note how the jetty head has receded landward, despite the repairs made. The number of repairs that can be made within the SRB hindcast is prescribed. The model can initiate repairs up to the prescribed number, but it is not required to initiate any repairs unless sustained damage exceeds an imposed threshold. No repairs were made to areas inshore of station 54, which explains why the jetty profile in 2006 was in poor condition. Figure A2- 48 shows the spatial variation of total cross-section area along the jetty for three periods of time (1917, 1922, and 2006) complements the results shown in Figure A2- 43.

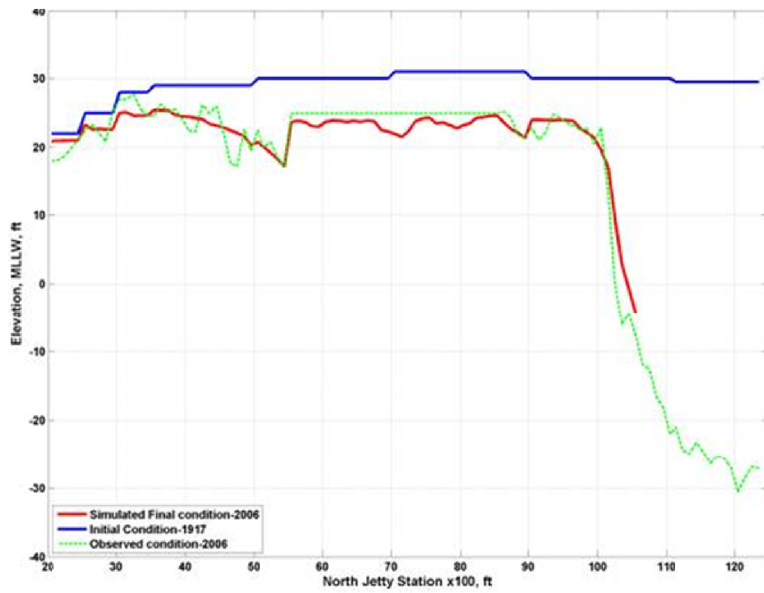

Figure A2- 43. Monte Carlo: North Jetty Crest Profile Evolution: 1917-2006

Centerline profile for MCR North Jetty: extends from landward limit (Sta. 20) to seaward limit (Sta. 124). Comparison of initial condition (1917) to observed and model simulated final condition (2006).

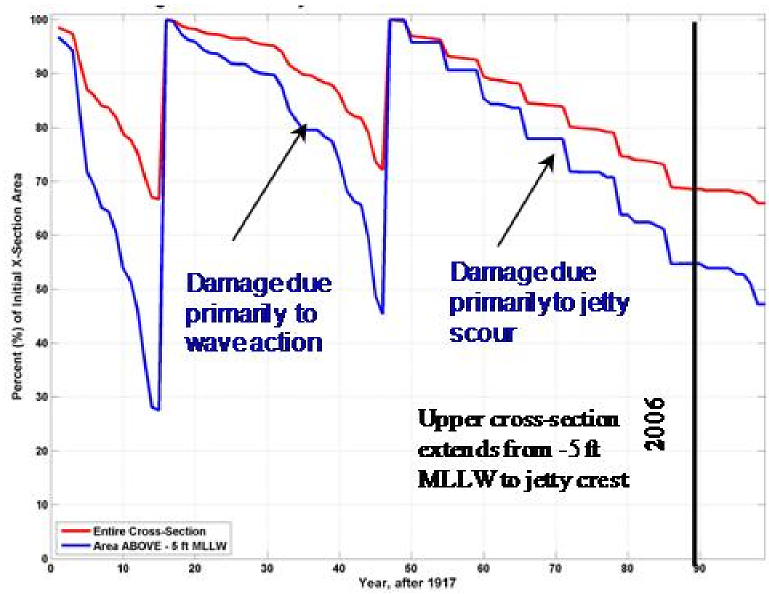

Figure A2- 44. Change in North Jetty Cross-Section Area at STA 97.5: 1917-2016

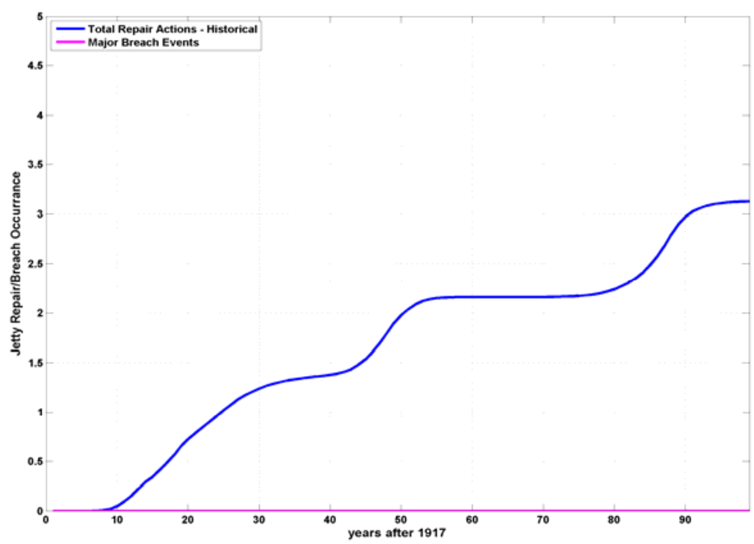

Figure A2- 45. Monte Carlo: North Jetty – Cumulative Occurrence of Repairs and Breaches: 1917-2012

Cumulative jetty repairs for hindcast simulation. The number of jetty segments repaired has been normalized based on the average repair length of 3,100 ft per North Jetty repair campaign.

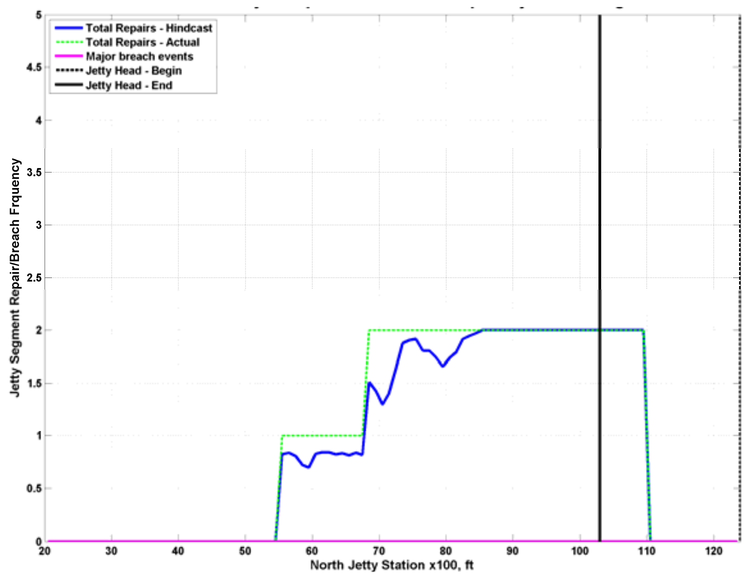

Figure A2- 46. Monte Carlo: North Jetty – Repair & Breach Frequency/100-ft Segment: 1917-2012

Comparison of actual jetty repair history to hindcast condition, based on frequency and location of repairs. The jetty head location is indicated for 1917 and 2006 (simulated condition).

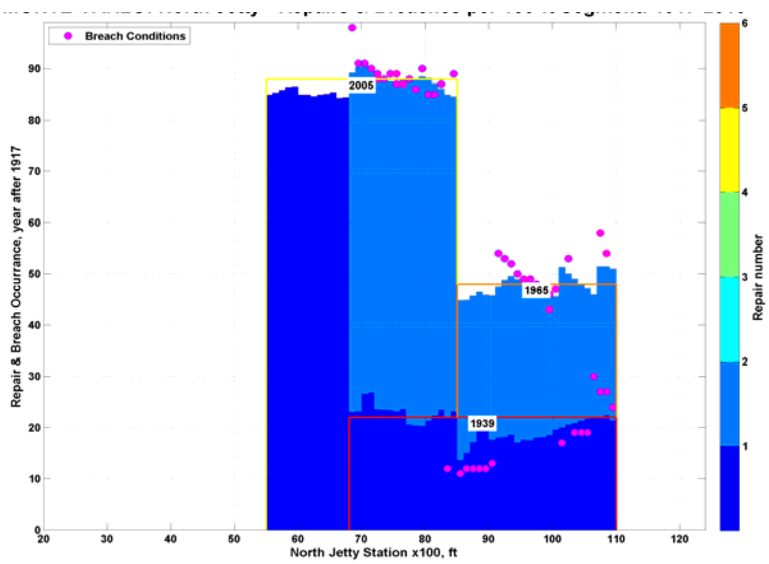

Figure A2- 47. Monte Carlo: North Jetty – Repairs & Breaches per 100-ft Segment: 1917-2016

Hindcast repair occurrence; dark bars are first repair, lighter bars are second repair. Onset of repairs is based on bar endpoint.

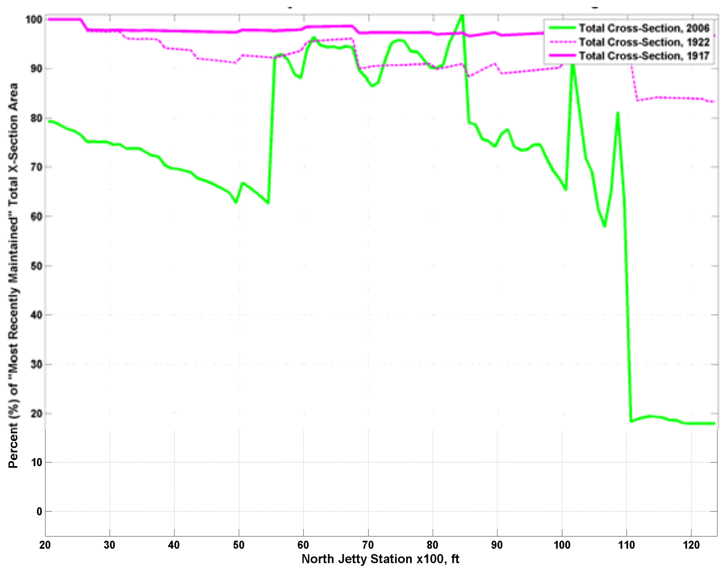

Figure A2- 48. Monte Carlo: North Jetty Total Cross-Section Area Change: 1917-2016

Variation in total cross section area along jetty for 3 different times during the North Jetty hindcast period.

Figure A2- 49 illustrates the time varying reliability for structural and functional jetty performance, pertaining to the upper cross-section of the jetty (above -5 ft MLLW). The values are shown for each year and have been averaged along the entire jetty, out to the seaward limit of the jetty head. Dynamic reliability indicates how well the jetty resists damage due to wave action. A value below 0.5 indicates that the overall jetty has a high probability of experiencing rapid degradation due to wave action (see Table A2- 3). Dynamic reliability is highly variable because the performance modes are very sensitive to wave height and water level. As wave height and water level can vary considerably, so does dynamic reliability. Functional reliability indicates the likelihood that the jetty will continue to perform its intended function to protect the MCR navigation channel from interrupted service initiated by a failed (breached) jetty section. A value above 0.8 indicates that the jetty is functioning adequately; a value below 0.4 indicates that jetty function is at risk of failure (see Table A2- 4). Functional reliability is based on the cross-section area remaining with the upper section and dynamic reliability, and displays less irregularity than dynamic reliability due to the buffering effect of the cross-sectional area. Immediately after initial construction, the North Jetty has full cross-section and moderate resilience to resist the wave conditions affecting the jetty. However, the rate of scour and elevated wave forcing along the outer end of the jetty quickly began to reduce the cross-section in this area, resulting in rapid reduction of reliability during the first 8-10 years of service life.

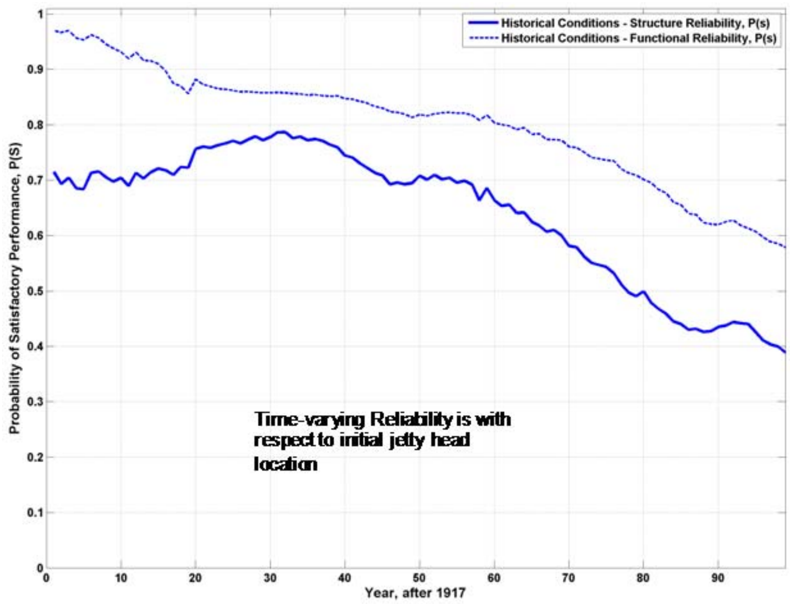

Figure A2- 49. Monte Carlo: Variation in North Jetty Reliability: 1917-2016

The abrupt change in reliability at year 10 (1927), is due to the rapid accumulation of sediment along the north side of the North Jetty acting to protect the jetty from wave action.

Around hindcast year 10 (1927), Peacock Spit began to rapidly accrete past station 100 along the ocean side of the jetty, protecting the ocean side of the jetty from wave action and scour. At the same time, jetty repairs begin to come on-line in the model. The combined effect of restored jetty section and "shoal protection" is shown in Figure A2- 49 as an increase in dynamic and functional reliability. Beginning in year 30 (1947), dynamic reliability began to fall off as Peacock Shoal began to recede and jetty segments become exposed to increase weave and current action. Functional reliability responds more slowly to these changing conditions, as this metric tends to decline after the jetty becomes damaged. In year 50, the North Jetty experiences another campaign of repairs and reliability increases slight. After year 60 (1977), the North Jetty experiences continual reduction in reliability as the previous repairs become degraded and Peacock Spit continues its landward recession exposing more of the un-repaired jetty to added degradation. Localized repairs executed late in the structure life-cycle do little to improve both reliability measures. The North Jetty ends its historic life-cycle in a state of deferred repair, low reliability, and high vulnerability. The future condition appears to be one of continuous repairs, uncertain reliability, and risky project performance.

Figure A2- 50 compares the actual repair cost to the simulated repair cost (shown in $2010). There is overall good agreement between the actual vs. observed costs, but there are some differences in repair timing. The difference between actual and hindcast total life-cycle cost is 1%. The cost stream associated with actual jetty repairs occurs as a stepwise function of time, due to the lagging nature of executing repairs on infrastructure which is inherently costly and difficult to maintain; interim repairs lag repair need by 1-6 years. The SRB model initiates repairs as the damage exceeds the maintenance threshold for each active jetty segment, sometimes resulting in a more continuous repair cost-stream than actual conditions;

jetty repairs are made when they are needed. There can be a minimal lag effect when simulating jetty repair within the SRB model. The absence of this lag effect should be considered when comparing SRB modeled cost-stream data to actual conditions, the timing of simulated repairs may occur sooner than actual staged conditions indicate.

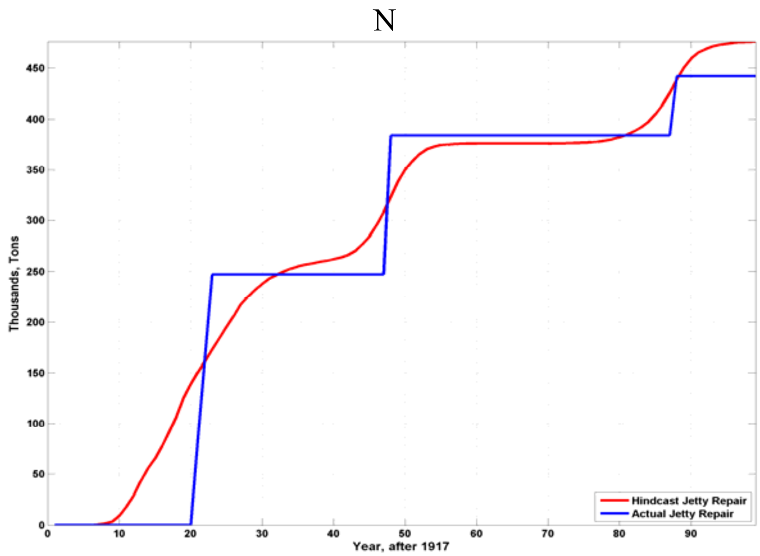

Figure A2- 50. Monte Carlo: North Jetty Life-Cycle Cumulative Repair Tonnage: 1917-2016

c. South Jetty Simulated Historical Performance, 1910-2007

Figure A2- 51 through Figure A2- 57 summarize the SRB model results from simulating the historical 97-year life-cycle of the South Jetty, based on a 1000-iteration Monte Carlo simulation. Figure A2- 51 shows the center line profile for "as-built" initial condition, observed condition in 2007, and simulated condition in 2007. There is good agreement between the observed and simulated end-state. Note the extent of jetty head recession, which is being aggravated by severe toe scour. The concrete cap is located at station STA 330 and shows signs of degradation (see Appendix A1). Figure A2- 52 describes cross-section evolution at jetty STA 300 for the last iteration of the Monte Carlo sequence. During this particular life-cycle iteration, STA 300 was simulated to have been repaired two times (1928 and 1963) after initial construction in 1910.

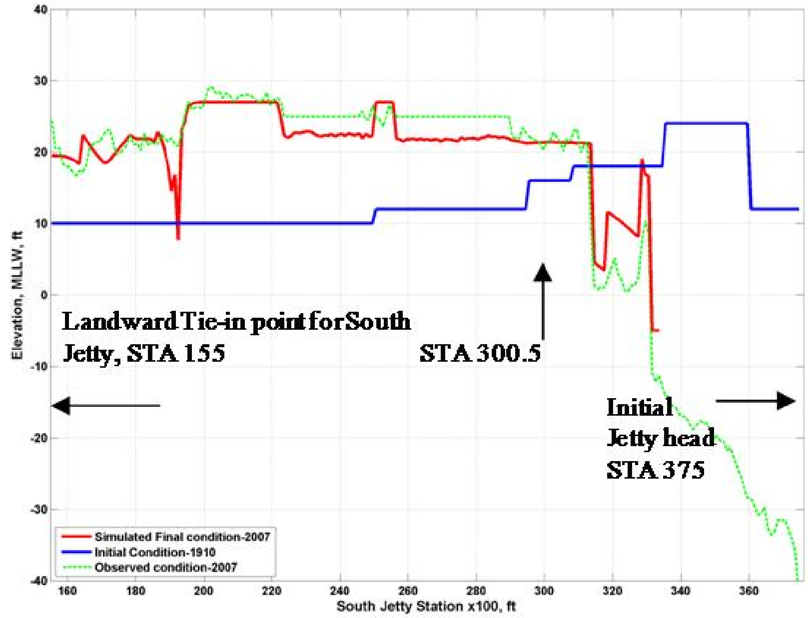

Figure A2- 51. Monte Carlo: South Jetty Crest Profile Evolution: 1910-2007

Centerline profile for MCR South Jetty: extends from landward limit (Sta. 115) to seaward limit (Sta. 375). Comparison of initial condition (1910) to observed and model simulated final condition (2007).

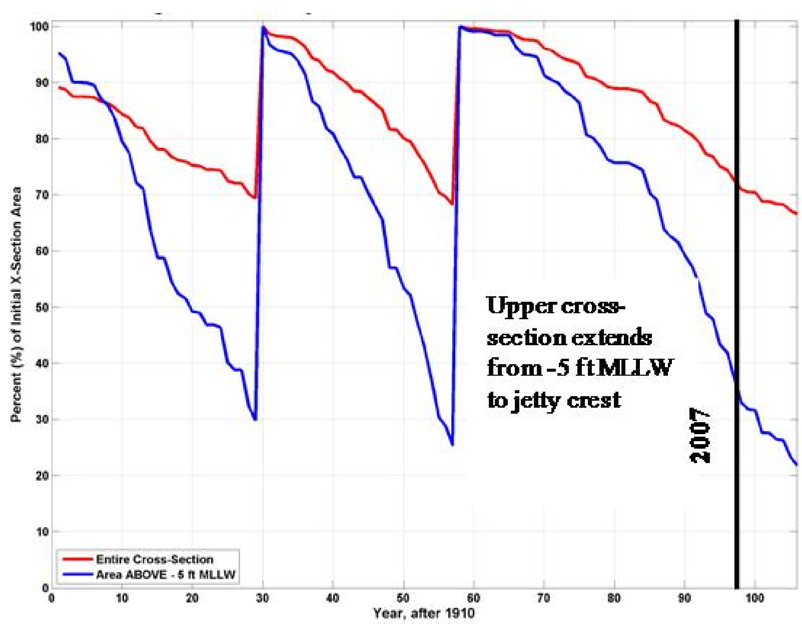

Figure A2- 52. Change in South Jetty Cross-Section Area at SAT 300.6: 1910-2016

Variation of upper cross-section area at Sta 300 during one Monte Carlo realization .The cross section accumulated damage and was then repaired at a the "interim repair" threshold. 2 repairs.

There are some differences in repair timing; as discussed for the North Jetty. Figure A2- 53 through Figure A2- 55 show the timing, number, and location of repairs historically made to the South Jetty. Areas along station 250-260 have relatively fewer repairs than adjacent area due to the sheltering effect of the "knuckle" area. Areas along station 200-250 require additional repair due to exposure to heavy wave action and the fact that past repairs featured less resilient jetty cross-section than areas further offshore. Compare Figure A2- 51 and Figure A2- 54, there is good agreement between actual repairs made and the simulated condition. Note how the jetty head has receded landward, despite the repairs made to the outer end of the jetty. Figure A2- 56 describes the time-varying reliability for the South Jetty during 1910-2007. Large upswings in reliability correspond with large-scale repair campaigns conducted during the 1930s and 1960s; significant areas of the jetty cross-section area was either restored or improved. The armor stone size used for most of these repairs was less than what was needed due to the severe exposure of the South Jetty. This is why the reliability was not significantly improved after each major repair campaign. By comparing Figure A2- 55 and Figure A2- 56, one can see that reliability is correlated with the onset (or absence) or jetty repairs.

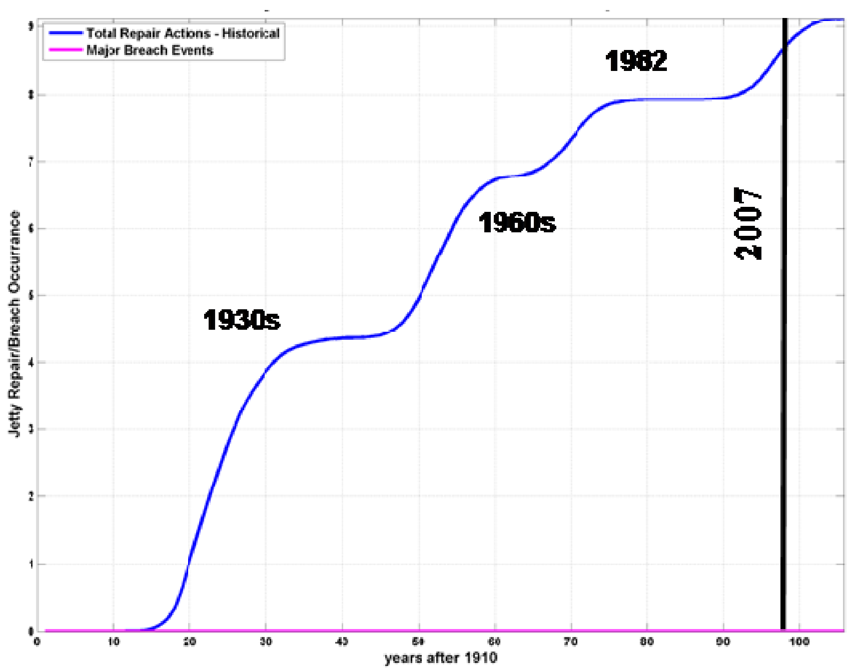

Figure A2- 53. Monte Carlo: South Jetty – Cumulative occurrence of Repairs and Breaches: 1910-2016

Cumulative jetty repairs for hindcast simulation. The number of jetty segments repaired has been normalized based on the average repair length of 5,000 ft per North Jetty repair campaign.

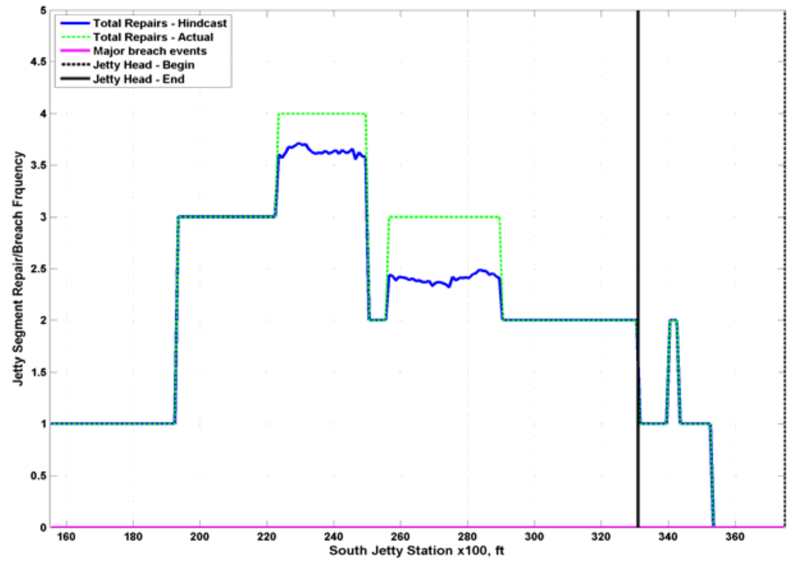

Figure A2- 54. Monte Carlo: South Jetty – Repair & Breach Frequency/ 100-ft Segment: 1910-2016

Comparison of actual jetty repair history to hindcast condition, based on frequency and location of repairs. The jetty head location is indicated for 1910 and 2007 (simulated condition).

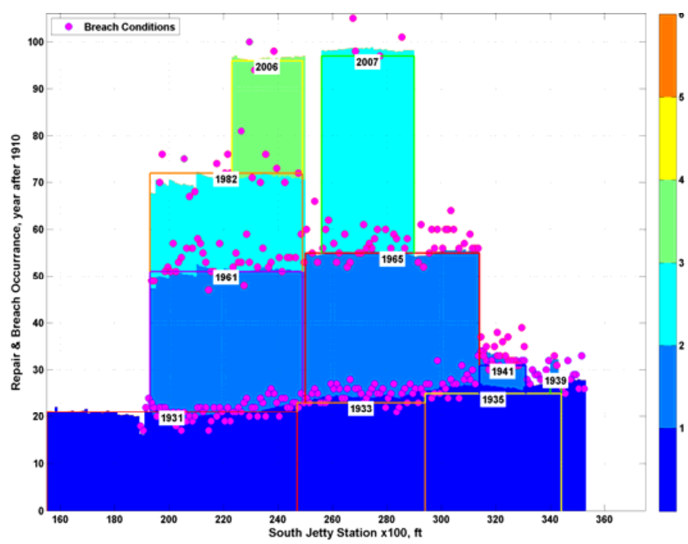

Figure A2- 55. Monte Carlo: South Jetty – Repairs & Breaches per 100-ft Segment: 1910-2016

Hindcast repair occurrence for MCR South Jetty, shown for each 100 ft jetty segment. Dark bars are first repair, lighter bars are second repair. Onset of repairs is based on bar endpoint.

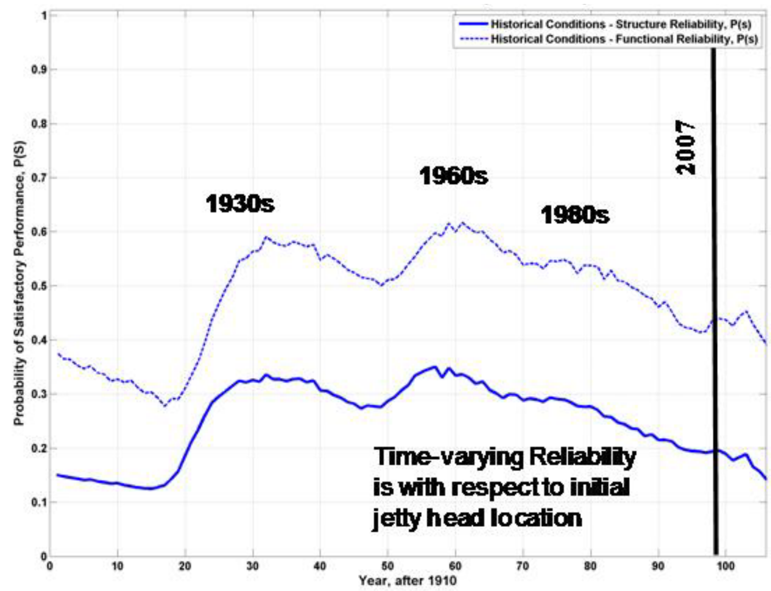

Figure A2- 56. Monte Carlo: Variation in South Jetty Reliability: 1910-2016

Hindcast reliability for the MCR South Jetty for hindcast condition (1910-2007). The upward change in reliability at year 25 (1935) and year 55 (1965) is due to major jetty repair campaigns.

Figure A2- 57 compares the actual repair cost to the simulated repair cost (shown in $2010). There is good agreement between the actual vs. observed costs; the difference between actual and hindcast total life-cycle cost is 1%.

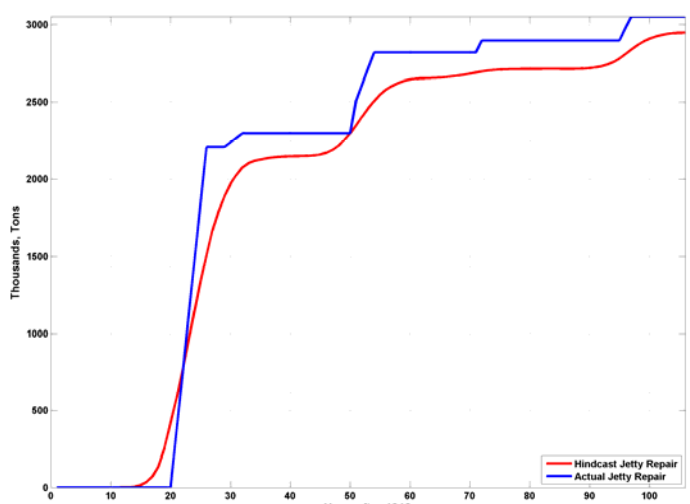

Figure A2- 57. Monte Carlo: South Jetty Life-Cycle Cumulative Repair Tonnage: 1910-2016

d. Jetty A Historical Performance, 1939-2006

Figure A2- 58 through Figure A2- 64 summarize the SRB model results from simulating the historical 67-year life-cycle of the MCR South Jetty, based on a 100-iteration Monte Carlo simulation. Figure A2- 58 shows the center line profile for "as-built" initial condition, observed condition in 2006, and simulated condition in 2006. There is good agreement between observed and simulated end-state. Note the extent of jetty head recession, which has been aggravated by severe toe scour at areas beyond station 95. Figure A2- 59 describes cross-section evolution at station 300 for the last iteration of the Monte Carlo sequence. During this particular life-cycle iteration, station 67 was simulated to have been repaired two times (1958 and 1963) after initial construction in 1939.

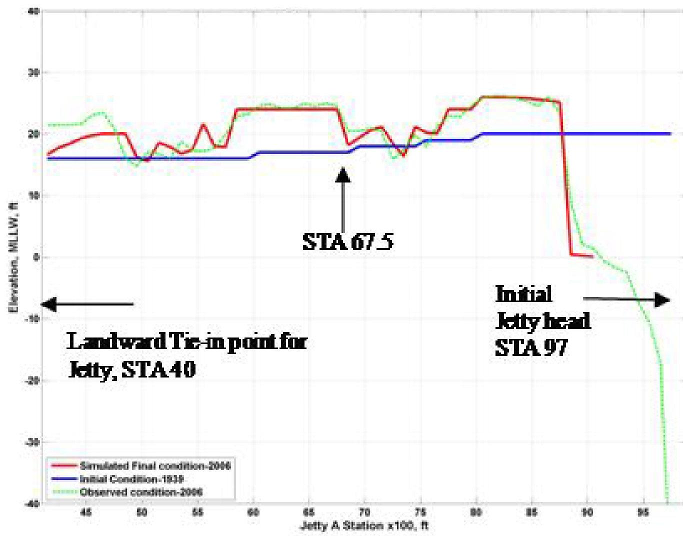

Figure A2- 58. Monty Carlo: Jetty A Crest Profile Evolution: 1939-2006

Centerline profile for MCR Jetty "A": extends from landward limit (Sta. 41) to seaward limit (Sta. 97). Comparison of initial condition (1939) to observed and model simulated final condition (2006).

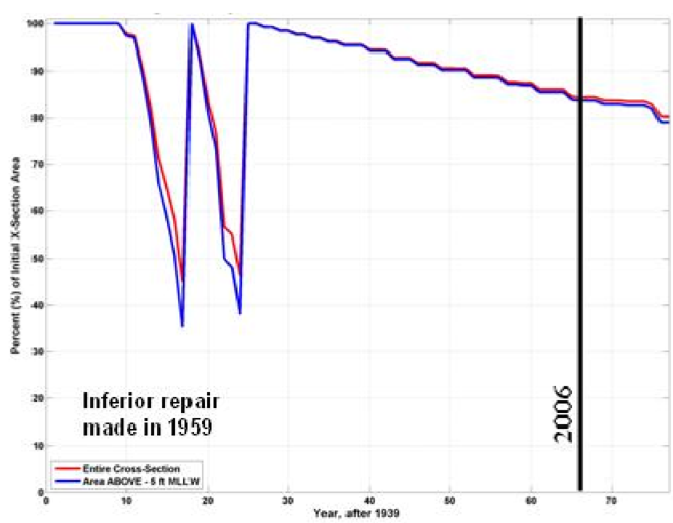

Figure A2- 59. Change in Jetty A Cross-Section Area at STA 67.5: 1936-2016

Variation of upper cross-section area at Sta 67 during one Monte Carlo realization .The cross-section accumulated damage and was then repaired using the "interim repair" threshold. Two repairs.

Overall, there is good agreement between actual repairs made and the simulated condition.

Figure A2- 60 through Figure A2- 62 show the timing, number, and location of repairs historically made to Jetty A. The area from station 41-46 was likely repaired based on the need to establish consistent equipment access to the rest of Jetty A. The tendency of the SRB model was to not repair this area due to low exposure to wave action during the life-cycle. Comparing Figure A2- 58 and Figure A2- 61 shows that the outer end of the jetty took a beating from station 90 outward. Note how the jetty head has receded landward, despite the repairs made to the outer end of the jetty. Figure A2- 63 describes the time-varying reliability for Jetty A during 1939-2006. The reduction in reliability during year 0 (1939) to 19 (1958) occurred despite a sustained program of continual jetty maintenance. The reason for this is based on two factors. First, Jetty A was constructed on a large sand shoal that rapidly retreated from station 89 in 1939 to station 49 by 1960. The recession of ocean side morphology exposed Jetty A to increased wave action. A second factor contributing to reduced reliability during 1939-1958 were the repairs made to the jetty during this period. The stone size obtained and the cross-section template for some of these early repairs was deficient. Jetty A repairs made during 1958 and 1962 were more robust, resulting in improved reliability. This condition persisted until the later repairs became damaged, with the jetty now in a serious condition of deferred maintenance. By comparing Figure A2- 62 and Figure A2- 63, it can be seen that reliability is correlated with the onset (or absence) or jetty repairs and retreating morphology.

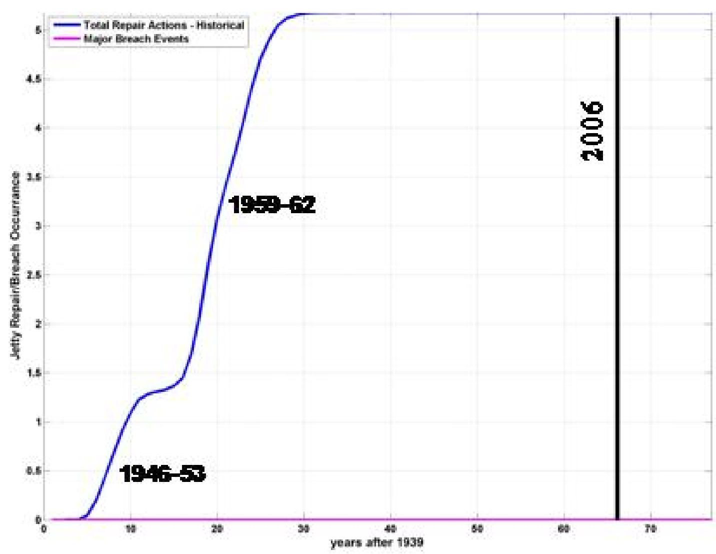

Figure A2- 60. Monte Carlo: Jetty A – Cumulative Occurrence of Repairs & Breaches: 1939-2016

The number of jetty segments repaired has been normalized based on the average repair length of 1,900 ft per Jetty A repair campaign.

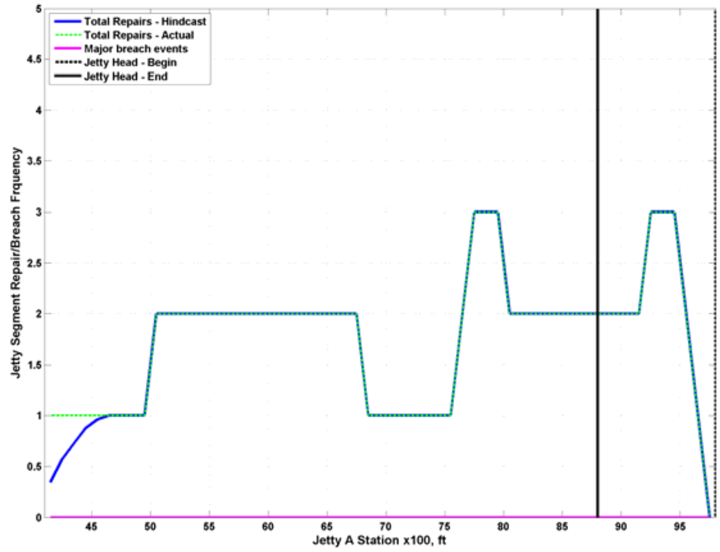

Figure A2- 61. Monte Carlo: Jetty A – Repair & Breach Frequency/100-ft Segment: 1939-2016

Comparison of actual jetty repair history to hindcast condition based on frequency and location of repairs. The jetty head location is indicated for 1939 and 2006 (simulated condition).

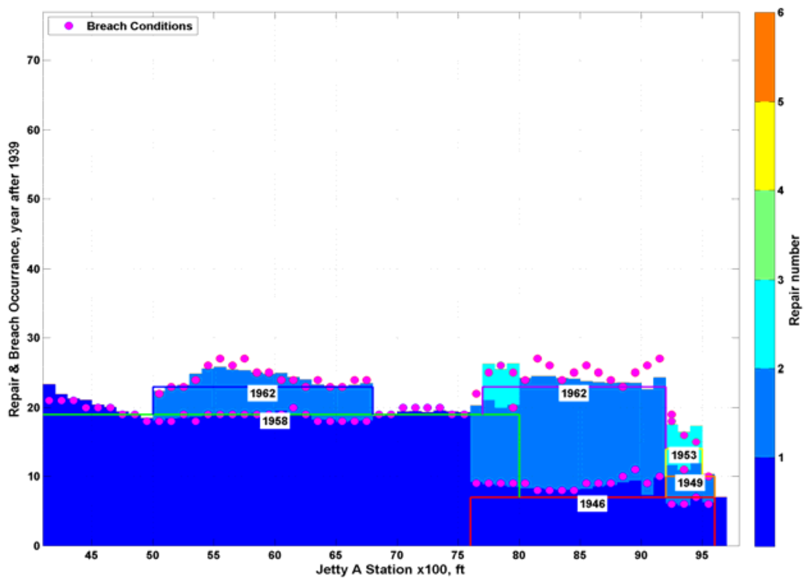

Figure A2- 62. Monte Carlo: Jetty A – Repairs & Breaches per 100-ft Segment: 1939-2016

Dark bars are first repair, lighter bars are second repair. Onset of repairs is based on bar endpoint.

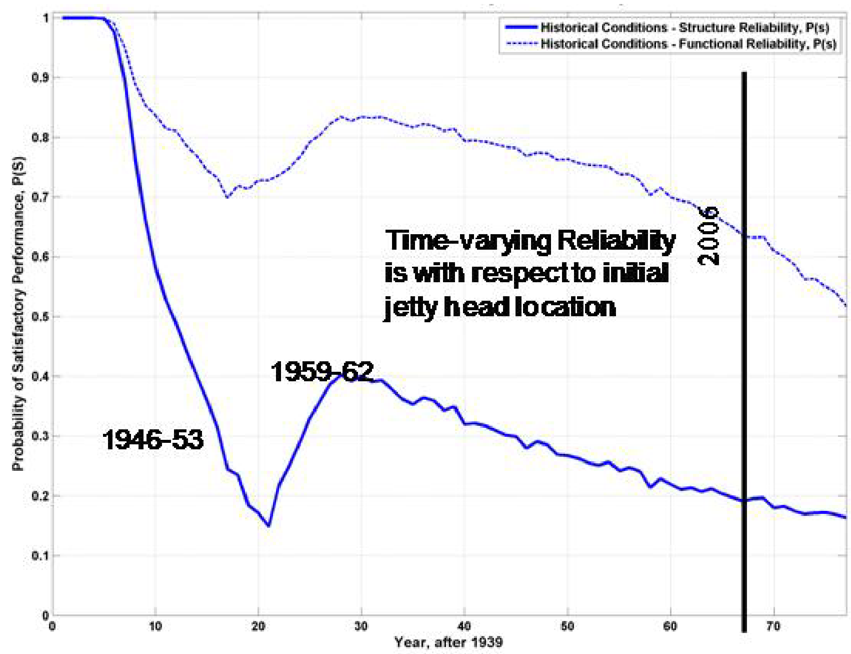

Figure A2- 63. Monte Carlo: Variation in Jetty A Reliability: 1939-2016

Hindcast reliability for the MCR Jetty A for hindcast condition (1939-2007). The upward change in reliability at year 25 (1962) is due the last major repair campaign for Jetty A.

Figure A2- 64 compares the actual repair cost to the simulated repair cost (shown in $2010). There is good agreement between the actual vs. observed costs; the difference between actual and hindcast total life-cycle cost is 4%. There is little difference in repair timing for the hindcast and observed condition.

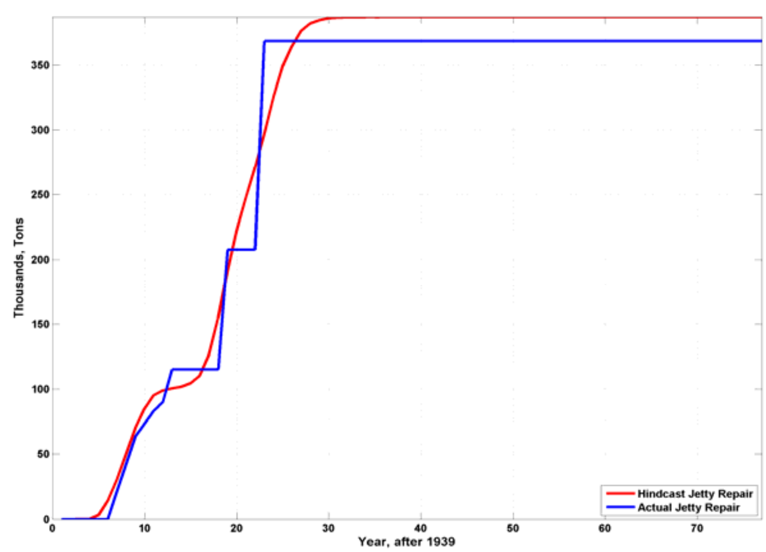

Figure A2- 64. Jetty A Life-Cycle Cumulative Repair Tonnage: 1939-2016

e. Jetty Reliability, Past and Present

Reliability of the MCR jetties has been highly variable through time, as shown in Figure A2- 43Figure A2- 64. Hindcast results for jetty reliability are shown with respect to initial jetty head location (at time of jetty construction). The most significant factors affecting MCR jetty reliability (during the previous life-cycle) have been the morphology evolution at the inlet and past jetty rehabilitation/repair campaigns. Morphology changes have acted to both increase and reduce jetty reliability; this is most notable at the North Jetty when Peacock Spit rapidly accreted during 1917-1939. All three jetties were adversely affected by severe scour that set up along various areas of each jetty. The rehab campaign during the 1930s significantly increased the reliability of the South Jetty and North Jetty, as did the 1960s rehab of the Jetty A. Since the time of previous jetty rehab, the MCR jetties have exhibited progressively lower reliability. The present reliability of North Jetty and Jetty A is significantly lower than at the time of jetty construction. Present reliability for the South Jetty is slightly lower now than at the time of jetty completion (1910). The South Jetty hindcast result is noteworthy because the South Jetty had very low reliability to start with; the 1930s rehabilitation effort had significantly improved the South Jetty reliability from its initial condition in 1910. The present reliability (for 2006/2007) shown in Figure A2- 43 through Figure A2- 64 are fairly LOW because these values are with respect to initial jetty head location (at time of jetty construction).

f. Hindcast Summary

The above hindcast modeling results indicate that the SRB model can accurately portray the historical life-cycle for the three MCR jetties in terms of the following performance metrics: jetty repair location, timing, and frequency; time-varying life-cycle cost; and jetty profile end state. Hindcast reliability clearly illustrates the emergent cyclical behavior of each jetty as it is damaged through time, becomes vulnerable, and is then repaired. As such, the SRB model was considered to be calibrated and verified to perform future life-cycle simulations for evaluation of optimal life-cycle investment strategies for the MCR jetties.

8. FUTURE CONDITION SRB SIMULATIONS

A number of alternatives were evaluated using the SRB Model. The list of alternatives for North Jetty, South Jetty and Jetty A are presented in Table A2- 18 through Table A2- 20; main governing parameters of each alternative are presented in Table A2- 21 through Table A2- 23. A more detailed description for each alternative is given in Appendix A1.

The selected results for each alternative are shown in figures A2-68 through A2-138 (provided at the end of this appendix). Each alternative figure number reference can be found in Table A2- 18 through Table A2- 20.

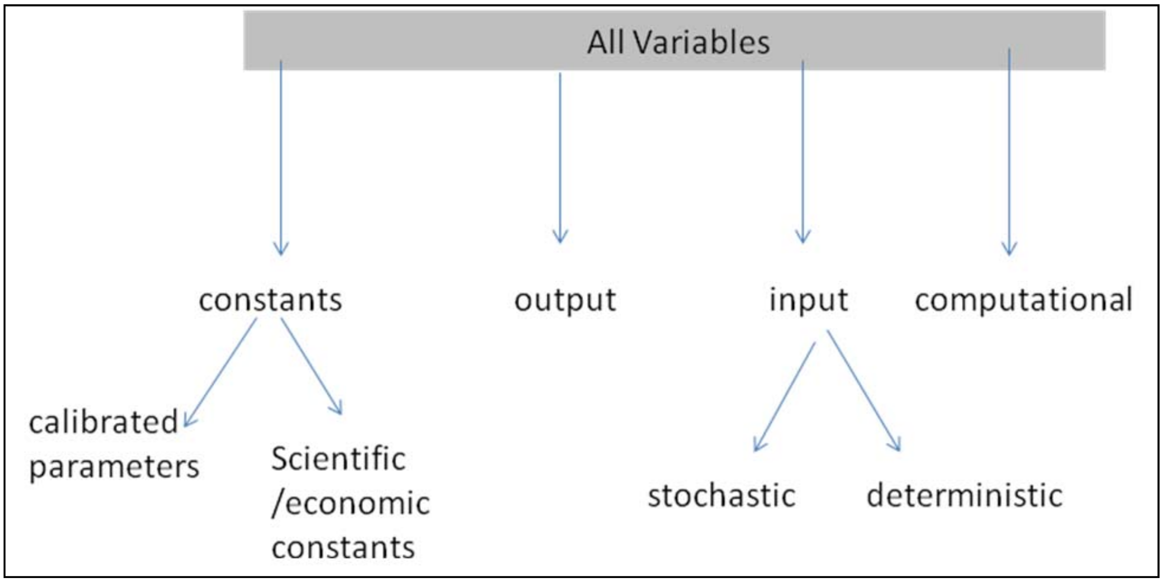
9. SRB MODEL SENSITIVITY ANALYSIS AND VARIABLE DEFINITION

a. Variables Used in SRB Model

There are approximately 600 variables used in the SRB model, all of which can be segregated into four categories: constants, output, computational, and input. The below graphic illustrates the four categories for variable definition. Refer to Appendix A3: SRB Model User's Manual for a listing of variables using within the SRB model.



b. Evaluation of Variable Variation

A model sensitivity analysis was conducted to ascertain the effect that random variation of 11 specific model parameters had on the overall predicted life-cycle cost ranges. These specific parameters were deemed to have the most impact on life-cycle performance estimates. The sensitivity analysis was run for each of the three MCR jetties for the base condition (no action alternative). One at a time, the 11 model parameters were allowed to randomly vary, while holding all other parameters at a constant value (mean value). Twenty-five Monte Carlo simulations were run for each varied parameter to obtain a representative range of life-cycle costs for "single parameter" variation.

In addition to allowing each individual parameter to vary one at a time, an additional Monte Carlo simulation was run allowing all parameters to randomly vary simultaneously (unconstrained run). The unconstrained run provided a life-cycle mean cost (global mean) by which to compare the "single parameter" variation results of the sensitivity analysis.

Through this procedure, a range of life-cycle costs, dependent on variation in one parameter, as well as a baseline for comparison (all parameters allowed to vary), were estimated. The results, when plotted, produce an immediate, ranked view of the parameters that have the largest impact on life-cycle cost range. The parameters that were included in this analysis are listed in Table A2- 24.

Table A2- 24. Randomly Varied Parameters, Description and Respective Nomenclature Used in Figure Labels.

Model Parameter Name	Parameter Description	Figure Label
dam_var	Variation on the amount of damage that is applied for a specific wave height in a particular storm event. Adds random variation to the applied damage functions.	**Jetty Wave Damage Variation**
COST_VAR	Variation on the cost labor and materials included in the model (e.g. dredging, breaching, stone costs, etc.). Adds random variation to costs of these items.	**Unit Cost Variation**
lowest_bound	Damage threshold variation for determining when a breach can occur. Adds random variation to the threshold below which breaching is allowed to occur.	**Breach Damage Threshold Variation**
upper_bound	Damage threshold variation for determining when repairs can be made. Adds random variation to the threshold below which repairs can be made.	**Repair Damage Threshold Variation**
B_COST_SEG_INCR	Variation on the dredging cost due to breaching. This is only activated when breaching occurs in the model.	**Breach Related Dredging Costs**
re_use_stone_factor_repair	Variation on the amount of jetty stone that is needed with each successive repair.	**Jetty Stone Repair Factor Variation**
storm_nyear	Variation on the number of storm events per year. Randomly varies the number of storm events predicted to occur annually.	**Annual No. Storm Events**
WAT_LVL	Total Water Level variation (including variation in tide level, storm surge and infragravity surge). Randomly varies the tide level, storm surge and infragravity surge components of the total water level. The sum of the random predictions plus the expected sea level rise for a given year is the total water level during a given storm event.	**Total Storm Water Level**
Wave_H_request	Variation in offshore storm wave height. Adds variation to the deepwater offshore wave height predicted for a given year.	**Offshore Storm Wave Height**
DIR_initial	Variation in primary offshore storm wave direction (Determines from NW or SW direction). Adds variation to the initial direction, which selects waves from the NW or SW, two different storm distributions.	**Offshore Storm Wave Direction [1]**
Wave_DIR_request	Variation in secondary offshore storm wave direction (Variation within NW or SW directions). Adds variation within the initial wave direction.	**Offshore Storm Wave Direction [2]**

Life-cycle costs in the analysis were computed by summing annual costs for each Monte Carlo simulation. Twenty-five (25) life-cycle costs (25 Monte Carlo simulations) were estimated for each varied parameter simulation. The minimum and maximum life-cycle cost for each varied parameter simulation defined the 'life-cycle cost range' of that respective parameter. Then, the life-cycle cost range for each parameter was normalized, ranked and plotted, using the following equation:

$$X_n = \left(\frac{X - \overline{X}_i}{\overline{X}_g} \right)$$

where X_n is the normalized lifecycle costs for variation of a specific parameter; X represents the lifecycle cost minimum and maximum values, in current dollar value; $\overline{X}_i$ is the life-cycle cost mean value computed from each *individual* varied parameter simulation result (mean life-cycle cost of 25 Monte Carlo simulations), and $\overline{X}_g$ is the life-cycle cost *global* mean value computed from the baseline simulation results (mean cost of 25 baseline condition simulations).

When plotted, the results produce a ranked view of the parameters that have the largest to least (top to bottom) effect on estimated life-cycle cost range with respect to the global mean value (Figures A2-29 to A2-31). The cost range associated with each varied parameter in the plots below denotes the amount of variation about the global mean life-cycle cost that can be expected from only the contribution of the specific varied parameter.

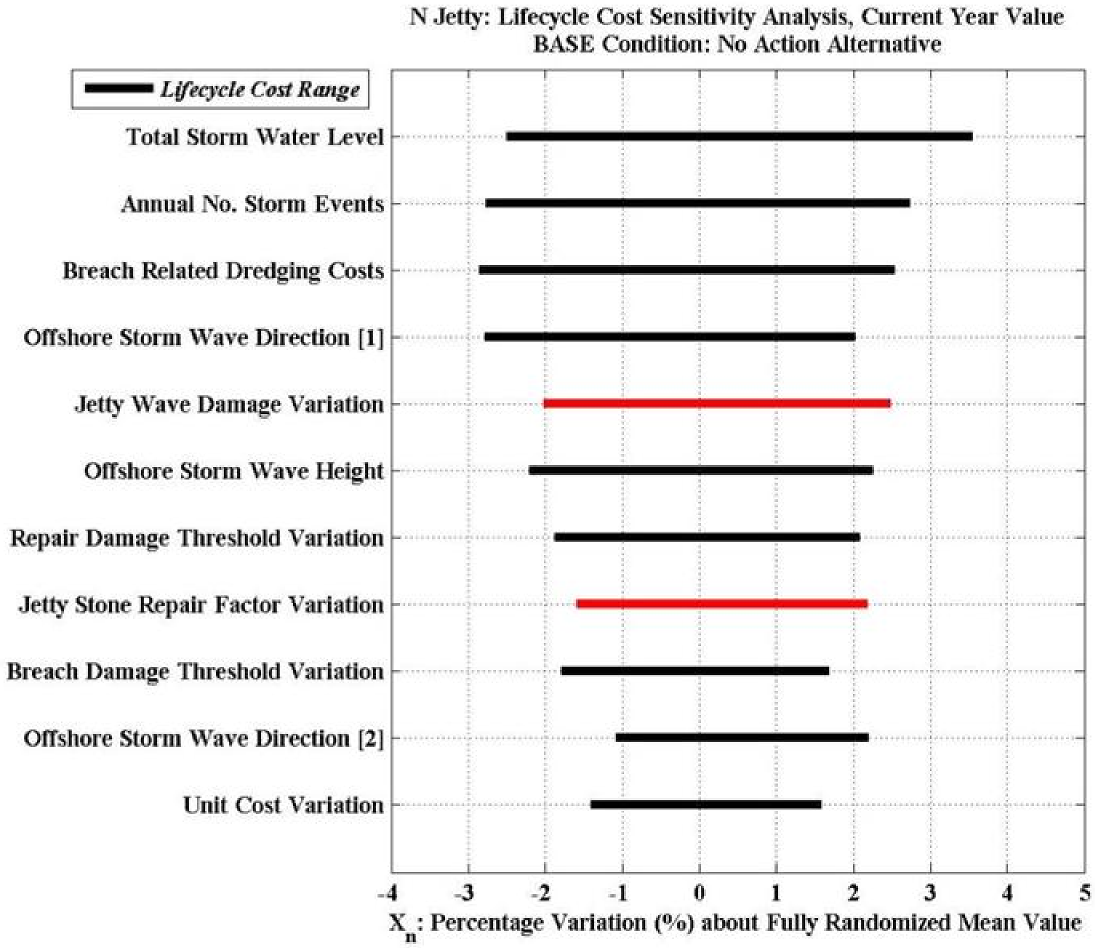


Figure A2- 65. Tornado Plot for North Jetty – Sensitivity Analysis for Key Variables

Red colors denote calibration parameters.

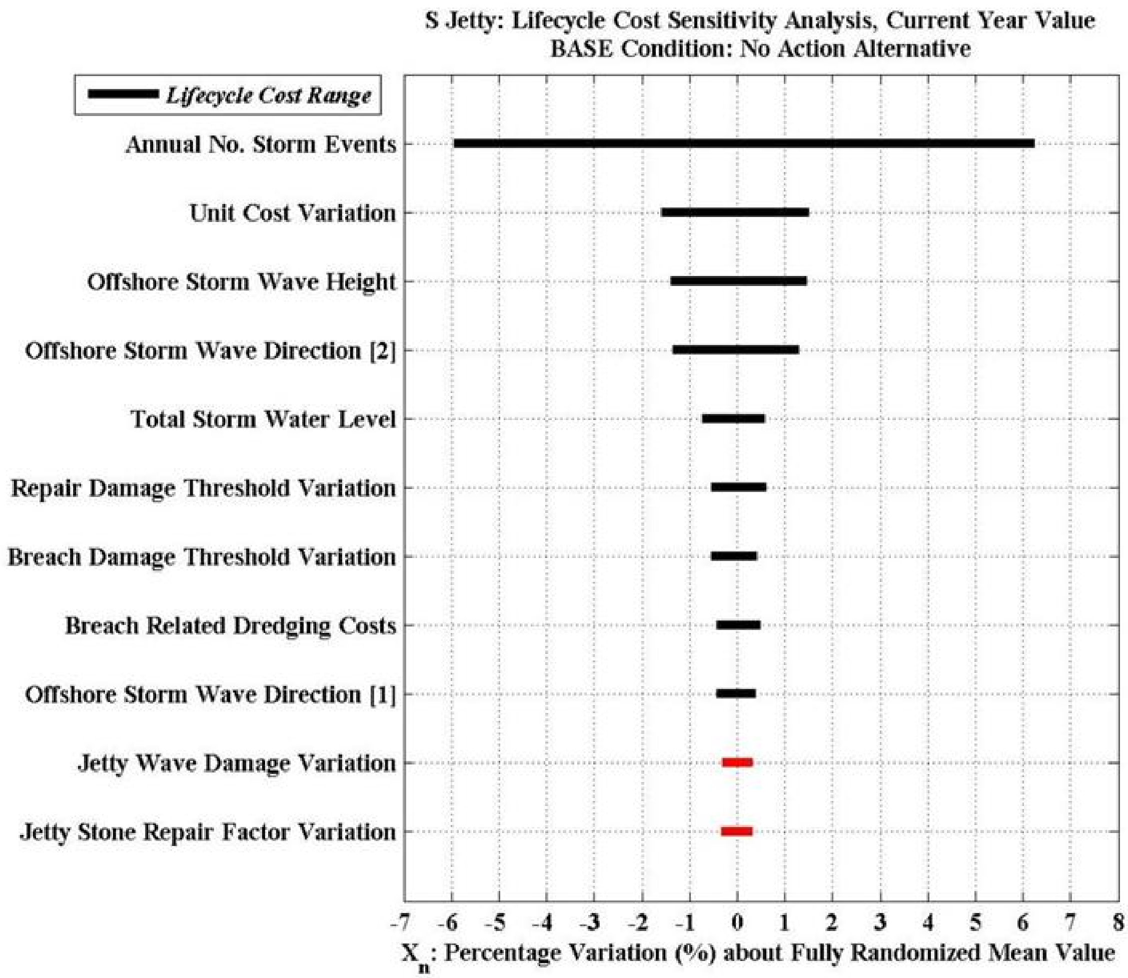

Figure A2- 66. Tornado Plot for South Jetty – Sensitivity Analysis for Key Variables

Red colors denote calibration parameters.

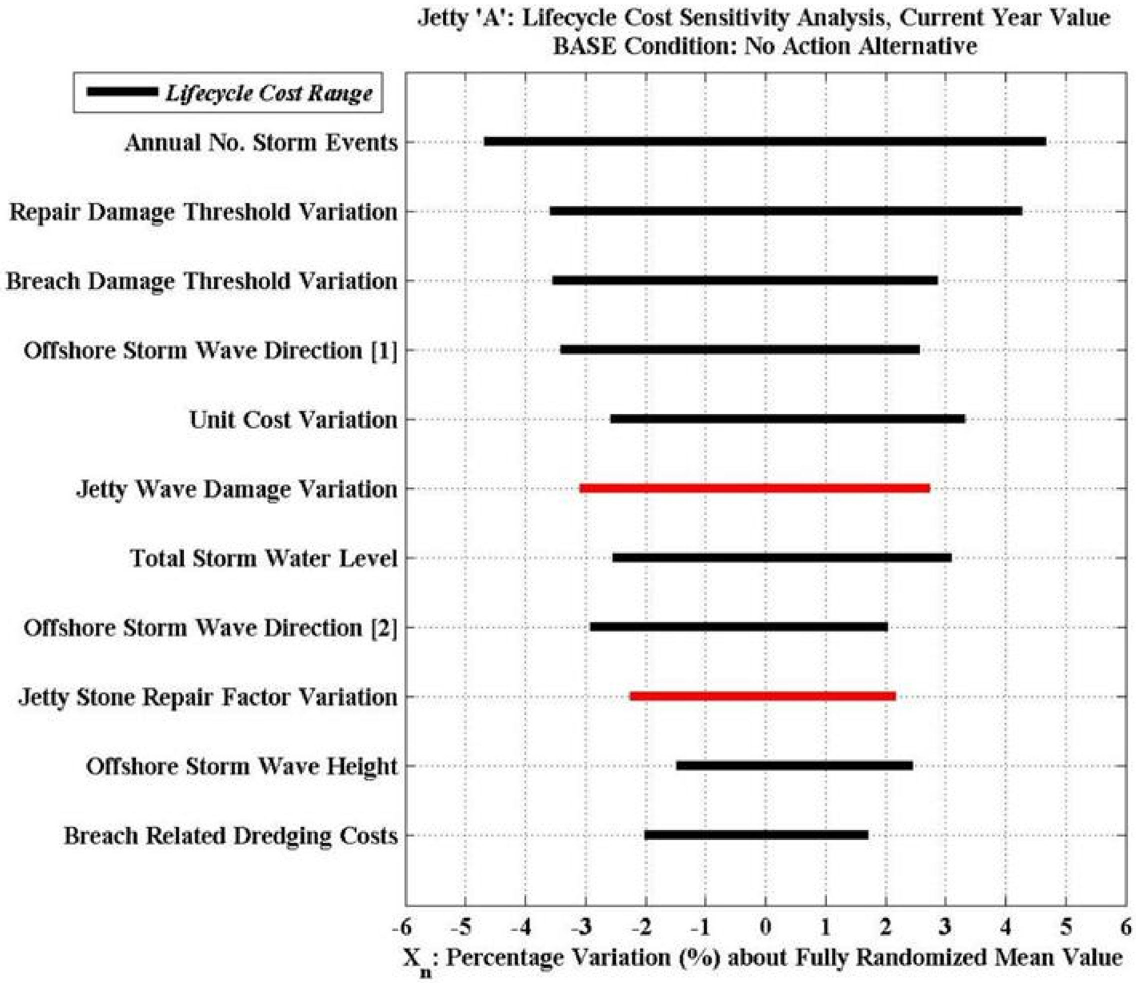

Figure A2- 67. Tornado Plot for Jetty A – Sensitivity Analysis for Key Variables

Red colors denote calibration parameters.

The parameters that were included in this analysis are listed in Table A2- 24. The results produce what is commonly referred to as a 'tornado plot' (a.k.a. tornado chart or tornado diagram) because the shape of the plot when ranked (maximum cost range at top, minimum cost range at bottom) resembles a tornado. An observer can immediately identify the randomized parameters that contribute to the largest variability in lifecycle cost ranges (located at the top of the figure).

c. Influence and Ranking of Key Variables

In Figure A2- 65 through Figure A2- 67, two of the parameters used to calibrate the models are highlighted in red to show the effect that varying the calibrated parameters has on expected life-cycle costs. The calibration parameters appear to have a larger influence over life-cycle costs for Jetty A than for the North or South Jetties.

It is noteworthy to point out that there is a significant difference in tornado plot results between the South Jetty and the other two jetties. The reason for this is that the South

Jetty life-cycle response is a product of the different environmental exposures between the jetties. The South Jetty is the longest of the jetties (i.e., more segments that are subject to damage and repair) and experiences a different storm wave environment (more exposed) than the other two jetties due to its location and orientation. Therefore, it has the potential to experience more damage and repair costs over its expected lifetime.

MCR Jetty System Major Rehabilitation Evaluation Report

Appendix A3

SRB Model User's Manual

Preface

This User's Manual contains a description of how to apply the Stochastic Reliability-Based (SRB) Model for evaluating future maintenance alternatives for the Mouth of the Columbia River (MCR) jetty systems. This User's Manual and the SRB model have been modified/improved to address review comments from the U.S. Army Corps of Engineers Headquarters (HQUSACE) and an Independent Engineering Peer Review (IEPR) team. This manual replaces the previous *Model Documentation Report* (USACE, 2010).

In order to address the IEPR team's unresolved comments, CENWP retained the assistance of Moffatt and Nichol, via a two-phase task order. Phase I of the task order was to review the model, associated documentation, and engineering regulations to identify specific changes that needed to be made in the model code and Phase II was to assist CENWP in making those changes. Phase I produced a letter report evaluating the functionality of the MCR SRB model and identified nine specific improvements to the model that addressed the outstanding concerns. All nine of the recommendations were adopted by the PDT and were then developed and implemented in Phase II. Among the specific improvements are: an improved user interface, a detailed user's manual, changes to the SRB model structure (including the use of one model for all three MCR jetties), changes to how costs are evaluated, and other modifications which were recommended by HQUSACE. The table on the following page lists the nine required improvements, how the improvements were implemented, and the related sections of this User's Manual.

A significant new aspect of the SRB model is the input interface. The model user is able to define and modify input parameters from a convenient Excel worksheet. A description of this input interface is included as an appendix to this manual, as well as within the main body of the manual.

It should be noted that the SRB model does not develop design criteria for the alternative plans. The alternative design process is performed external from the SRB model and the alternative design parameters are then input into the SRB model by the user in the form of an Excel file. Other input parameters include damage functions, storm events and wave heights, initial jetty geometry, and other simulation control variables such as the desired duration of the lifecycle model. Various alternatives can be evaluated by the SRB model by changing the input parameters to the SRB model.

The cost analysis is performed separately from the structural calculations and is further described in the *MCR Major Rehabilitation Evaluation Report* (USACE, 2012). The structural analysis is performed first, via the SRB model, resulting in calculations of jetty degradation and repair (e.g. life-cycle material quantities) for each repair alternative. The output files from this SRB model analysis are then used as inputs to the Excel spreadsheet-based cost analysis to estimate life-cycle costs and other parameters for each alternative.

This User's Manual starts with an overview of the MCR SRB model operation in order to facilitate basic understanding. Additional sections provide details of the specific model input procedures, output options, variables definitions, model subroutines, a narrative of how the model handles a typical jetty section, and a discussion of the model calibration approach and results. Appendix B of the manual provides a comparison of results between the original model and the new model.

Required Improvement	Model Improvement Completed	Related Section of This Manual
1. Modularize the model code using the existing approaches where they are appropriate. Specifically, separate parts of the code related to the following: Setup of global variables, setup of MC simulation, specification of alternatives, calculation of damage functions, geometry adjustment after damage, creation of output and plotting.	Separate scripts created for these and other parts of the model code.	Sections 3.5 – *Input Setup* and 3.7 – *Running the Model* – Table 5
2. a) Validate independent modules based on available literature and previous experience with the MCR jetties. b) Alternative formulations of the damage functions used in the model should be provided for comparison of model results with alternative published analytical formulations.	a) Model applied in hindcast mode and compared to historical records of MCR jetty maintenance. b) Damage functions were developed through detailed physical model studies conducted at ERDC, featuring MCR jetty cross-section attributes.	a) Section 6 – *Model Calibration* b) 5.3 – *Damage Quantification / Function*
3. Calibration results for the model need to be clearly documented. To accomplish this, the calibration process and parameters must be clearly documented within the model and in the model output and reporting.	Calibration was completed for hindcast conditions. The results are shown in the figures in Section 6.	Section 6 – *Model Calibration*
4. During the process of modularizing the existing model, the structure should be changed to allow a single model code capable of evaluating alternatives for all three jetties.	A single model code is used for all three jetties. Information for each specific jetty is input to the single model and MC simulations are run for each specific jetty.	Sections 3.5 – *Input Setup* and 3.7 – *Running the Model*
5. Improvements are required in the user interface to allow the user to easily review all input and output parameters. Existing hard-coded parameters should be removed from the model code to provide greater transparency.	The input parameters can be specified in an Excel file. The Excel file provides a convenient interface for editing the input parameters.	Sections 3 – *Model Input Interface* and 4 –*Model Output*
6. A well-documented user's manual needs to be prepared to allow qualified modelers to apply the model to evaluate alternatives.	A User's Manual (this document) has been created. This manual replaces the previous *Model Documentation Report* (USACE 2010).	Entire manual.
7. The economic and structural analyses should be separated into independent routines. The economic analysis calculations would be based on the output from structural simulations with an interface between the two models. This approach also permits the use of different economic analysis approaches for a single structural simulation.	The cost analysis is separate from the structural analysis. The structural calculations of jetty degradation and repairs are first performed and results are saved into output files. These output files are the inputs to the separate cost analysis.	Section 2.1- *Intent*. The cost analysis is described in the Evaluation Report
8. Additional metrics for evaluating alternatives can be output from the model to assist in the economic evaluation of the alternatives. These include structural and functional reliabilities, and stone volumes which were lost, placed, or moved. A facility can be created to easily calculate and output new metrics as needed.	Additional metrics, in the form of model output files, include these parameters.	Sections 2.6 – *Reliability* and 4 –*Model Output*
9. Shoaling related to jetty breaching should be eliminated while the repair requirements to the jetty section should be retained for the breaching.	The shoaling related to jetty breaching was eliminated. Breach occurrences and frequency are output files.	Section 4 – *Model Output*

1. INTRODUCTION

This User's Manual contains a description of how to apply the Stochastic Reliability-Based (SRB) Model for evaluating future maintenance alternatives for the Mouth of the Columbia River (MCR) jetty systems. Further background on the model formulation is available in Appendix A1: Coastal Engineering and Appendix A2: Reliability Analysis, Event Tree Formulation and Life-Cycle Analysis of the *MCR Jetty System Major Rehabilitation Evaluation Report* (USACE 2012), (a separate document from this user's manual).

1.1. BACKGROUND

The U.S. Army Corps of Engineers-Portland District coastal engineers have developed a stochastic SRB model to evaluate future jetty repair and rehabilitation alternatives for the MCR jetty systems.

Three jetties presently control the dynamic morphology of the MCR inlet (North Jetty, South Jetty and Jetty 'A'), each of which is in a varied state of deterioration. The jetties each provide an important individual function which contributes to the ultimate objective of securing and maintaining the configuration of the authorized navigation channel through the MCR inlet. Initial construction of the South Jetty began in the late 1800's; North Jetty construction began in 1917. The jetties were designed to minimize navigation channel maintenance and provide a safe entrance to the inlet. Over time, the channel thalweg migrated north, in proximity of the North Jetty. Jetty 'A' was constructed in 1939 to direct river (and ebb tide) currents away from the North Jetty, minimizing the potential for scour along the North Jetty foundation. The North and South Jetties have been repaired several times since original construction; the latest repairs occurred in 2005 on the North Jetty and 2006-2007 on the South Jetty (Jetty 'A' has only been repaired once since initial construction, in 1965). The recent repairs on the North and South Jetties were interim repairs designed to maintain jetty functionality until a longer-term maintenance and repair plan was designed.

The MCR SRB model described in this manual is intended to be a statistical tool that assists engineers and project managers in determining the most cost-effective and reliable method of maintaining and repairing the jetties in the future. The jetties have been functioning for over 70 years (South Jetty for over 100 years) and the SRB model is being implemented to determine the best repair and maintenance plan so that the jetties can continue to provide reliable function into the future.

1.2. RECENT MODEL DEVELOPMENTS

The MCR SRB model has been developed over several years and was subjected to an Agency Technical Review (ATR). After incorporating the ATR comments, the model was evaluated during the Independent Engineering Peer Review (IEPR) of the MCR Major Rehabilitation Study.

This User's Manual and the SRB model have been modified/improved to address the review comments from the IEPR team and HQUSACE. Among the specific changes are: an improved user interface, a detailed user's manual, changes to the SRB model structure (including the use of one model for all three MCR jetties), changes to how costs are evaluated, and other modifications. These improvements allow CENWP personnel to more easily evaluate various modifications to the alternatives analysis. This manual replaces the previous *Model Documentation Report* (USACE, 2010).

This User's Manual contains a description of how to apply the SRB Model for evaluating future maintenance alternatives for the MCR jetty systems. The MCR SRB model is intended to be operated by a person with some general knowledge about the model flow and implications of selecting alternative values for variables.

2. MODEL OPERATION OVERVIEW

2.1. INTENT

The general intent of the MCR SRB model is to provide data to predict the lifecycle costs of MCR jetty repair and maintenance alternatives. The ultimate objective is to utilize the predicted lifecycle cost ranges computed for each plan to select the option with the minimum cost. One of the basic assumptions of the model application is that the functional performance of the MCR jetties, in terms of stabilizing the navigation channel, will be not be compromised. Therefore, jetty reliability becomes less important relative to maintenance costs. At the foundation of the model is a Monte Carlo (MC) simulation which comprises numerous model runs (often in the thousands), each with varying random parameter values. The model, therefore, relies heavily on replicating stochastic processes that affect jetty life-cycle performance. The cost analysis is performed separately from the MRB model structural analysis and is described further in Chapter 2 and Appendix C of the *MCR Jetty System Major Rehabilitation Evaluation Report* (USACE 2012).

Random variation of specific parameters is necessary due to the uncertainty involved in predicting the future demand on, and resultant response of, the jetty structures. Random hydrodynamic effects (waves and currents), structural instabilities (improper interlocking of stones, poor foundation, etc.) and an uncertain future climate are just a few examples of the factors that will affect jetty structural performance. These uncertainties and others, however, will impact the total lifecycle cost of repairing and rehabilitating the jetties in the future. The degree of impact each parameter will have in the future is unknown.

Implementing a MC simulation in this model provides a means to estimate ranges of expected future jetty lifecycle performance metrics for different repair alternatives; these ranges are akin to confidence limits in a statistical analysis. Through this analysis, it is possible to observe the parameters that are most sensitive to random variation and have the largest impacts on lifecycle costs and/or reliability. If the impacts of these parameters are understood and their variation can be controlled to a certain degree, it should follow that the lifecycle costs can likewise be managed to a similar degree.

2.2. OPERATION

The SRB model is considered to be an engineering model and was developed based on USACE guidance for major rehabilitation evaluation and life-cycle analysis. Table 1 summarizes the physical processes that affect jetty life-cycle performance versus how those processes are addressed in the SRB model.

The MCR SRB model was built on the MATLAB® platform, a high-level language and interactive environment that enables performing computationally intensive tasks faster than with traditional programming languages such as C, C++, or FORTRAN. The model is constructed of a master routine that calls other subroutines throughout model execution.

The SRB model can be operated in two distinct manners: as a *hindcast* model typically used for calibration of critical model parameters or a *forecast* model. The hindcast mode for each jetty incorporates historical jetty geometries (e.g., cross-sectional elevations and widths), and other relevant information from the actual repairs that occurred to each structure since original construction (or since a specified historical date in the case of the South Jetty). Generally, if there is good agreement between modeled and historically measured data, then the model has good skill (predictability) and is deemed performing well. In calibrating the SRB model, historical repair schedules are compared to modeled schedules. Based on a qualitative assessment (i.e., observing plots of repair schedules), the hindcast predictions for the MCR jetties appear to have good model skill. The model calibration utilizing the hindcast mode will be discussed in a later section of this User's Manual.

Table 1: Physical Processes and Jetty Responses Emulated within the SRB Model

DEFINE INITIAL CONDITIONS Hindcast or Forecast →	SIMULATE ENVIRONMENTAL FORCING & STRUCTURE RESPONSE →	EVALUATE END STATE
Jetty Segment Attributes	**Environmetal Forcing and Jetty System Response**	**SRB Life-Cycle Performance Metrics**
(mean value, std dev)	(mean value, std dev for each side of jetty)	(mean value, std dev)
toe elevation	time-varying shoreline evolution	time-varying structural reliability
crest elevation	time- and spatially-varying scour rates	time-varying functional reliability
crest width	time- and spatially-varying wave conditions	timing and location of repairs
jetty side slope	time-varying water levels	repair tonnage & shoaling volume
armor stone size	variable jetty root degradation rates	jetty breach occurrence
armor stability number	repair history by jetty segment	components of life cycle cost
stone density	tonnage placed on the jetty	jetty crest elevation change
core stone presence	cost functions for jetty repair scenarios	cross-section evolution
jetty head position	channel shoaling associated with jetty performance*	jetty end state
	cost functions for dredging effect scenarios*	
*** = used for life-cycle cost forecasting**		

The hindcast model results are also used to initialize the model for operation in forecast mode. In forecast mode, the MCR SRB model predicts structural damages (based on randomized storm conditions), implements repairs and rehabilitations, and calculates material quantities involved over an anticipated jetty lifecycle. The jetty repair and rehabilitation responses that occur during forecasting in the SRB model are based on a user-selected repair plan and are activated when computed jetty damages exceed specified thresholds. The forecasting procedure is similar to the hindcast procedure within the SRB model. For simplicity, only the model forecasting procedures will be described below, but the general methods are essentially equivalent.

2.3. ORGANIZATION

Within the SRB model, lifecycle simulations are facilitated as nested loops. 'Nested' indicates that routines are called to run within other routines; in essence, creating loops within loops. This makes it possible to break the model into smaller, more manageable sections while still achieving modeling efficiency (fast computation times). The model can be setup to run for several years (e.g., lifecycles) and damages can be estimated over a range of storms (annual number of storms) on individual jetty segments (100-ft segments).

The model is controlled by the main procedural module, which calls routines as required to perform the specific simulation. Within the main procedural module, the loops are nested in the following order:

- Number of MC simulations to run (currently set to 1,000 simulations)
- Number of years to forecast in the future (jetty dependent, beginning in year 2006; or hindcast)
- Number of jetty segments (broken into 100-ft segments, or Stations)
- Number of storms predicted to occur in each year (randomly determined from a distribution)

In other words, for each MC simulation, and for each year in the forecast, each 100-ft jetty segment is analyzed for damages from each storm predicted to occur in that year. This continues sequentially until all jetty segments have been analyzed for all predicted annual storms in a given year. Subsequently, the model year is incremented and loops through the routines again until a complete lifecycle has been modeled. This process is repeated for each MC simulation (1,000 simulations) until the total number of simulations has been analyzed. Figure 1 graphically depicts the concept.

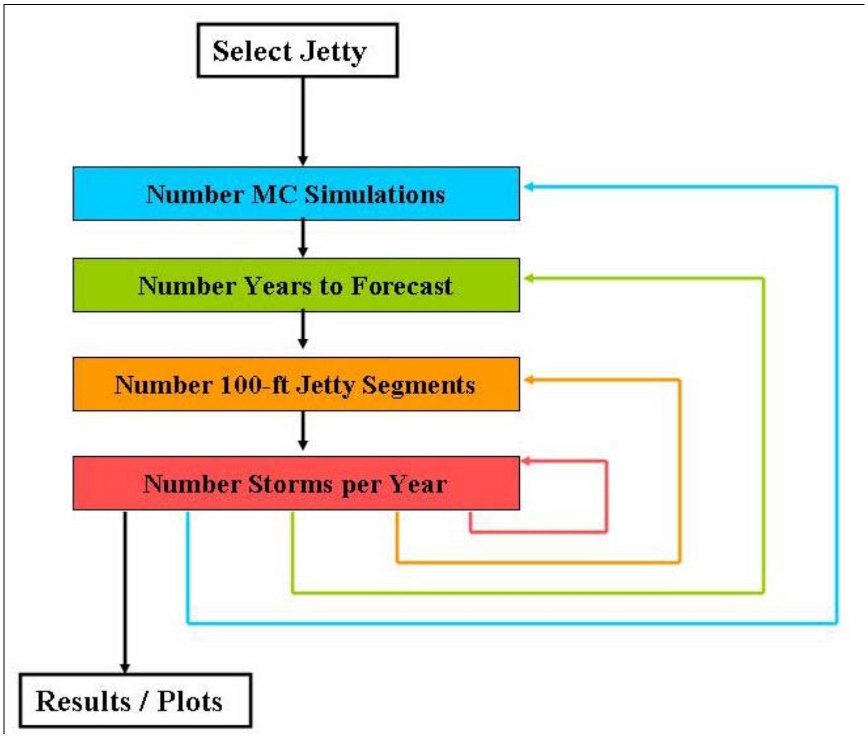

Figure 1: Basic MCR SRB Model Flowchart

2.4. STORM EVENTS

Storm wave heights used in the model are generated utilizing a numerical wave propagation model (STWAVE). STWAVE computes nearshore wave heights, periods, and directions by propagating offshore deepwater wave conditions to the nearshore area adjacent to the jetties. A total of 52 observed storm events were selected as representative events to include in the storm database. These are the largest storm events on record, as measured by offshore observation buoys in proximity to the MCR inlet. Each event has impacted the MCR in the recent past; the potential exists for similar events to occur and impact the structures at the MCR inlet in the future.

The storm database used in the MCR SRB model was created prior to any forecast modeling. It comprised near-jetty wave heights at specific along-jetty locations that were predicted by the STWAVE model. Each near-jetty wave height correlated directly with an offshore storm condition.

In the MCR SRB model, for each storm predicted to occur in any given model year, a storm event was randomly selected from the database of 52 storms. Subsequently, the corresponding near-jetty wave heights for that particular storm event are selected from the storm database. The wave heights are interpolated along the lengths of the jetties, so that wave heights at each 100-ft jetty station are known, and damages calculated at each jetty segment.

2.5. JETTY DAMAGE

In the MCR SRB model, both static and dynamic effects contribute to structural damage of the jetties. Static damage is attributable to toe scour and side slope failure. Toe scour and resulting toe and slope stone settlement typically results from river and tidal currents scouring the foundation sediments away. Side slope failure often occurs subsequently because of foundation settlement, and may also be a result of scour. The damage associated with static effects are estimated based on historical observations of scour and slope failure occurrences which occurred as an aggregate of all relevant processes. Therefore, detailed knowledge of the individual processes is not required. In the SRB model, damages from scour are only applied below the wave elevation surface (defined as the elevation below which wave action does not affect jetty stone).

Dynamic effects are attributable to wave action on the jetty stone (wave breaking and wave overtopping). The damage associated with wave action is computed directly from damage functions resulting from extensive physical modeling of various jetty repair alternative designs. The physical model results, which are specific to the MCR Jetties, are critical for defining the damage functions. The damage functions are simply correlations between wave height and damage. Damage is measured as area damage (square feet [sf]) with respect to the jetty cross-section for a particular 100-ft jetty segment (e.g., for a certain wave height at the jetty, a corresponding amount of damage [in sf] is expected to occur). The damage is combined with any previous damage that has occurred at a particular jetty segment such that cumulative damages are tracked at all stations along a jetty from storm to storm and year to year. The damage thresholds set in the model determines when repairs are implemented and when failures occur.

2.6. RELIABILITY

Jetty reliability is a metric by which to quantify the likelihood of jetty damage occurring. Reliability is considered in two modes in the MCR SRB model: *structural* and *functional*. Structural reliability is a measure of how likely a structure will resist damage during a given time period. Oftentimes, rubble-mound structures can incur damage without affecting the functionality of the structure (because they are not rigid structures). A jetty's ability to incur damage while still performing its function is its resilience. Jetty segments with high resilience can incur a great deal of damage while still performing their intended function. Functional reliability is a measure of how likely a structure will continue to perform its function without failing (e.g. breaching).

Within the MCR SRB model, as jetty segments incur damages, the structural and functional reliabilities are adjusted accordingly (decreased). Likewise, when segments are repaired, reliabilities are increased to reflect the increased structural stability of the repaired segments. If a jetty segment fails (e.g., the functional reliability falls below a certain threshold) emergency repairs may be initiated.

3. MODEL INPUT INTERFACE

3.1. INPUT PARAMETERS

Input parameters utilized within the SRB model include: time-varying shoreline evolution along each side of the jetty; time- and spatially-varying scour rates along each side of the jetty; time and spatially varying wave conditions along each side of the jetty; time-varying water levels; variable jetty root degradation rates; spatially variable and time-varying jetty cross-section attributes (for each side of the jetty). The pre-loaded input files are shown in Table 2 below.

Table 2: Pre-loaded Excel Input Files

Filename	Purpose
SUMMARY_NJ.xls **SUMMARY_SJ.xls** **SUMMARY_JA.xls**	Summary of jetty geometry
50Waves_Verified.xls	Data for 50 preselected representative storm conditions
STWAVE_MCR2008_comps_L.xls	Storm event wave heights and periods for jetty perimeter locations at low water level condition (all 3 jetties)
STWAVE_MCR2008_comps_M.xls	Storm event wave heights and periods for jetty perimeter locations at medium water level condition (all 3 jetties)
STWAVE_MCR2008_comps_H.xls	Storm event wave heights and periods for jetty perimeter locations at high water level condition (all 3 jetties)
Eroded_A_plots_NJ_FINAL_HS.xls **Eroded_A_plots_SJ_FINAL_HS.xls**	Damage functions for North and South Jetty. Damage functions determine the jetty damage that occurs for a storm event of given wave height.

Two stand-alone scripts for each jetty are used to convert Excel-based data into MATLAB MAT files for input to the SRB model. The input data conversion process (from Excel to MATLAB) deals with data that defines the present physical condition of the jetty, STWAVE model output, and wave damage functions. The data file conversion is performed only one time; after which the SRB model reads the input data from the MAT data file every time the SRB model is run. Other data types and SRB model control parameters are specified in the main XML file.

When executing a hindcast SRB simulation, the initial condition geometry, jetty armor/core stone attributes, and jetty foundation scour rates are defined for the entire jetty, on a segment by segment basis. A jetty segment is 100-ft long. The historical repair sequence is defined within the model, to define the number of times segments can be rebuilt, repair cross-section attributes, and the applicable threshold to initiate repairs. Future lifecycle simulations use the ending jetty condition from the hindcast to describe the initial jetty condition (geometry and armor stone characteristics) in the forecast. This means that a calibrated hindcast simulation must be completed (with hindcast MATLAB .mat output files saved), prior to initiating a future lifecycle simulation.

The SRB model does allow for the use of observed geometry data (present jetty survey) to override the simulated end-state jetty geometry obtained from model hindcast. In this case, the SRB model would use "observed" survey data to define the initial forecast condition when conducting future simulations. The "observed" geometry option was used to define the initial condition for jetty geometry for all SRB life-cycle forecasts conducted in this study. Because there is no objective way to estimate the armor layer characteristics for the forecast initial (present day) condition along each jetty, the calibrated SRB hindcast solution was utilized to define initial conditions for armor stone characteristics along each jetty, when forecasts where conducted.

The model requires a certain amount of input information in order to complete a MC simulation for a specific jetty. During a MC simulation, the bulleted items below are loaded into the model workspace from existing user-defined input data files.

- Damage Functions
    - Damage functions are previously created correlations that were obtained from physical modeling of the jetties at Engineer Research and Development Center (ERDC).
    - They are direct relationships of the near-jetty wave heights to the amount of damage the jetty segment is expected to sustain when that wave height occurs at the jetty.
- Storm Events and Wave Heights
    - Storm wave heights at specific locations along the jetties are known from STWAVE modeling for specific storm conditions.
    - Wave heights for three expected water levels were modeled in STWAVE: low, medium and high water levels.
    - The wave heights and water levels create the storm wave database from which storm wave events are selected and used to compute jetty damages.
- Jetty Initial Geometry (Crest Heights and Widths)
    - Geometries for hindcasts are obtained from historical records.
    - Initial geometries for forecasts are either obtained from the most recent surveys of the jetties (2006) or the final hindcast geometries.
- Simulation Control Variables
    - Hindcast or Forecast model mode selection.
    - Repair alternative plan selection for forecast mode (determines what repairs are implemented and when repairs are necessary).
    - Length of lifecycle model (number of years).
    - Engineering feature options (spur groins, head caps, lagoon fill).
    - Switches for various parameters (how to defer repairs, RSM, shoreline positions and shoreline change positions, etc.).

The basic variables that ensure proper setup and operation of the MCR SRB model are indicated below. These variables determine, among other things, the length of the modeling simulation (number of MC simulation model loops), the length of the lifecycle model duration (number of years into the future simulated), and the type of repairs to be implemented as damage occurs.

3.2. Selection of Repair Strategy

The repair strategy variable determines which repair scenario will be modeled during the simulations.

- ***fut***: The value activates specific repair functions and parameters, determining which repair scenario is implemented and when repairs are made. The values of fut for each jetty and corresponding repair scenarios are listed in Table 3.

Table 3: Repair Strategy Selection

fut for NJ	fut for SJ	fut for JA	Repair Alternative
0	**0**	**0**	Hindcast Condition (for calibration and historical analysis)
1	**1**	**1**	Future Condition: No action alternative (a.k.a. base condition)
10	**10**		Future Condition: NON-Rehab, but includes engineering features
11	**11**		Future Condition: Minimum template (MT), immediate rehab
	12	**12**	Future Condition: Rehab plan A, immediate rehab
13	**13**	**13**	Future Condition: Rehab plan B, immediate rehab
14	**14**		Future Condition: Rehab plan C, immediate rehab
20	**20**	**20**	Future Condition: Composite rehab, immediate rehab
21	**21**		Future Condition: Minimum template (MT), scheduled rehab
	22	**22**	Future Condition: Rehab plan A, scheduled rehab
23	**23**	**23**	Future Condition: Rehab plan B, scheduled rehab
24	**24**		Future Condition: Rehab plan C, scheduled rehab
30	**30**	**30**	Future Condition: Composite rehab, scheduled rehab

3.3. Number of MC Simulations

The numbers of MC simulations over which the model will run are determined with this variable. For a thorough analysis, the value should be large (e.g., 200 simulations); however, caution should be employed when selecting this variable due to the high computational time required for this number of simulations (days).

- ***MC_sim***: The variable sets the number of MC simulations over which the model will run.

3.4. Other Modifiable Model Parameters

The files in Table 4 below are only used or created when damage functions need to be updated. The *.mat MATLAB files are used as model input during model execution. In agreement with the statements above, unless the user has adjusted damage function values, there will be no need for adjustment of any of these files. The remaining files are data files that are loaded by the *master* or subroutine scripts as input files during the MC simulations. They incorporate the storm event wave conditions (wave height and wave period) at specific locations around the perimeter of all three jetties, for three different water levels (low, medium and high). The wave conditions are used to directly compute damages resulting from wave attack.

Table 4: Model Code Input Files

Filename	Purpose
NORTH_XLS_new.mat	MATLAB data file created from damage functions given in SUMMARY_NJ.xls
NJ_2006_ARMR.mat **SJ_2007_ARMR.mat** **JA_2006_ARMR.mat**	Armor stone sizes and standard deviations along both sides of each jetty for future condition simulations. Values are the end result of hindcast simulations.
NJ_2006_GEOM.mat **SJ_2007_GEOM.mat** **JA_2006_GEOM.mat**	Cross-section geometry of each jetty for future condition simulations. Values are the end result of hindcast simulations.
PRE_THRESH_XSECT_NJ **PRE_THRESH_XSECT_SJ** **PRE_THRESH_XSECT_JA**	Repair initiation threshold for each segment of the jetty for scheduled repairs. Result of "fix-as-fail" simulation.

It should be noted that there are some other hard-coded variables and data distributions incorporated throughout the code. These variables are not listed in this guide, but the user is referred to the model code to become informed. Environmental data distributions (e.g., wave heights, directions, etc.) were used to randomize storm event characteristics. These distributions best modeled the data at the time the model was created, based on existing offshore measurements. However, these are subject to change based on the user's discretion.

3.5. INPUT SETUP

Most governing parameters are specified in an XML file; a text file which uses a special markup language to store information. The files are easy to read in a text editor. Also, many software programs can work with these files to transfer information. Both MATLAB and Excel support reading and writing XML files, which makes XML a convenient format for model interface.

The input parameters can be modified in an Excel file which is linked to the main XML file. The Excel file provides an interface for editing input parameters. One can also utilize Excel's capabilities to plot relevant inputs for initial visual verification, such as jetty geometry. The steps to create the input files are detailed in Appendix A.

The model requires many parameters to be specified. In an Excel file, the parameters are grouped in separate sheets. "Global" and "Setup" sheets define parameters of model behavior and definitions of alternatives. Specific parameters are used in calculations for a given jetty; they are defined on special sheets. For example, sheet "NJ" contains variables for North Jetty. The "Geometry" sheet defines locations of nodal points along and across the jetty and their elevations. Because each cross-section profile is defined with eight nodes, all eight node elevations should be defined before the simulation starts.

The parameters are defined with their names and values and a description is provided for convenient inline reference. The values can contain strings or numbers. It is also possible to define vector arrays of numbers, for example, "0.1 0.2" defines a variable with two elements.

Because of a large number of parameters, they are grouped in several sheets. "Global" and "Setup" variables define parameters of model behavior and alternative definition. Some specific parameters are used in calculations for given jetty. They are defined on special sheets. For example, sheet "NJ" contains variables for North Jetty. "Geometry" sheet defines locations of nodal points along and across jetty and their elevations. Because each cross-section profile is defined with eight nodes, all eight nodes elevations should be defined before the simulation starts.

After the variables are saved in the Excel file they need to be exported back into the XML file with the XML export command. The resulting XML file is used as an input into the model.

3.6. INPUT FILE SAMPLES

Figures 2 – 5 show examples of input file editing using Excel. The input Excel file is linked to an XML file, which stores all parameters. The Excel file provides a convenient interface for editing the input parameters. It is also possible to use plotting capabilities for initial data validation.

	name	value	desc
2	comp_num	0	index of composite alternative (fut 20 or 30)
3	total_LC	1	flag to calc total LIFE cycle costs for fut > 20 (initial
4	constrain_foot_print	1	(0/1) force upper cross-section to not extend beyc
5	defer_repair_begin	1	initial repair strategy, before rehab (see defer_rep
6	defer_repair_set	1	0 - fix-as-fails, 1 - interim repairs, 2 - aggressive re
7	proj_impl	0	(year from begin_year) rehab implementaiont (0 f
8	root_fill	0	(0/1) filling jetty root lagoon
9	head_cap	0	(0/1) enure that head cap option is enabled for fut
10	spur_place	0	(0/1) 1 - spurs are built, 0 - no spurs
11	spur_mit	0.3	reduction in scour along jetty toe and related adja
12	spur_mit_morph_fore	0.7	reduction in shoaling volume entering MCR chann
13	spur_mit_morph_near	0.9	reduction in shoaling volume entering MCR chann
14	spur_mit_scour	0.3	reduction in scour afftecting jetty toe due to spur
15	rand_shore_edge	1	(0/1) 1 - allow randomness for ending position of s
16	jetty_extension	0	(ft) extension of rehabbed jetty beyond present h

3.7. RUNNING THE MODEL

After the input parameters are specified and the main XML file is created, the model can be started to perform calculations. Note that input MAT files should be placed under the folder specified by the "path_input" variable in the XML file. The user is to start MATLAB and navigate to the folder where the XML file is stored; this is the main working folder. All paths specified in "path_NNN" variables are treated as relative to this main folder. The model can be started from the command line in MATLAB by typing "mcr". A dialogue will appear where you can select the XML file.

Table 5 shows the folder structure and list of subroutines within the MCR model.

The model will perform calculations and save outputs into folders specified by variables "path_output" and "path_output_mc". Results of each MC simulation are saved in separate files, which allows for post processing analysis without rerunning the simulations. These results also become an input into the cost analysis calculations.

Table 5: Model Code MATLAB Scripts

Folder			Subroutine	Description
C:\SRBMODEL				Main folder
	mcr			MCR Model Code
			Installation	
			install	Install MCR model
			remove	Remove paths for MCR model
			Main routines	
			mcr	Main jetty structural performance calculation routine
			mcr_add_stats	Calculate additional statistics
			mcr_plot	Plot results from MC output folder for arbitrary cross-section
			Service functions	
			addpathtool	Adds paths to Matlab search path from a text file
		geom		Geometry calculation using M&N algorithm
			findint	Find intersection of two line segments.
			geom_core_area	Calculates core area based on shape of cross-section.
			geom_core_area_diff	Calculate change in core area.
			geom_shp2xy	Convert cross-section shape into node coordinates.
			geom_toe_adj	Calculate new cross-section geometry from toe scour.
			geom_wav_adj	Calculate new cross-section geometry from wave damage.
			geom_wav_area	Calculates wave area based on shape of cross-section.
			geom_xy2shp	Convert cross-section node coordinates into shape definition.
			run_test	Example and test of cross-section degradation calculations.
		subs		
			Main routines	
			damage_calc_ja	Damage calculations for Jetty A.
			damage_calc_nj	Damage calculations for North Jetty.
			damage_calc_sj	Damage calculations for South Jetty.
			damage_hudson	Damage calculations using Hudson formula.
			geometry_calc_ja	Geometry adjustments for Jetty A.
			geometry_calc_nj	Geometry adjustments for North Jetty.
			geometry_calc_sj	Geometry adjustments for South Jetty.
			geometry_calc_new	Geometry adjustments using M&N formulation.
			geometry_calc_orig_ja	Geometry adjustments for Jetty A (original code).
			geometry_calc_orig_nj	Geometry adjustments for North Jetty (original code).
			geometry_calc_orig_sj	Geometry adjustments for South Jetty (original code).
			mcr_global	Setup global parameters.
			mcr_main	Main loop of Monte-Carlo simulations.
			mcr_main_ja	Perform Monte-Carlo simulation for Jetty A.
			mcr_main_nj	Perform Monte-Carlo simulation for North Jetty.
			mcr_main_sj	Perform Monte-Carlo simulation for South Jetty.
			mcr_mc_post	Post Monte-Carlo calculations.
			mcr_prealloc	Preallocate variables.
			mcr_print	Output results to DAT files.
			mcr_repair_ja	Perform repair for Jetty A.
			mcr_repair_nj	Perform repair for North Jetty.
			mcr_repair_sj	Perform repair for South Jetty.
			mcr_setup	Setup parameters from XML file.
			mcr_setup_ja	Setup parameters for Jetty A.
			mcr_setup_nj	Setup parameters for North Jetty.
			mcr_setup_sj	Setup parameters for South Jetty.
			mcr_stats	Calculate statistics after Monte-Carlo simulations.
			mcr_plot_main	Create plots.
			repair_calc_ja	Repair calculations for Jetty A.
			repair_calc_nj	Repair calculations for North Jetty.
			repair_calc_sj	Repair calculations for South Jetty.

Table 5: Model Code MATLAB Scripts (continued)

Folder			Subroutine	Description
			Subroutines	
			JettyA_Wave_Interpolate_new	Calculate damage wave height along Jetty A.
			MCR_Jetty_Reliability_Waves_2	Reliability calculations.
			MCR_Storm_Environment_fx	Calculate storm parameters.
			North_Jetty_Wave_Interpolate_head_new	Calculate damage wave height along North Jetty.
			North_Jetty_Wave_Interpolate_new	Calculate damage wave height North Jetty.
			South_Jetty_Wave_Interpolate_new	Calculate damage wave height along South Jetty.
			mcr_cost_main	Submodule to perform cost calculations (main).
			mcr_cost_part1_ja	Submodule to perform cost calculations for Jetty A (part 1).

		tables		Location of input Excel files
	xmltool			Low level lools to build input XML files

4. DESCRIPTION OF MODEL OUTPUT

Various types of SRB model output can be saved to files, depending upon SRB parameters set within the model. Output produced by the SRB model includes ACSII text-based data files (for life-cycle repair tonnage and incremental dredging volume) expressed in a mean value and standard deviation. Multiple graphical summaries are produced for pertinent model metrics describing the spatial and time-varying conditions of a given jetty. The entire MATLAB simulation environment, containing all variables accessed or created by the SRB model, can be saved as a .mat file. Presently, the MCR SRB model outputs variables and files in MATLAB *.mat format, ASCII text files in *.dat format, and various figures illustrating results of the hindcast and MC forecast simulation.

Model outputs are saved under the folder specified in "path_output" variable. The model outputs plots of specific lifecycle parameters and exported datafiles of all data as computed in the model. There are several model 'switches' that can be set to output additional files and/or figures. Results of each Monte Carlo simulation are saved into a MAT file under path defined in "path_output_mc" variable. Each MAT file has a name equal to sequence number of the MC simulation. These results can be used to perform the cost analysis.

Tables 6 and 7 list the figures and data files which can be exported from the model.

Table 6: List of Exported Simulation Figures

Lifecycle Simulation Figures	
1	**Lifecycle:** Plot of initial & simulated final cross-section(s) for a specific STA.
2	**Lifecycle:** Jetty crest profile evolution (hindcast and forecast modes)
3	**Lifecycle:** Change in cross-sectional area evolution for a specific STA.
4	**Lifecycle:** Simulated cross-section change (UPPER cross-sectional area)
5	**Lifecycle:** Simulated cross-section change (TOTAL cross-sectional area)
6	**Lifecycle:** Jetty reliability over a lifecycle (CHANNEL-side and OCEAN-side)
7	**Lifecycle:** Jetty Structural reliability
8	**Lifecycle:** Variation in Jetty reliability
9	**Lifecycle:** Jetty Functional reliability
12	**Lifecycle:** Jetty repair and breach frequency / 100' segment
13	**Lifecycle:** Jetty cumulative occurrence of repairs and breaches
14	**Lifecycle:** Jetty repairs and breaches / 100' segment
Figures from Monte Carlo Simulations	
15	**Monte Carlo:** Jetty crest profile evolution (hindcast and forecast modes)
16	**Monte Carlo:** Simulated cross-section change (UPPER cross-sectional area)
17	**Monte Carlo:** Simulated cross-section change (TOTAL cross-sectional area)
18	**Monte Carlo:** Variation in Jetty reliability over a lifecycle
21	**Monte Carlo:** Jetty repair and breach frequency / 100' segment
22	**Monte Carlo:** Jetty cumulative occurrence of repairs and breaches
23	**Monte Carlo:** Jetty repairs and breaches / 100' segment

Table 7: List of Output Data Files and/or Formats (if Several Files are Output in this Format)

Possible Data Exports		Format / Filename
1	Threshold values for various repair alternatives	***.MAT**
2	Cross-section geometries from last year of hindcast (for forecast simulations)	**NJ_2006_GEOM.mat** **SJ_2007_GEOM.mat** **JA_2006_GEOM.mat**
3	Jetty armor values (armor stone size and stability coefficients, for forecast simulations)	**NJ_2006_ARMR.mat** **SJ_2007_ARMR.mat** **JA_2006_ARMR.mat**
4	Time-varying Wave areas (upper cross-section)	**WAVE_AREA_NJ.DAT** **WAVE_AREA_SJ.DAT** **WAVE_AREA_JA.DAT**
5	Time-varying wave areas before repairs are made	**WAVE_AREA_REPAIR_NJ.DAT** **WAVE_AREA_REPAIR_SJ.DAT** **WAVE_AREA_REPAIR_JA.DAT**
7	ALL variables for a given hindcast or forecast	***.MAT**

Table 8 lists the figures that are output from the model. In addition to exporting figures, the model will also save and export the data from each of the modeling simulations. Table 9 lists the datafiles that are saved at the end of each model run. Datafiles are in MATLAB .mat and ASCII text file .dat format.

Table 8: Exported Figures of Simulation Results

Figure	Description
1	Jetty lifecycle cross-section and profile evolution plot
2	Jetty lifecycle profile evolution
3	Jetty lifecycle cross-sectional area evolution (1 STA)
4	Simulated lifecycle change in jetty upper cross-section
5	Simulated lifecycle change in total jetty cross-section
9	Variation in jetty lifecycle reliability
15	Lifecycle repair and breach frequency per 100-ft segment
16	Lifecycle cumulative repair and breach occurrences
17	Lifecycle repair and breach occurrences per 100-ft segment

5. DESCRIPTION OF MODEL PROCEDURE FOR A TYPICAL JETTY SEGMENT

Jetty Segments are the basis in the SRB life-cycle model. Environmental loading, structure response, project consequences, and life-cycle cost are all evaluated based on jetty segments. In this section, the model procedure for a typical jetty segment is described, including the jetty segmentation, damaging process, damaging function, repair tonnage and the event tree.

5.1. JETTY SEGMENTATION

Jetty Segmentation

Within the SRB model, a jetty is divided into 100-ft long semi-independent responding segments. Segmentation allows for the jetty to be modeled as a system of interacting components, the response of each being described by a specific performance mode relating to head recession, foundation erosion, slope stability, and wave-induced damage. The SRB model uses these performance modes to simulate jetty response over a specified period of time (a given life-cycle), by evaluating the cumulative structural response of the jetty cross section in 1-year time steps.

Lateral Subdivision of Jetty Cross Sections

For each segment, the initial condition is described by specific cross-section geometry and armor-core stone attributes, which can vary along segments and on each side of the jetty (ocean side vs. channel side). The centerline of the present jetty crest serves as the boundary to split the segment cross section into channel vs. ocean side. Refer to Figure 8 for jetty cross-section element definition. Segment attributes include toe elevation, crest elevation, crest width, jetty side slope, armor stone characteristics (size-tons, stability number, density), and core stone presence. All segment attributes are described in terms of a mean value and standard deviation, to enable segment-based reliability calculations.

Vertical Subdivision of Jetty Cross Sections

Each segment is divided into two vertical areas (upper section and lower section) based on an elevation of -5 ft MLLW. Above this elevation (WAV_EL) wave damage generally controls jetty cross-section evolution; below WAV_EL the cross-section evolution is generally controlled by scour or static slope instability issues. If jetty toe elevation is higher than -7 ft MLLW, then the demarcation between upper and lower sections is set at the jetty toe elevation, plus 2 ft. This allows for the vertical subdivision of a jetty cross section in shallow water regions, where the jetty toe may be higher than -5 ft MLLW. The 2-ft offset is the minimum vertical distance required to represent geometric changes in the lower section of a jetty (within the SRB model), as motivated by slope/foundation adjustment processes associated with jetty toe scour.

5.2. ENVIRONMENTAL FORCES AND DAMAGE PROCESSES

Wave height is the environmental parameter that drives the damages in this model based on the damage function defined for each jetty segment. Damage to structures exposed to waves is determined by water depth and wave height. Waves may be depth limited if the water depth is shallow. If the structure is located in relatively deep water, wave damage is typically limited to the upper part of a structure and there was limited foundation-related degradation to affect the lower part of the structure. However, if a given structure is located in relatively shallow water and wave loading is both severe and depth-limited, then the entire cross-section can be degraded by wave action (from the structure toe to the crest). If the foundation of a structure is subjected to severe toe scour or slope instability, then much of the structure's entire cross-section can be degraded within the expected life-cycle.

As discussed above, each jetty segment section is divided into two areas, upper section and lower section. The upper section is damaged by dynamic effects which are attributable to wave actions (wave breaking and wave overtopping). The lower section is damaged by static effects due to toe scour and side slope failure.

Static stability affects the lower part of the jetty cross section, generally below –5 ft MLLW, on the ocean side and channel side of the jetty (Figure 6). Within this analysis, static stability addresses the susceptibility of the jetty toe to be affected by wave-current scour, and resistance of the jetty slope to fail along a slip-plane. The jetty toe is the interface where the jetty intersects the morphology on which it is founded. Jetty damage motivated by static stability propagates up-slope to affect the upper region of the jetty cross-section, above -5 ft MLLW. Static stability of the lower cross-section region (below -5 ft MLLW) is evaluated stochastically within the SRB model based on jetty slope re-adjustment (creeping failure) in response to toe scour. Static stability performance is indirectly evaluated through the analysis of the upper jetty cross section, which can be affected by both static and dynamic stability performance modes.

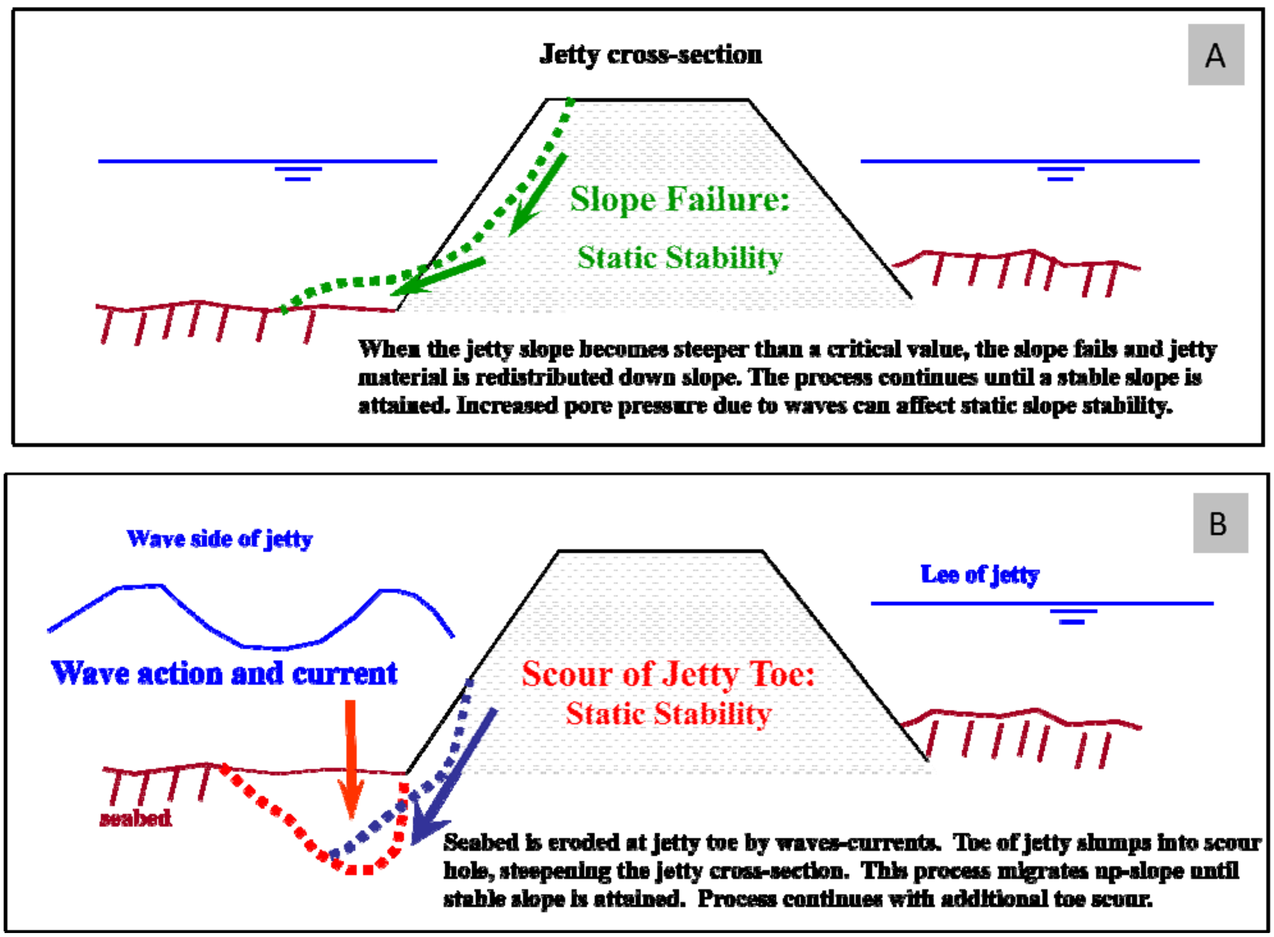

Figure 6: Jetty Performance Modes for Static Stability

Dynamic stability affects the upper part of a jetty cross section as a result of wave action, generally from –5 ft MLLW up to the jetty crest, on the ocean side and channel side of a jetty, as shown in Figure 7. On the side of the jetty directly exposed to wave action, dynamic stability is manifest by the direct impact of waves on the jetty and the potential displacement of individual armor units. On the lee side of the jetty, dynamic stability addresses the effect of waves overtopping the jetty crest and displacing armor or down-slope, off of the jetty cross-section. There are many locations along MCR jetties which experience direct wave attack along both sides of each jetty, in which case each side of the jetty experiences direct wave action and overtopping wave action.

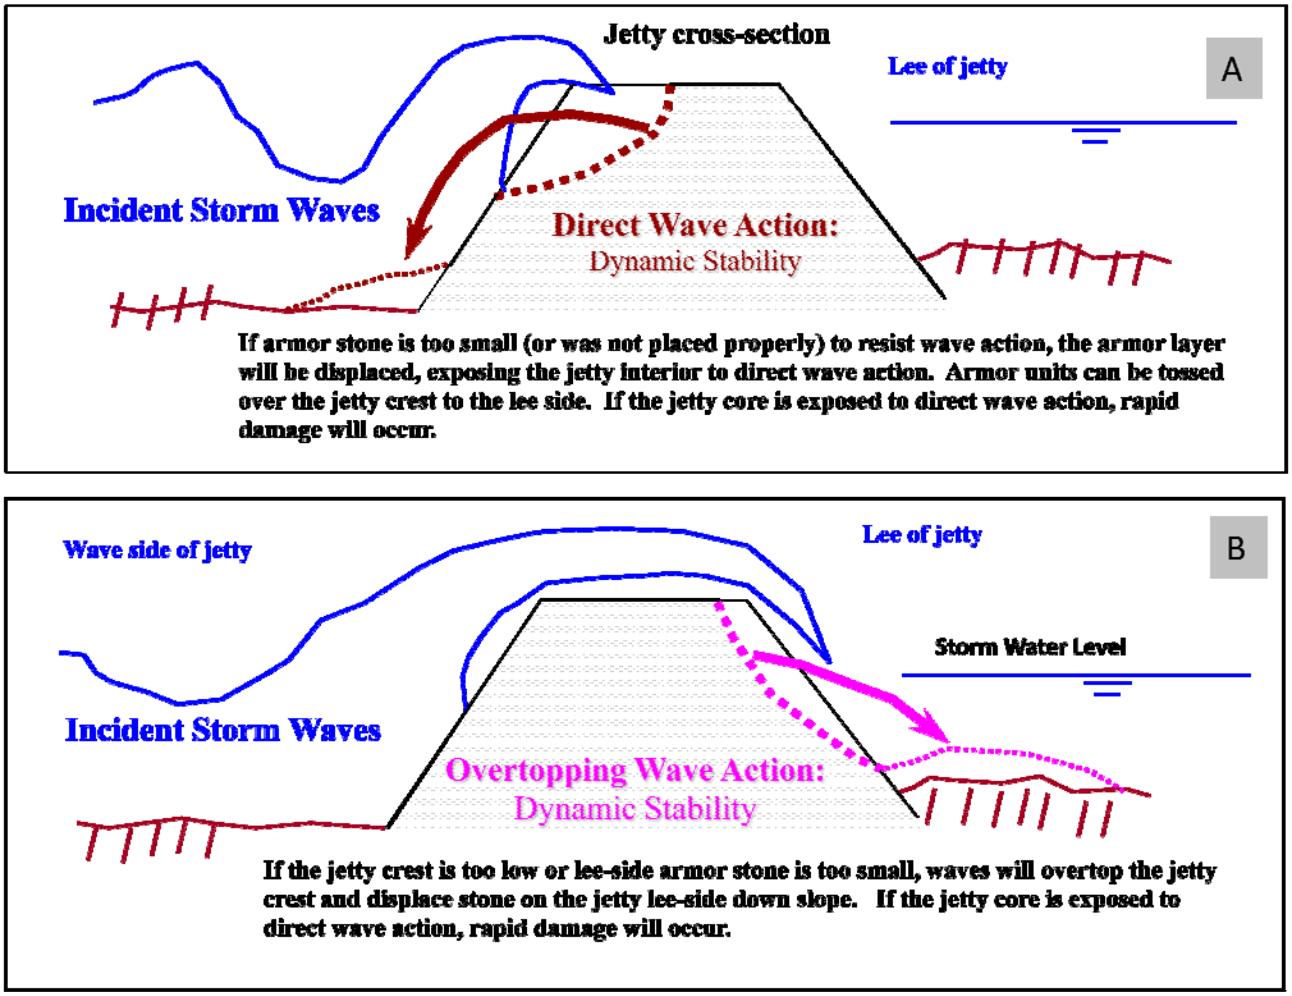

Figure 7: Jetty Performance Modes for Dynamic Stability

All the possible damage modes for a jetty segment are illustrated in Figure 8.

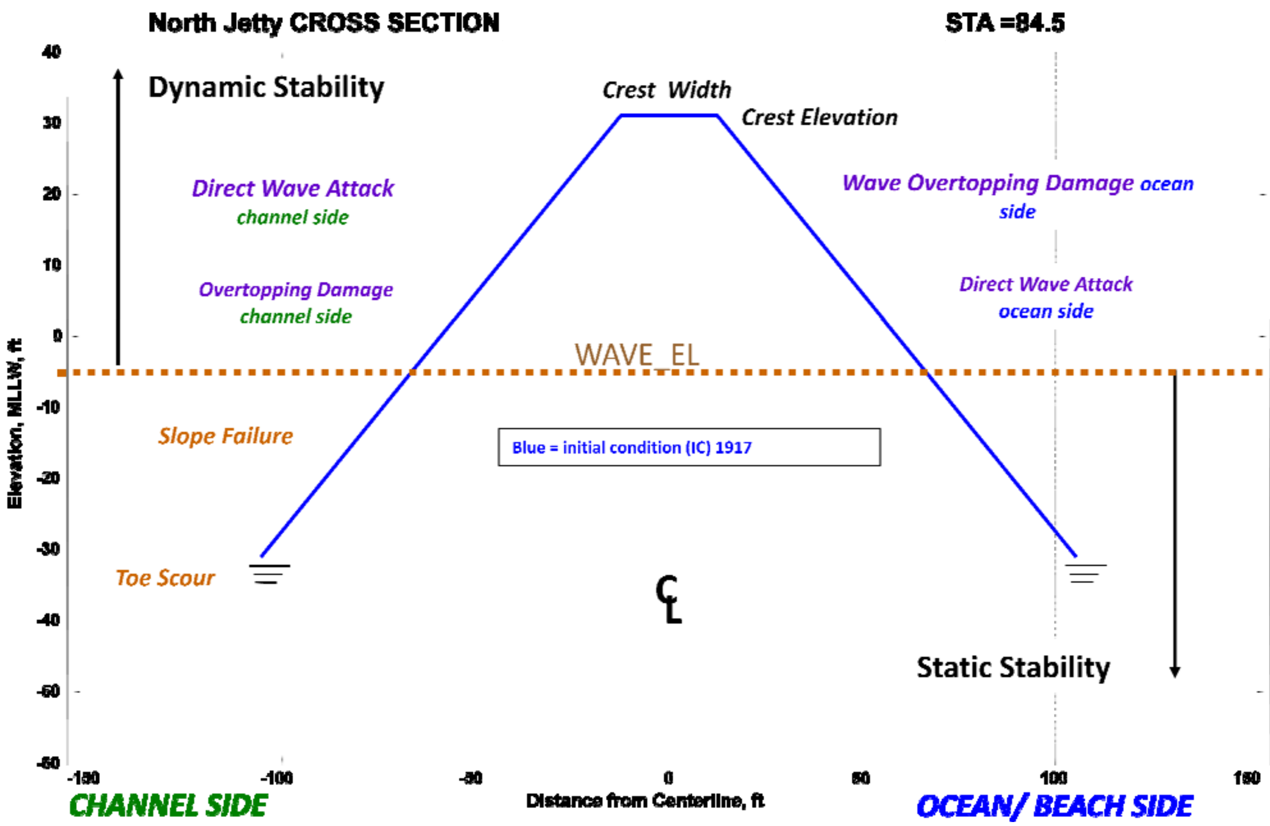

Figure 8: Representation of a Jetty Cross-Section Segment

5.3. DAMAGE QUANTIFICATION/DAMAGE FUNCTION

The structure response or damage due to the environmental force is evaluated in terms of cross-section area change (loss) over time due to jetty degradation. Jetty repairs are activated within the SRB model, after the jetty cross-section is reduced below a specified threshold value. Jetty repairs are calculated in terms of the tonnage of armor stone required to re-establish the jetty cross section to its standard dimensions.

The degree and rate of structure degradation (as affected by wave action) is evaluated using damage functions which are based on incident wave height vs. incremental cross-section damage. The damage functions were developed through detailed physical model studies conducted at ERDC, featuring MCR jetty cross-section attributes [Ward et al., 2007]. Within the SRB model, wave- induced jetty damage is calculated for each storm event realized within each year, using wave-damage functions. Figure 9 through Figure 12 describe wave damage functions developed for specific jetty cross section configurations, for North Jetty. North Jetty damage functions were used to simulate Jetty 'A' cross-section response. The wave height ordinate values expressed in the damage functions are equivalent to the significant wave height averaged during the peak two hours of prototype storm duration.

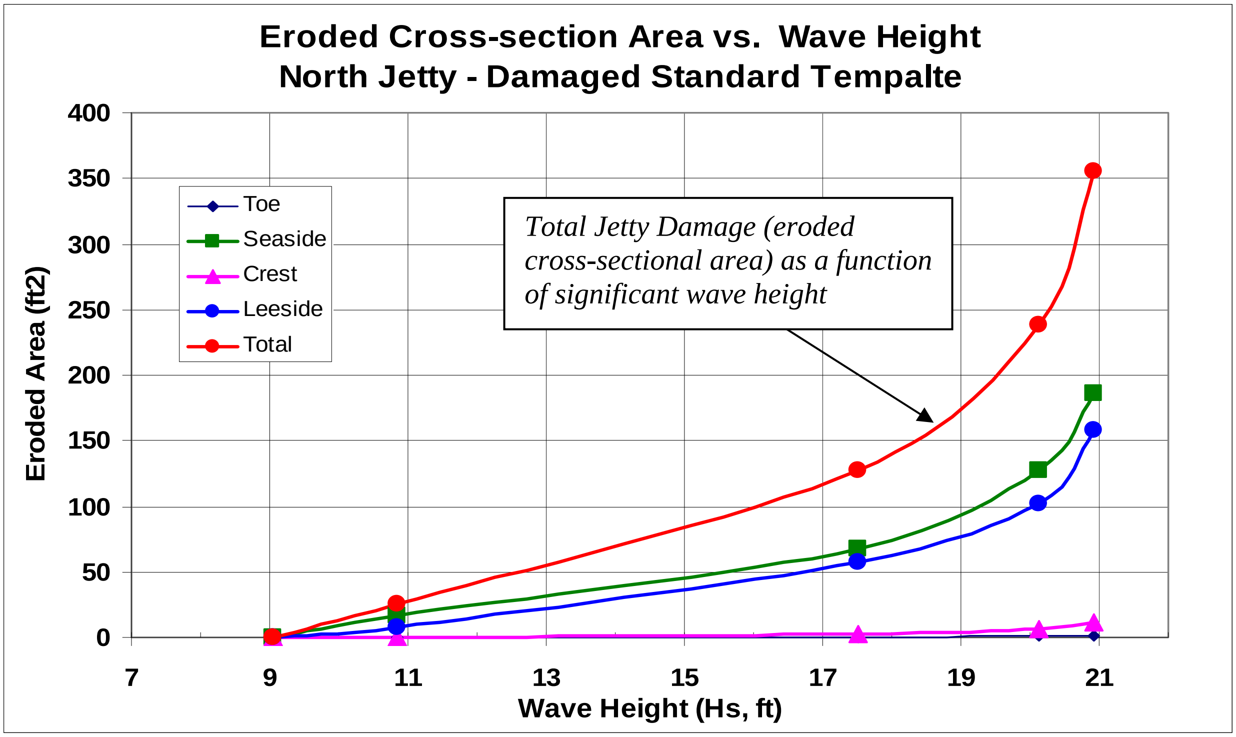

Figure 9: Damage Functions for MCR North Jetty and Jetty 'A' – for Jetty Segments Where a Standard Cross-Section has been used and Becomes Damaged

(Damage functions developed through detailed physical model studies conducted at ERDC [Ward et al., 2007]).

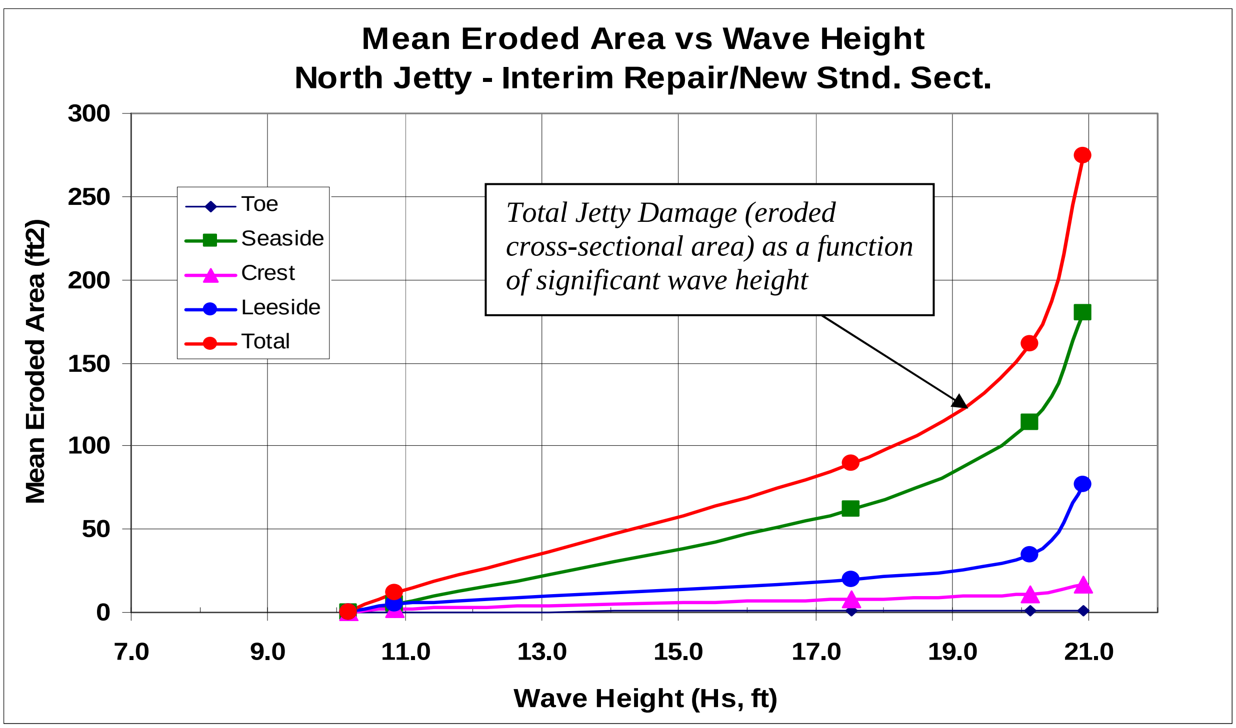

Figure 10: Damage Functions for MCR North Jetty and Jetty 'A' - for Jetty Segments Based on a Standard Template that Has Not Been Damaged

(Damage functions developed through detailed physical model studies conducted at ERDC [Ward et al., 2007]).

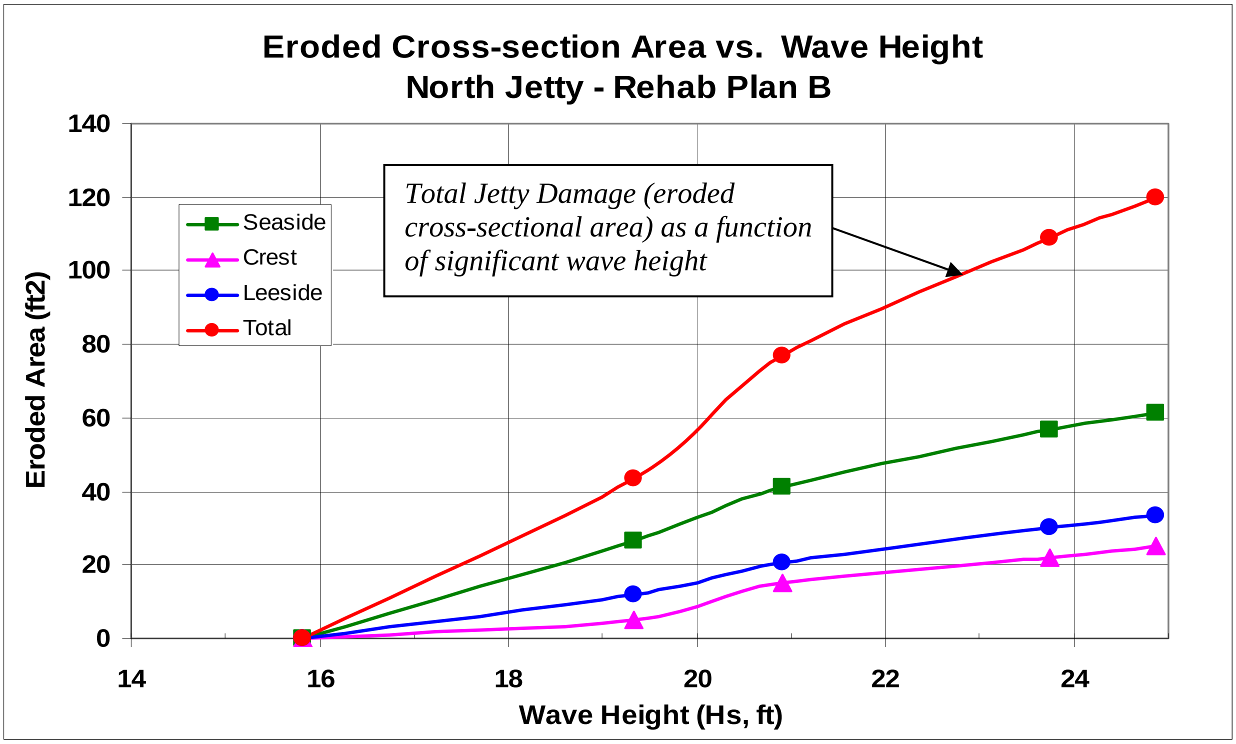

Figure 11: Damage Functions for MCR North Jetty – for North Jetty Rehab Plan B
(Damage functions developed through detailed physical model studies conducted at ERDC [Ward et al., 2007]).

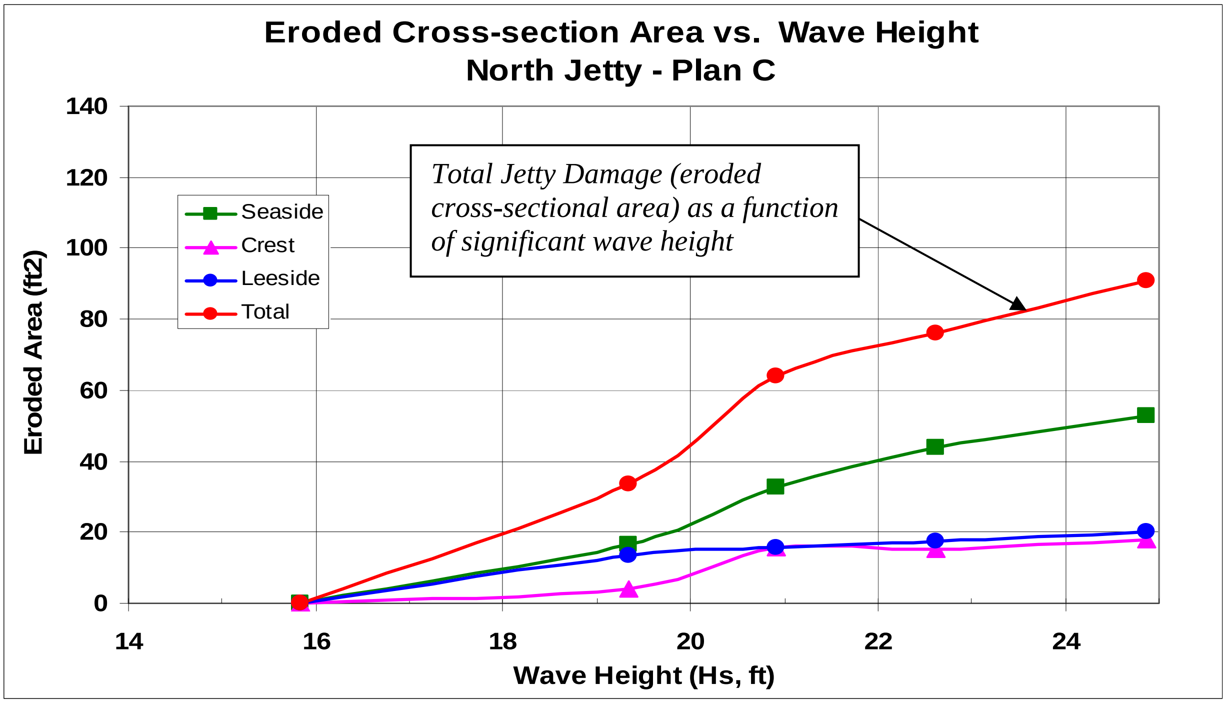

Figure 12: Damage Functions for MCR North Jetty- for North Jetty Rehab Plan C
(Damage functions developed through detailed physical model studies conducted at ERDC [Ward et al., 2007]).

Specific jetty cross-section configurations were used to emulate existing damaged jetty sections, repaired "standard repair template" sections, and rehabilitation alternatives. The threshold value for the onset of wave damage, as described by specific damage function, was adjusted depending upon the level of progressive deterioration for the jetty cross-section of interest. The wave damage threshold was also adjusted to account for the robustness of various jetty maintenance scenarios.

The threshold values for jetty head cross-sections were adjusted to account for increased or decreased resilience for a given jetty head configuration. Figure 13 shows how the maintenance threshold for enacting repairs can vary based on the type of maintenance strategy assigned to a given jetty. The cross-section at this location of the jetty was repaired two times during 1917-2006. The scheduled repair strategy is more proactive than the base condition by allowing jetty repairs to occur earlier in the degradation phase, to reduce the chance of segment failure (before repairs can be initiated). Scheduled repairs also employ a more resilient (better built cross-section) than the base condition, so the degradation rate for scheduled repairs is usually less than for the base condition. Threshold adjustment (for value of wave height initiating jetty damage) was implemented based on stability equations indicating: when a given armor unit size (W_{50}), stability number (Kd or equivalent), and cross-section configuration would be damaged by wave action.

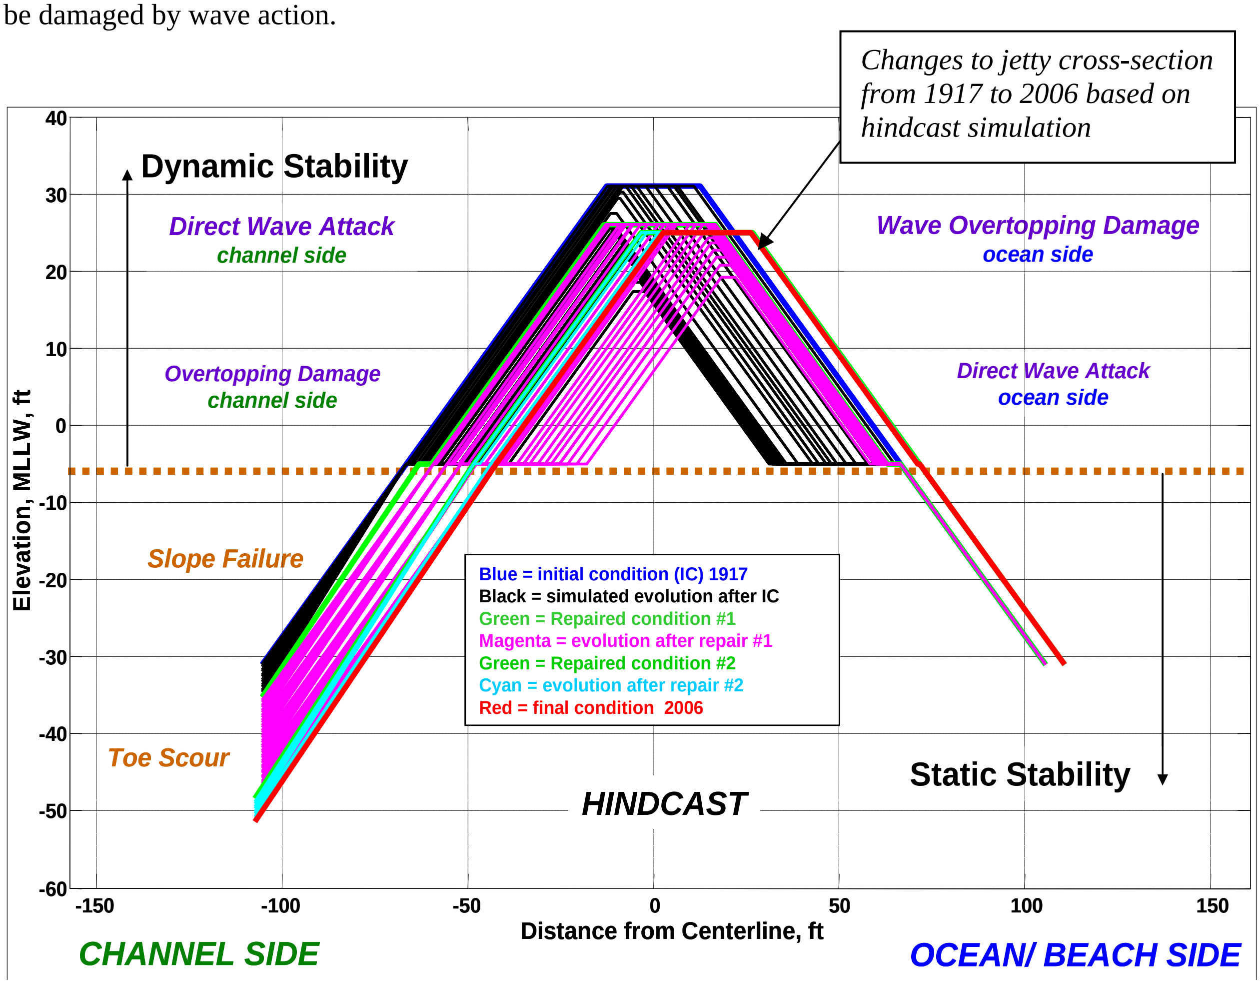

Figure 13: Evolution of Jetty Cross-Section at Station 84+50 Based on One Realization for Hindcast Simulation for the MCR North Jetty

5.4. MAINTENANCE AND REPAIR TONNAGE

Jetty repairs may be enacted at 3 different levels of response, depending on the urgency for repairs. In a normal O&M level, jetty repair areas are identified and executed in a methodical manner (multi-year planning effort). In an expedited level, jetty repairs are fast-tracked and made within 1 year of problem identification. Expedited repairs may be made to prevent the onset of a breach, when the jetty is in an advance state of degradation. Expedited repairs are enacted for the South Jetty and Jetty A, in response to a jetty breach. In an emergency level, jetty repairs are executed within 2-6 months, in response to a serious breach along the North Jetty. Within the SRB model, jetty repairs associated with normal O&M and expedited repair efforts are tracked separately from emergency repairs, which are associated with significant breach events.

The longer a damaged jetty segment goes without repair, the higher the rate of cross-section degradation due to wave action, and the more likely that the jetty segment could breach before repairs are made. In rare instances, a jetty segment may be damaged at such a high rate as to fail (loose function) before timely repair can be implemented. A given jetty segment has the potential to lose function when the upper cross-section area has been reduced to less than 20% of the standard upper cross-section. Within the SRB model, a jetty segment is assumed to fail when the upper cross-section is reduced to less than 15% of the standard upper cross-section. If a jetty segment adjacent to a breached segment has less than 40% of its cross-section remaining, the adjacent segment can be induced to breach. This process is intended to account for the destabilizing effect that a breached jetty has on adjacent areas of the jetty. Within the SRB model, the maximum length for a given breach event-location is 3 segments.

For each year within a life-cycle simulation, there can be 1 to 11 storms that can affect the individual segments along a given MCR jetty. If the incident wave height for a given storm event exceeds a specified damage threshold value, the jetty segment cross-section is damaged according to applicable damage functions. Wave damage is expressed in terms of cross-section loss. Each side of the jetty is evaluated for a given storm, and wave damage is rendered onto each side of a segment's upper cross-section based on whether the waves are incident to or overtopping the jetty. Annual wave damage imparted onto a given jetty segment results in variable cross-section reduction, per year. The cumulative effect of wave damage reduces the upper cross-section of the jetty over time (for each segment). The when the area of the upper cross-section is reduced to a specified maintenance level, the upper cross-section is repaired to restore the cross-section to a specific design template area. The amount of armor stone (repair tonnage) needed to restore the damaged jetty segment is based on the difference between the design template area and the cross-section just prior to repairs. Repair tonnage for a given jetty segment is calculated assuming that the void ratio for placed armor is 0.7:

Repair Tonnage per 100-ft Jetty Segment (for the upper cross-section) = 0.7 x gamma x 100 x (Initial Template Area – Area Immediately Prior to Repair) / 2000

As an example, based on a typical North Jetty segment repair, the repair tonnage would be:

0.7 x 167 lb/ft3 x 100 ft/segment x (2250 ft2/segment – 800 ft2/segment) / 2000 lb/ton = 8,475 tons

The damage trends and repair scenarios emulated in the SRB model are intended to follow closely with prototype conditions. As the upper cross-section becomes significantly damaged (>1/2 of the crest width is missing on a given side of the jetty), the wave height threshold for initiating damage is reduced and rate of damage sustained by the "damaged" section increases. At this point, the armor layer has been highly disturbed (Kd has decreased) with much of the armor layer being displaced off of the upper cross-section. If sufficient armor stone has been displaced off the jetty cross-section such that core stone is subjected to direct wave action, then the effective size of the "armor" stone is decreased in proportion to the relative amount of true armor stone remaining on the jetty slope.

5.5. EVENT TREE

Jetty segments are the basis in the SRB life-cycle model. The SRB life-cycle model has a yearly base in time and a 100-ft segment base in space. Each segment is modeled following the event tree diagram shown in Figure 14. An annual cycle of a jetty is repeated for every year in term of structural performance modes (static and dynamic), sustained damages, consequences, and life-cycle costs.

The event tree starts with the initial condition at year "i". The jetty segment initial condition is derived based on the accumulated previous years damage and repair. The segment attributes include toe elevation, crest elevation, crest width, jetty side slope, armor stone size, armor stability number, stone density, and core stone presence. The shoreline position is adjusted based on present jetty head location. Each parameter is represented by a mean value and standard deviation. Forcing environment (Wave heights and water level) of the year is applied on the initial segment condition. The forcing environment for year "i" is realized through stochastic simulation. Jetty performance modes are assessed for each jetty segment "j" based on the realized forcing environment, and jetty damage for year "i" is stochastically evaluated.

Each year, random k (1 to 11) storms are modeled. The following two evaluations are applied in each storm for each segment. The dynamic stability of the segment is first evaluated. The evaluation is applied on both ocean and channel side including based on selected appropriate wave damage functions and threshold values. The damages (cross-section area loss) are quantified by incident wave damage, overtopping damage, and jetty crest damage. The following step is the segment static stability evaluation, including the scour at the toe and slope failure along both channel side and ocean side of the channel. Cross-section degradation is evaluated.

The total damage in the "i" year to the segment is determined by the combination of the dynamic effects and static effects during the k storms in the year. The cumulative cross section damages are tabulated and the cross-section geometry is adjusted accordingly. Then the cross-section damages resulting from the static slope adjustment due to toe scour are accessed and the cross-section geometry is adjusted if jetty slope exceeds critical value.

Finally, the consequences and the corresponding jetty life-cycle performance metrics are calculated. Consequences for year "i" can include repair activities for jetty segments, functional loss of a jetty segment, and incremental channel dredging due to segment function loss. Implementation of jetty repairs as year "i" is based on a threshold evaluation. Jetty repairs are enacted if the jetty cross-section at a given segment falls below a specified maintenance threshold, which is a random variable. If a jetty segment sustains a loss of function within a given year "i" (jetty head recession or a jetty breach), then additional adverse consequences may be realized in terms of added channel dredging costs; which is also a random variable. The event tree diagram is repeated for n-years for all jetty segments, until the entire life-cycle period is realized.

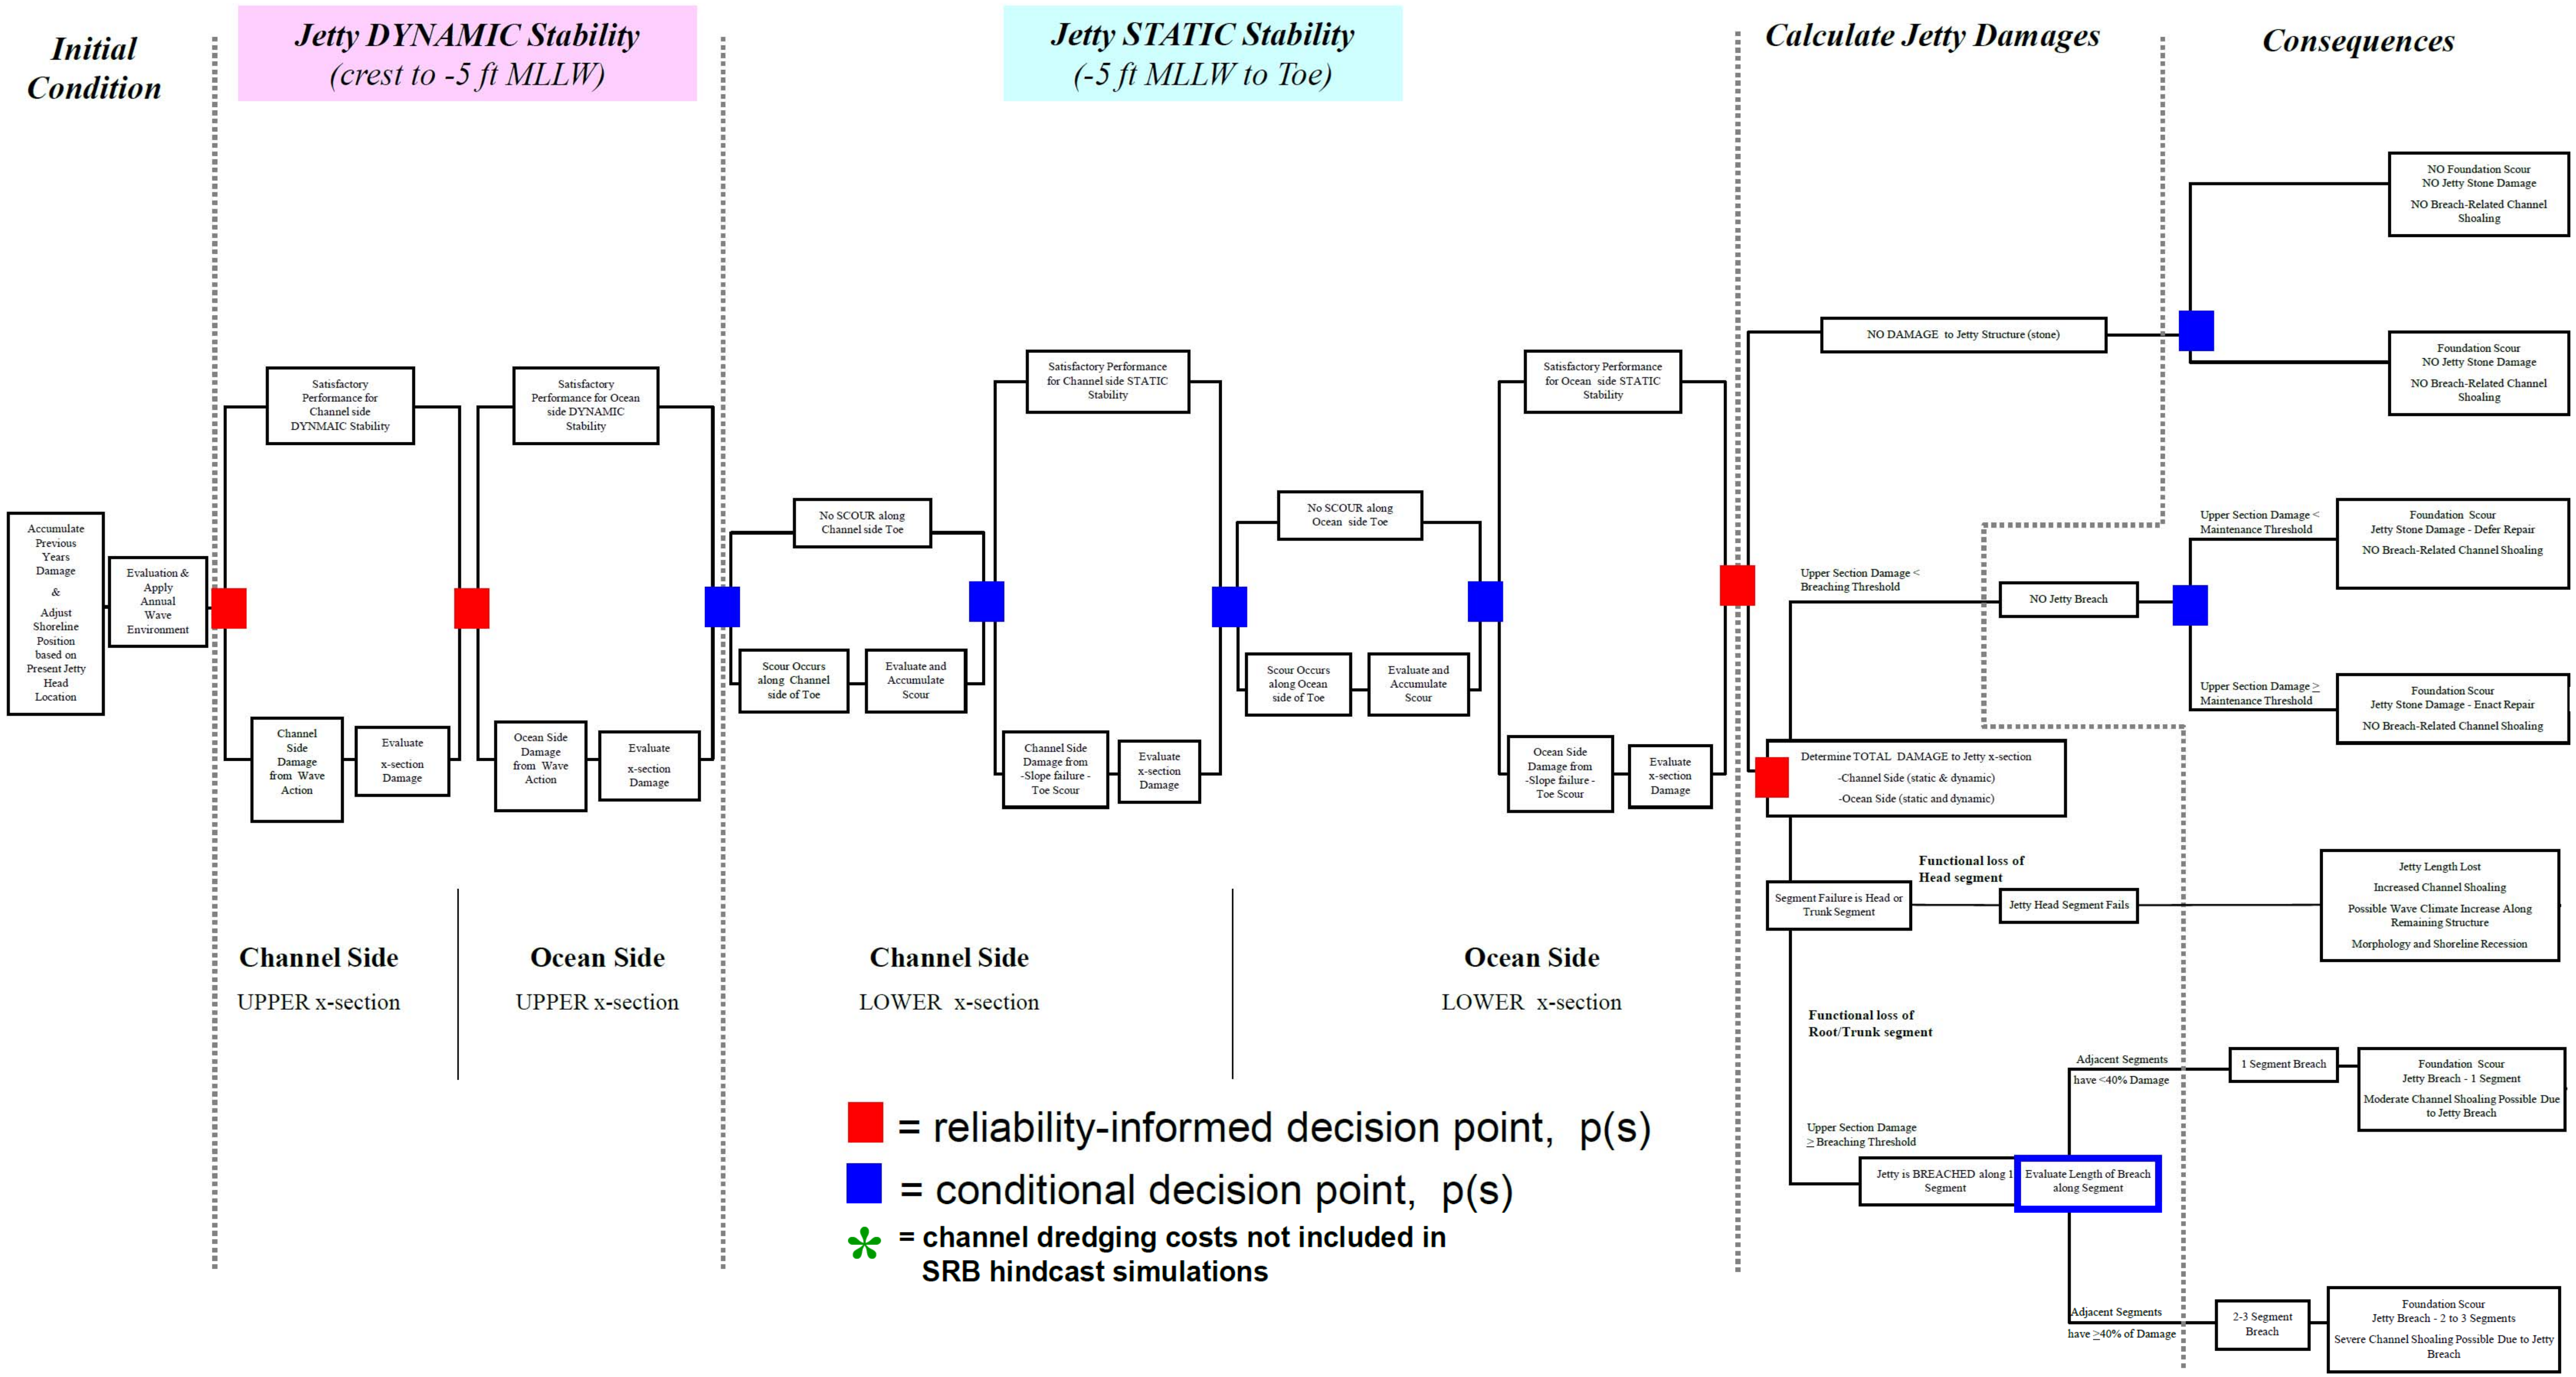

Figure 14: MCR Jetties Project Event Tree Schematic Diagram

6. MODEL CALIBRATION

To validate forecasted lifecycle simulations (future conditions) of jetty damage and alternative repair scenarios, the model is first applied in hindcast mode for each jetty; the results of which are compared to historical records of jetty maintenance to provide calibration of relevant parameters. Previous historical stone volumes used and jetty repair locations have been well-documented and the maintenance histories of each were used to calibrate specific variables. The hindcasts extend back to the approximate date of initial construction of each jetty and are simulated to the present day.

Before performing hindcast simulations for a given structure, it is essential that a structure's as-built condition be established to match the actual post-construction condition of the prototype as the initial condition of the MCR SRB model. The historical record for the MCR jetties is good and data are available to define the initial conditions for jetty toe elevation, jetty cross-section geometry, armor/core stone attributes, and historical scour rates for MCR jetties. (Refer to Appendix A1 of the *MCR Major Jetty System Major Rehabilitation Evaluation Report* for historical jetty repair details. Repair history for each jetty is summarized in terms of the location and type of jetty stone placed, construction methods, and unit repair cost). The SRB model hindcast jetty maintenance strategy was set at "interim repair" as discussed in the input procedures section of this User's Manual to emulate the maintenance conditions actually undertaken during the historical life-cycle of each jetty.

When executing a hindcast SRB simulation, the initial condition geometry, jetty armor/core stone attributes, and jetty foundation scour rates (based on historical data) are defined for the entire jetty, on a segment by segment basis. Table 11 summarizes the observed scour rates along the MCR North Jetty, as employed in the SRB model.

Table 11: North Jetty Morphological Factors for Future Base Case Scour Depth at Jetty Toe

Jetty Station	**Side of Jetty**	**PAST Life-Cycle 1917 - 2006**		**Present Seabed Elevation**	**FUTURE Life-Cycle 2006-2070**	
		Estimated	**Observed**		**Estimated**	**Estimated**
		Morphological Factor 1917 : 2006	Total Scour @ jetty (ft)	200 ft offset from toe (ft, NGVD)	Morphological Factor 2006 : 2070	Total Scour @ jetty (ft)
20+00	Ocean	0.70 : 1	deposition	*18*	-	0
50+00	Ocean	0.75 : 1	deposition	*12*	-	0
65+00	Ocean	0.77 : 1	deposition	*2*	1 : 1.1	-5
75+00	Ocean	0.79 : 1	deposition	*-5*	1 : 1.2	-10
85+00	Ocean	0.80 : 1	deposition	-16	1 : 1.3	-10
100+00	Ocean	0.75 : 1	0	-27	1 : 1.2	-15
124+00	Ocean	0.65 : 1	-15	*-31*	1 : 1.1	-10
20+00	Channel	0.6 : 1	0	-27	1 : 1.3	0
40+00	Channel	0.7 : 1	-5	-36	1 : 1.3	0
60+00	Channel	0.8 : 1	-10	-41	1 : 1.3	-10
80+00	Channel	0.8 : 1	-10	-50	1 : 1.3	-15
100+00	Channel	0.7 : 1	-30	-68	1 : 1.3	-10
124+00	Channel	0.65 : 1	-40	*-64*	1 : 1.2	0

The calibration parameters of wave-induced damage thresholds and stone "re-use" parameters are defined and input to the model. The storm wave and water level climate is generated for a given lifecycle iteration (89 years for North Jetty, 97 years for South Jetty, and 67 years for Jetty 'A'), and then jetty lifecycle calculations are performed sequentially for each year, for all jetty segments.

MC simulations are performed by running multiple lifecycle iterations and generating statistical estimates of the life-cycle ensemble. The model skill of the hindcast was assessed by comparing the simulated hindcast result to actual metrics based on sequence of repairs, number of repairs made per jetty segment, and crest elevation of the jetty at the end of the historical performance period. Other available informative metrics include time varying reliability, cross-section area, and cost expended per segment.

Calibration parameters that affect jetty degradation in the model include "wave-damage thresholds" for:

A) initial state jetty cross-section,

B) damaged initial state cross-section,

C) repair cross-section, and

D) damaged repair cross-section.

An additional calibration parameter that affects unit repair costs is the "armor stone re-use factor", which defines how much of the damaged-displaced armor stone is re-used in the subsequent repair; this can be different for each observed repair event. Within the framework of hindcast simulations, the calibration parameters are held constant as user input values. For future lifecycle simulations, the calibrated parameters are allowed to randomly vary about the mean value (the value achieved through calibration).

The model calibration variables are:

- ***dam_var***: the jetty wave damage threshold variation parameter
- ***re_use_stone_factor_repair***: the jetty stone repair factor variation

Calibration of jetty damage thresholds is achieved when simulations from the SRB model converge with the observed lifecycle history in terms of the occurrence and frequency of when the jetty was actually repaired through its historical lifecycle. The model is considered to be calibrated when the simulated jetty profile for the end-state condition is equivalent to the observed end-state condition. The observed end-state condition for each jetty was defined by detailed topographic/bathymetric surveys conducted during 2006-2007.

Upon completion of the North Jetty in 1917, the entire ocean side of the jetty was exposed to wave action due to the inlet's morphological condition. Soon after completion of the North Jetty, the presence of the jetty radically reformed Peacock Spit producing subareal deposition along the north side of the North Jetty. The SRB model simulated the time-varying condition of Peacock Spit, as its rapid accretion first acted to protect the ocean side of the North Jetty from wave and currents, and then re-exposed the jetty to the elements during gradual recession of the spit.

The intensity of wave action along exposed areas of the North Jetty in 1917 was estimated to be less than the present condition due to the orientation and geometry of the underwater shoals. Because of this, the initial condition wave environment along the ocean side of the North Jetty was reduced from present average conditions using a morphological factor varying from 0.7 near the landward end of the jetty, to 0.75 at 4/5 of total jetty length, to 0.65 at the jetty head. For similar reasons, the initial condition wave environment along the channel side of the North Jetty was reduced (from present day value) using a morphological factor ranging from 0.6 at the landward end, to 0.8 at 3/5 of total jetty length, to 0.65 at the jetty head. Morphological factors for the North Jetty are shown previously in Table Table 11: North

Jetty Morphological Factors for Future Base Case Scour Depth at Jetty Toe. These morphological adjustments to the wave environment were estimated based on empirical evidence and professional judgment. The morphology factors changed through time, from the initial condition values, to 1.0 for the present condition. Wave events realized within the SRB model are modified "at the jetty" using the time varying morphology factors (Table Table 11: North Jetty Morphological Factors for Future Base Case Scour Depth at Jetty Toe). A key assumption in the SRB model is that the average long-term *offshore* wave (deepwater) climate, at the time of jetty construction, was similar to present.

The previous Figure 13 presents a somewhat typical cross-section evolution for one realization of the historical 89-year lifecycle at Station 84 for the last iteration of the MC sequence. During this particular lifecycle iteration, Station 84 was simulated to have been repaired two times (1939 and 1997) after initial construction in 1917. The actual timing of repairs for Station 84 occurred in 1939 and 2005. The results for this particular station show that the initial damage to Station 84 occurred along the ocean side due to wave action (upper section damage) before Peacock Spit accretion. During later stages in the lifecycle, the damage affecting Station 84 was motivated by channel-side toe scour and channel-side wave action. Note that by this time the ocean side of the jetty was protected by Peacock Spit accretion; the subareal spit reached maximum accretion in 1930 and began receding in 1935.

A calibration of the new SRB model was performed by converging simulations from the model with the observed life-cycle history, in terms of the occurrence and frequency of when the jetty was actually repaired, the repair year and the amount of repair tonnage through its historical life-cycle, as well as the end-state condition. The observed end-state condition for each jetty was defined by detailed topographic/bathymetric surveys conducted during 2006-2007. The comparison of calibration results (hindcast model as compared to historical observation) are shown in Figures 15 to 20 for North Jetty, Figures 21 and 22 for South Jetty, and Figures 23 and 24 for Jetty A.

The jetty cross-section damage/degradation was modeled based on the two-dimensional physical model study results by ERDC. Damage functions (cross section area damage vs. wave height) were applied for the different jetty cross-sections, including: a) initial state jetty cross-section, b) damaged initial state cross-section, d) repair cross-section, and d) damaged repair cross-section. The "wave-damage thresholds" parameters were used to adjust the wave heights in the damage functions for different type of cross-sections for the purposes of calibration. The "wave-damage thresholds" parameters are expected to be variable along the jetty segments and for different repair/rehab scenarios. These adjustment parameters were determined through the model calibration (hindcast). They are allowed to randomly vary within a range about the mean value (obtained through calibration) in each of the future life-cycle Monte Carlo simulations.

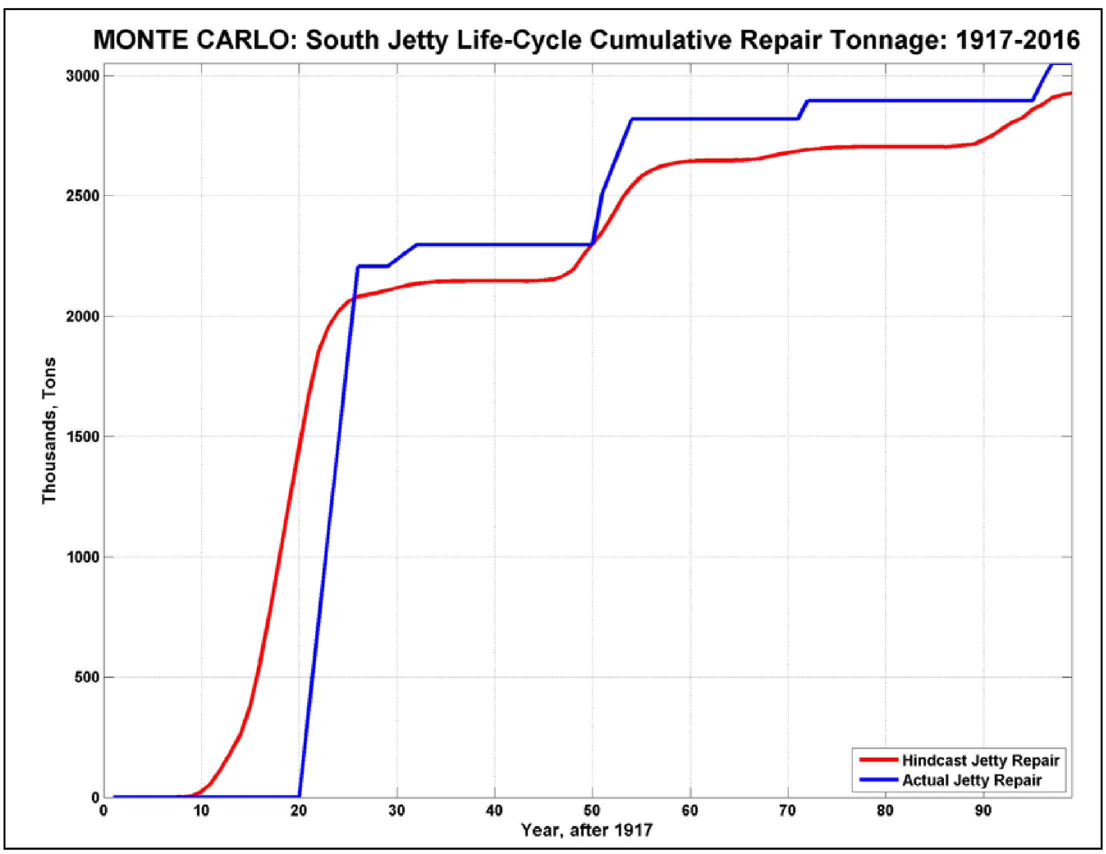

Figure 22: MCR South Jetty Cumulative Jetty Repair Tonnage for Hindcast Simulation

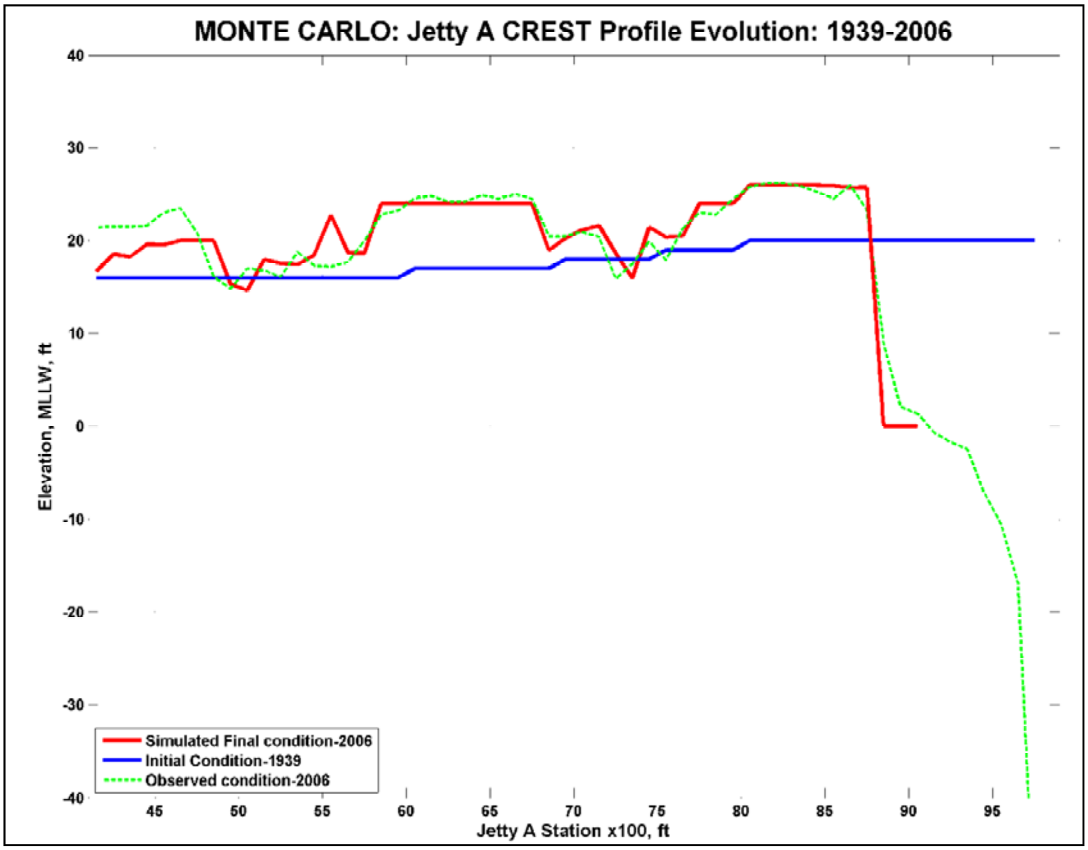

Figure 23: Centerline Profile for the "As-Built" Initial Condition for the Jetty A

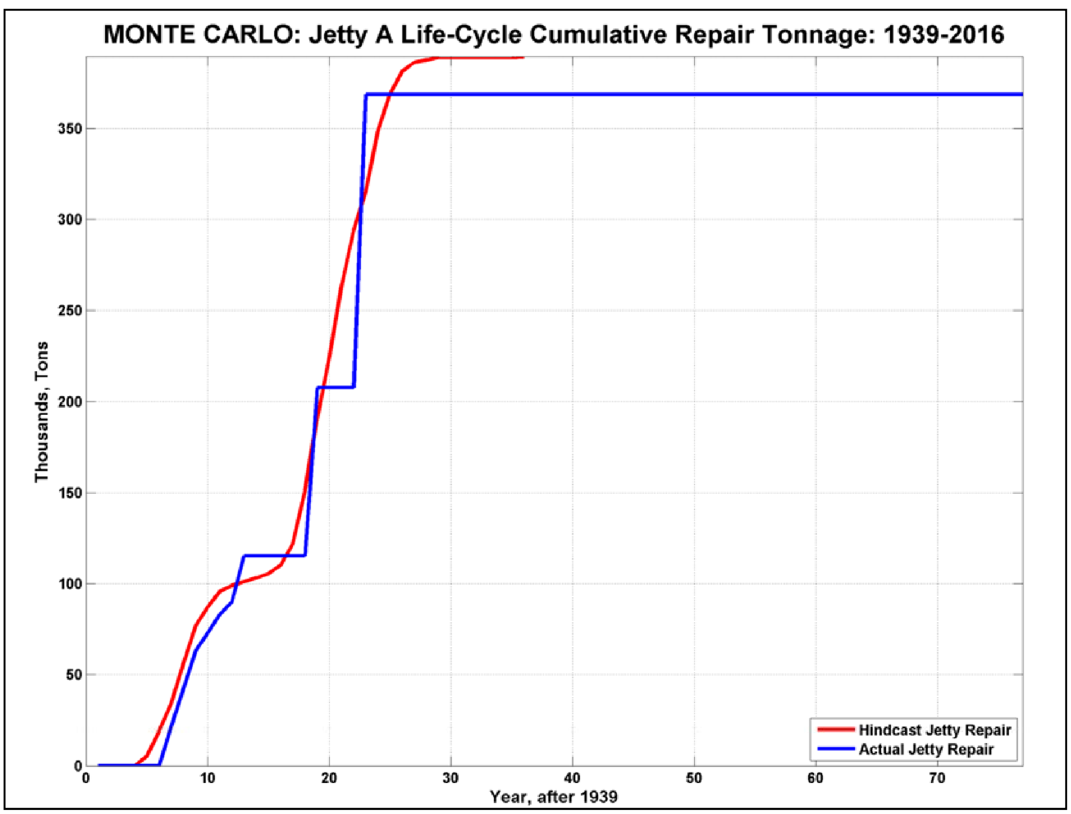

Figure 24: MCR Jetty A Cumulative Jetty Repair Tonnage for Hindcast Simulation

Figure 15 shows the center line profile for the "as-built" initial condition for the North Jetty, observed condition in 2006, and simulated condition in 2006. There is good agreement between the observed and simulated end-state. Note the extent of jetty head recession, which is being aggravated by severe toe scour. As Peacock Spit continues to recede landward in the future, the toe scour effect will translate landward.

Figure 16 shows the progression of damage to the cross section at Station 79.5 and subsequent repairs for the last MC iteration, and complements the information shown in Figure 13. Figures 17, 18 and 19 show the timing, number, location, and tonnage of repairs historically made to the North Jetty. Areas further seaward from Station 70 require greater repair efforts due to the increased exposure to wave action and toe scour. There is good agreement between actual repairs made and the simulated repair requirements. Note that the jetty head has receded landward, despite repairs.

The number of repairs that can be made within the SRB hindcast is controlled by an input parameter. The model can initiate repairs up to the prescribed number, but it is not required to initiate any repairs unless sustained damage exceeds an imposed threshold. No repairs were made to areas inshore of Station 54, which explains why the jetty profile in 2006 was in poor condition. Figure 20 shows the spatial variation of total cross-section area along the jetty for three periods of time (1917, 1922, and 2006), complementing the results shown in Figure 15.

Figures 21 and 22 show some of the calibration results for the South Jetty and Figures 23 and 24 show results for Jetty A, based on hindcast simulations. A complete set of calibration results and discussion for all three jetties can be found in Appendix A2 of the *MCR Major Jetty System Major Rehabilitation Evaluation Report*.

Note: the reader is also referred to the previous user's guide, *Model Documentation Report* (USACE, 2010), for a sensitivity analysis discussion. This model sensitivity analysis was conducted to ascertain the effect that random variation of specific model parameters had on the overall predicted lifecycle cost ranges. The sensitivity analysis was run for each of the three MCR jetties for the BASE-condition (no action alternative). One at a time, model parameters were varied randomly while holding all other parameters at a constant value (mean value). Twenty-five (25) MC simulations were run for each varied parameter to ultimately obtain a representative range of lifecycle costs. This discussion is not repeated in this user's manual as the new model contains the same formulation for all sensitivity parameters and so no significant differences would be expected between the original model and the new model.

APPENDIX A

SRB Model Input Steps

The inputs to the SRB model are completed via a straightforward user interface. The four steps involved are shown below.

Step 1 – Input variables ("values") into Excel file worksheets – shown below.

"Global" worksheet:

name	value	desc
work_jetty	NJ	(NJ, SJ, JA) specify jetty to work with
fut	1	(0,1,10-14,20-24,30) modeling scenario
MC_SIM	200	sets the number of Monte Carlo Simulations to run
draw_hindyear	1	set to 1 to draw ending jettty postion at hindcast_year for hindcast runs, set ~= 1 to draw at n
write_out	0	(0/1) write ascii data for life-cycle solution
write_out_wav_area	0

CENWP-EC-HY FY10

MEMORANDUM FOR RECORD

SUBJECT: The Mouth of the Columbia River (MCR) jetties: North, South and Jetty 'A' Site Inspection, 13-15 September 2010. Figures *MCR-2010JettyInspection_NJ_1.pdf, MCR-2010JettyInspection_NJ_2.pdf, MCR-2010JettyInspection_SJ_1.pdf, MCR-2010JettyInspection_SJ_22.pdf, MCR-2010JettyInspection_SJ_3.pdf*, and *MCR-2010JettyInspection_JA.pdf* show damage areas noted on aerial photographs, for each jetty, respectively.

1. Introduction. Inspections of all three MCR jetties were made by Richard Gunsolus and Michelle Rhodes, EC-DC, Rod Moritz, and Lynda Charles, EC-HY, from 13 to 15 September 2010. A handheld Garmin 60C GPS was used to record the spatial coordinates of the starting, ending and/or center points of damage areas. Additionally, hip chain measurements were taken to maintain consistency with historic methods.

Jetty 'A' was inspected on 13 September 2010 between 13:00 and 17:30 PDT. The tide was flooding during the inspection, increasing from 4.2' to 7.5' MLLW. The south jetty was inspected on 14 September 2010 between 10:30 and 17:30 PDT. The tide was approaching the bottom of ebb at the 10:30 am (2.7 ft MLLW) and turning to flood tide at 12:30 pm (reaching 7.1 ft MLLW at 17:30). The north jetty was inspected on 15 September 2010 between 10:30 am and 14:00. The tide was ebbing during 10:30 to 13:00 (decreasing from 3.7' to 3.1' MLLW) and flooding for the later part of the north jetty inspection (increasing from 3.1' to 3.7 ft MLLW).

Weather Description during inspection. *On 13 September (Jetty 'A') the weather was clear and sunny; with a light breeze estimated at 5to 10 mph. Wave conditions were flat with little to no wave action. On 14 September (South Jetty) the weather was light fog and high overcast with a mild temperature. The wind speed was low and west waves wave were 1 to 3 ft. On 15 September (North Jetty) the weather was partly cloudy-threatening rain at inspection start and onset of heavy rain at inspection completion. Wind speeds were low and west waves were 2-4 ft, and increasing.*

2. Background

Jetty 'A'

Jetty 'A's primary purpose is to divert (or train) river and tidal currents away from the north jetty. The jetty also serves as a breakwater, stabilizing the West channel and providing shelter from waves for vessels in route to the Ilwaco, WA, boat basin. Original construction of Jetty A was in 1939 from Sta. 40+93.89 to 96+83 using two trestles. The crest width of the jetty varied from 10 ft at the shoreline to 90 ft in the midsection to 30 ft in the offshore reach beyond the dog leg. The first repair was from Sta. 78+00 to Sta. 96+00 in 1945-47; the crest width between these stations was increased to 40 ft during this repair. Five subsequent repairs to the outer section of jetty were performed between the years of 1948-62. The midsection of the jetty which has not been repaired since original construction has received the most damage over the years and has been deteriorating progressively. The entire MCR jetty system is currently being intensely studied under a Major Rehabilitation Study by the Portland District's Engineering and Construction Branch. The study objective is to develop a long term plan for repairing and maintaining the jetties at the MCR.

South Jetty
Original construction of the South Jetty began in 1886 and was completed in 1896. Construction began at Ft. Stevens (Sta. 25+80) and continued west across Trestle Bay and Clatsop Spit to Sta. 250+20. Between 1903-1913, the jetty crest was raised to the high water level between Sta. 210+35 and 250+20. In addition, the jetty was extended from Sta. 250+20 to Sta. 375+52. Repairs have been made to several sections of the jetty since, and are listed below with the dates in parentheses:

- Sta. 175+00 to 257+68.7 (1931-32);
- Sta. 257+68.7 to 305+05 (1933-34);
- Sta. 305+05 to 353+05 (1935-36), including a stone/asphalt terminal from Sta. 340+30 to 344+30;
- Sta. 318+00 to 330+30 (1940-42), including a concrete terminal and stone foundation;
- Sta. 194+00 to 249+00 (1961);
- Sta. 249+00 to 314+05 (1962-65);
- Sta. 194+00 to 249+00 (1982);
- Sta. 223+00 to 245+00 (2006);
- Sta. 258+00 to 285+00 (2007);

North Jetty
Original construction of the North jetty began in 1917 and extended offshore to Sta. 122+00. A seaward dogleg was constructed toward the north, beginning at Sta. 111+80. In 1965, 2,020 feet (Sta. 89+47 to 109+67) of the north jetty was repaired. At this time a 220-foot long resilient jetty head was established. The North Jetty has been inspected every year since 2002. The north jetty underwent an interim repair during the summer/fall of 2005 to repair critical jetty sections between Sta. 55+00 and Sta. 86+00. The reach between Sta. 55+00 to 75+00 received a continuous span of repairs, whereas the reach between 75+00 and 86+00 was repaired in discrete areas only.

The evolution of the North Jetty and surrounding areas has been studied recently as a part of the Regional Sediment Management (RSM) program. One objective of the RSM program is to investigate the effectiveness of dredge disposal at the Shallow Water Site (SWS), located immediately west of the North Jetty head, as well as alternative disposal areas (e.g. near-shore placement on Benson Beach, or south of the south jetty) for supplying sand to the sediment-starved Benson Beach and Clatsop Spits. Additionally, the North Jetty Site (NJS), located channel-side of, and adjacent to, the North Jetty, has been utilized as a disposal site since 1999 to retard the channel-side scour along the North Jetty, in an attempt to prevent further damage to the jetty. The MCR Major

Rehabilitation Study will attempt to utilize all known facts of the region to develop a long term outlook for maintenance and repair of the MCR jetty system.

3. Damage Assessment. Damaged areas are ranked from **minor** (low concern) to **moderate** (needs watching) to **major** concern (imminent failure). Minor areas noted consist of sections that exhibit some minor stone movement or loss, but which does not affect the overall stability of the slope and body of the jetty. Areas noted as moderate damage affect larger regions of stone and have the potential to develop into more imminent areas of concern. Moderately damaged areas typically involve sloughing of slope stone with encroachment on, but no intrusion into, the jetty crest stone. Major damage areas indicate that failure has already occurred and functional impacts are imminent. Major damage areas include those in which the jetty crest stone has been affected (for example, jetty breach or jetty crest stone movement and sloughing as a result of lower slope stone movement that can destabilize rapidly).

4. Historical Observations

Jetty 'A'

As mentioned above, the mid-section of the jetty, which has not been repaired since construction, has received the most damage over the years and is progressively deteriorating. In addition, the jetty head has lost a significant amount of length since original construction.

In 2009, the jetty head was reported to have lost 969 ft since original construction in 1939. Damage to the trunk and root has previously been split into three separate reaches (outer section, midsection, and landward section). The outer section (Sta. 82+00 to the jetty head) was considered to be in moderately good condition in 2004 without any significant damages. The midsection (Sta. 67+00 to 82+00) has been damaged the most heavily. The landward section (Sta.41+00 to 67+00), was noted as having several minor Oceanside scallops in addition to an area of reduced crest elevation in 2004. Beginning in 1995, the shoreline adjacent to the jetty A root has been monitored for continued erosion to the foredune (i.e. scarp).

In 2006, the offshore extent of the jetty head was measured via GPS as Sta. 87+97, or a total loss of 886 ft (within hip-chain accuracy). At the time, the head of Jetty 'A' had not receded since 2004, but the area was still classified as major damage. The importance of the length of Jetty A has to do with the structure's effectiveness for diverting currents away from the north jetty and maintaining the present alignment of the navigation channel.

The midsection of the jetty has experienced the worst damage, as noted in 2006. Specifically, in the reach between Sta. 70+60 to 76+52, armor stone has been displaced resulting in crest elevations 5-10 ft below the design crest elevation. At some of the lowered crest locations, there is visual evidence of tidal flows through the jetty resulting in pools of water forming along the eastern (bayside) side-slope. Although this may be considered an effective breach condition on many jetties, currently the damage does not pose an imminent functional threat because due to the widened footprint in this reach of jetty. The section would require extensively more damage to become hydraulically connected through the jetty. This area should be monitored frequently because the damage has the potential to progress over time and further destabilize the jetty and surrounding areas.

The landward reach of jetty was noted in 2006 as remaining in good condition with only minor scalloped damage areas. The major, moderate and minor damage areas noted in 2006 are listed below:

- *Jetty A head position:* Sta. 87+97 (Major)
- *Midsection (jetty trunk)*: Sta. 74+14 to 76+39, worst area (Sta. 74+80 to 75+40) / Sta. 72+00 to 76+39 / Sta. 70+70 to 71+18 (Major)
- *Midsection (jetty trunk)*: Sta. 78+37 to 78+92 / Sta. 77+68 to 78+05 / Sta. 71+33 to 71+68 / Sta. 68+10 to 69+52 Sta. 55+72 to 56+44 / Sta. 54+67 to 55+30 / Sta. 49+64 to 50+12 (Moderate)
- *Midsection (jetty trunk)*: Sta. 84+94 to 85+56 / Sta. 83+29 to 84+00 / Sta. 79+11 to 79+39 / Sta. 76+67 to 76+95 (Minor)
- *Landward Section*: Sta. 67+20 to 67+40 / Sta. 62+20 to 62+38 / Sta. 56+67 to 57+56 / Sta. 54+00 to 54+20 (Minor)

In 1995, a baseline was established in effort to measure the progression of erosion occurring at the shoreline between jetty A and Cape Disappointment. As of this year many of these baseline points have been destroyed making the year to year comparison of the monitoring difficult. In effort to re-establish a measurement of the erosion, GPS points were recorded in 2005 and 2006 at 30 ft intervals along the top of the scarp edge. In this manner, large changes in horizontal positioning of the shoreline can be easily and quickly compared.

South Jetty

The most recent South Jetty repairs (in 2006 and 2007) focused on repairing the most critically damaged sections of the jetty. At the time, there were other sections that had sustained extensive damage, but were not considered critical (on the verge of breaching). These sustained damages, and others that have formed since, will be addressed in the Major Rehabilitation Study. The South Jetty was last inspected in 2008 in which the following major and moderate damage areas were noted:

- *South jetty head:* Sta. 312+65 (major)
- *South jetty trunk:* Sta. 287+87 to 289+00 / 258+00 to 290+00 (Interim Repairs 07) (major)
- *South jetty root:* Sta. 161+67 to 161+96 / Sta. 163+20 to 163+40 (major)
- *South jetty trunk:* Sta. 303+56 to 304+54 (Moderate)

North Jetty

Jetty sections shoreward of the 2005 interim repair (inshore of Sta 55+00) have not been repaired since original construction. In this region, the jetty side slopes have been damaged and become steepened/unstable. The jetty crest width is very narrow and consists of jumbled stone. It has been referred to as 'knife-like' in reference to the peaked-ness shape of the jetty crest and slope. Inshore of Sta. 55+00, the channel side of the jetty has been damaged by wave action and foundation scour; such that one-quarter to one-half of the jetty cross-section is missing. The beach side of the jetty inshore of Sta. 55 has reduced stability due to poor stone-stone contact and steepened side slope. Reaches of the north jetty offshore of the 2005 repairs (Sta 86+00) have exhibited signs of extensive damage. In 2009, minor, moderate and major damage areas were noted as follows:

- *North jetty head:* Current Sta. 100+40 (Major)
- *North jetty trunk:* Sta. 91+30 to 92+24 / Sta. 87+40 to 88+91 (Major)
- *North jetty root:* In general, areas inshore of Sta. 55+00 are moderately damaged. Specific areas of major damage include (byt a are not limited to) Sta. 53+05 to 55+00 / Sta. 52+23 to 52+55 / Sta. 50+60 to 51+14.
- *North jetty trunk:* Sta. 89+03 to 90+32 / Sta. 89+27 to 89+76 (Moderate)
- *North jetty channel-side trunk:* Sta. 98+74 to 99+28 / Sta. 94+57 to 95+09 / Sta. 92+54 to 93+29 (Minor)
- N*orth jetty ocean-side trunk:* Sta. 97+67 to 97+90 (Minor)

Overall, the channel-side section of the North Jetty has suffered damage resulting from scour at the toe. Continued loss to the north jetty head and the corresponding relation to the shoreline recession north of the jetty (Benson Beach) are of concern and are being monitored within the RSM program.

5. <u>2010 Observations</u>

a. Jetty 'A' Inspection

In 2010 Jetty 'A' remained in various degrees of degradation along the entire length of the jetty. Damaged areas spanned the range from minor to major, with the worst damage being noted at the head and mid-section. The offshore extent of the jetty head was not orthogonal to the jetty axis, but, rather, at an angle. The southeast edge of the jetty head extended further offshore than the southwest edge. The armor stone on all sides of the jetty head are exhibiting signs of damage in the form of sloughing or cascading stone, leaving the much smaller diameter sub-material stones exposed to waves and currents. In-house stationing reconfiguration took place this year which changed the previous readings slightly, including an adjustment to the head reading. No additional head loss was noted from the 2009 inspection with the head reading standing at Sta. 87+17 which is 966' loss from the original construction length.

The mid-section of the jetty trunk has multiple locations of lower crest elevations. Some of these locations are most likely under water at the highest tides and storm surges. The width of the jetty footprint is wide through this mid-section, which is probably preventing a complete breach of the jetty.

Along the ocean-side of the landward section, the jetty is experiencing many moderate and minor scallops due to slope sloughing and stone cascading. A large amount of wood debris is stacked along the shoreline area of the jetty, where the jetty crest elevation appears to be lower than offshore jetty crest elevations. The specific minor, moderate and major damage areas along the length of the jetty observed during the 2010 inspection are noted below:

Minor damage

a. Ocean-side sloughed slope stone adjacent to stacked slope stone; Submaterial visible beneath the armor stone: Sta. 81+97 to 82+32.
b. Narrow, ocean-side slot forming from the toe to the crest: Sta. 79+22 to 79+48.
c. Ocean-side area of stone loss and lower slope shifting: 66+75 to 66+94.
d. Ocean-side scallop with toe stone loss and slope shifting extending to edge of crest: 65+73 to 66+44.
e. Ocean-side scallop extending to edge of crest: 63+57 to 63+99.
f. Crest elevation lowers by 1-2 stone diameters: There is a large amount of wood debris stacked along this section: Shoreline to 50+31.

Moderate damage

a. River-side scallops forming from the erosion of, and movement of, toe stone. Steep slopes above; sub-material is exposed where armor stone has cascaded: 84+00 to 84+91.
b. Large slope stone has cascaded down to toe; steep slopes and perched large stone above: 83+06 to 83+66.
c. Ocean-side location of a length of settled slope stone extending 5’ into the crest stone; lower elevations throughout the damage area: 77+75 to 79+07.
d. Narrow crest width and up to 1 stone low: 69+66 to 69+81.
e. Narrow crest width (2 stone diameters wide). Ocean-side mild slope due to stone slumping. Jumbled and settled crest stone: 67+66 to 68+92.
f. Narrow slot forming a scallop; low stone perched over moved toe stone. Slope stone movement is affecting the crest stone: 66+99 to 67+51.
g. Ocean-side sloughing and cascading of mid-slope stones. One section has formed a scallop with vertical faces at the upper slope stone and crest stone: 61+31 to 63+22.
h. Several ocean-side scallops with damage encroaching crest by 1 stone width: 53+83 to 58+36.
i. Crest breach with jumbled crest stone. New crest elevation is 1 to 2stones low and damage to both side slopes: 54+63 to 55+43.
j. Ocean-side scallop forming, encroaching into jetty crest stone: 50+64 to 53+39.

Major damage

a. Jetty head becomes increasingly narrow: 87+00 to 87+80.
b. Ocean-side scallops forming: 86+00 to 86+80 and 85+16 to 85+56.
c. River-side section of nearly vertical side slopes. Slope stones have cascaded down exposing sub-material beneath: 85+56 to 86+31.
d. River-side sloughed toe stone and side slope leaving steep, perched stone above: 85+00 to 85+40.
e. Ocean-side scallop between76+77 and 77+04.
f. Area of jetty breaching between Sta. 70+60 and 76+52. Significant narrow crest widths and lower crest elevations throughout. Complete jetty breach between Sta. 71+96 and 73+13 with only a few stones remaining above high tide.
g. Major damage is observed offshore of the existing 2010 head location. This represents a total of 966' of head loss from the original constructed length.

b. South Jetty Inspection

In 2010 the South Jetty was inspected from shoreline (Sta. 189+00) to the existing jetty head (~Sta 312). Two areas recently repaired (2006 and 2007), and some minor-moderate damage has appeared within the repaired areas. Areas that were not repaired recently are experiencing increased (continual) deterioration. The range of damage observed was from minor to major. These areas should continue to be monitored frequently to observe if any active change is threatening the function of the jetty. The specific minor, moderate and major damage areas along the length of the jetty observed during the 2010 inspection are noted below. Areas shown in **bold** designate damage that has been realized since the last jetty inspection in 2009:

Minor damage

a. Ocean-side location that is potentially forming a scallop; mild slope with some cascaded stones, some stones have been knocked back up onto the crest: 299+30 to 300+50.
b. Ocean-side narrower crest width possibly due to slope sloughing; there is a mild slope between wider crests and some perched stones adjacent to mild slope: 294+00 to **299+30**.
c. Ocean-side low to mid-slope slough leaving upper stone perched: 284+60 to **286+00**.
d. Ocean side armor stone popping off slope, coming to rest along lower slope (below water level); general steepening of slope due to armor displacement along lower slope: 282-30 to 284+60.
e. Ocean-side over-steepened slopes and perched stones: 279+00 to **280+00.**
f. Ocean-side 2-3 large perched stones (including one green colored stone from the 2007 repair stone); toe stone movement: **279+00** to **280+00.**
g. Ocean-side slope; armor along lower slope missing leaving oversteepened slope ready for washout to crest: St 271+80 to

275+80

h. Ocean-side section of lower stone sloughing; some toe stone holes: 269+20 to 269+60.
i. Ocean-side section of low and toe stone movement (including some green-colored stone); perched and steeper slopes above: **264+00** to 267+70.
j. Ocean-side large green-colored stone knocked nearly vertical to the crest stone: 258+60.
k. Ocean-side slope slough leaving some adjacent perched stone; mild low slope as stones bunch at toe: 257+80 to 258+20.
l. Channel-side slope slough: 257+50 to 257+80.
m. Ocean-side steep side slope and perched stone; some low slope movement: 255+30 to 255+80.
n. **Ocean side damage (chute) extending from lower slope to crest: 246**.
o. **Ocean-side damage to slope, armor zone blow leaving upper slope unstable, susceptible to slope failure extending to crest: Sta 39+30 235+70, and 233.**
p. **Ocean-side damage to side slope extending from lower slope to crest, armor rolling off side slope: 223- 226.**
q. Ocean-side 'slot' scallop: 216+80 to 217+20.
r. Ocean-side scallop forming affecting slope up to crest stone: 205+60 to 206+00.
s. Ocean-side toe stone holes with steep slopes above; some adjacent slope slumping: 203+50 to 203+90.
t. Ocean-side toe stone hole: 201+80.
u. Low crest elevation possibly from loss of haul road material. In addition, ocean-side slough of slope stone: 193+30 to 193+70.

Moderate damage

a. Ocean-side scallop affecting side-slope stone: 309+20 to 309+80.
b. Ocean-side narrowing of crest width and several scallops in a row: 306+30 to 306+80; 305+70 to 306+10; 304+80 to 305+30.
c. Ocean-side mild slope and narrow, jumbled crest: 304+30 to 304+70.
d. Lower crest elevation (by 1-2 stone diameters); wave overtopping has potentially knocked stones towards channel-side; potential to breach in the future: 303+90 to 304+30.
e. Ocean-side scallop encroaching into crest stone: 302+90 to 303+90.
f. Ocean-side scallop encroaching into crest stone: **291+00** to 292+80.
g. Ocean-side section of low stone slump (including some new repair green-colored stone); upper slope stone is perched, some precariously; upper slopes are steep: 281+30 to 282+30.
h. Ocean-side slope slump with some perched stone and steeper slopes: 280+00 to 280+60.
i. **Ocean-side significant damage along lower slope affecting upper slope areas. Large scallops though most of slope; will affect crest:**

275+80 to 279.

j. Ocean-side scallop with steeper slopes and settlement of low slope stone: 218+00 to 218+50.
k. Ocean-side long section of sloughing slope stone, narrow crest and perched stone: 214+60 to 216+30.
l. Ocean-side scallop encroaching into crest stone; mild slope from stone settlement: 213+80 to 214+40.
m. Ocean-side scallop encroaching into crest stone: 213+20 to 213+60.
n. Lower crest elevation (10-15') from loss of haul road material ocean-side sloughing of slope stone, general blow-out of armor stone along base of active wave slope, damage extending to crest: 192+60. In 2008, this area was noted as "minor damage"
o. Lower sections of crest stone (2'-4' lower than surrounding crest stone), general blow-out of armor stone along base of active wave slope, damage extending to crest, local crest washouts: 191+00 to 191+40; 189+00 to 189+40. In 2008, this area was noted as "minor damage"
p. Sand erosion from backside of jetty. At higher water levels, wave action overtops the jetty and water passes through the jetty to the backside and erodes from the sand dune: 160+00 to 164+60.

Major damage

a. Crest stone is narrow (2-3 stones wide): 311+00 to 313+00.
b. Toe stones are jumbled on both ocean- and channel-side: 311+00 to 313+00.
c. Ocean-side steeper slopes: 311+00 to 313+00.
d. Several dislodged crest and upper slope stone: 311+00 to 313+00.
e. Large ocean-side scallop encroaching halfway into crest stone: 310+00 to 311+00.
f. Ocean-side scallop immediately inshore of 2006 repair area, encroaching halfway into crest stone: 222+40 to 222+90.
g. Ocean-side scallop encroaching halfway into crest stone; steep slopes and perched stone with some cascading stone down-slope. Crest is 10' wide at the smallest width; there is some associated crest stone settlement: 221+00 to 222+40.
h. Ocean-side scallop encroaching halfway into crest stone; steep slopes and perched stone with some cascading stone down-slope. Crest is 15' wide at smallest width; there is some associated crest stone settlement and some channel-side stone cascading that has occurred: 218+70 to 219+80.
i. Two locations of ocean-side scallops encroaching halfway into crest stone; steep upper slope, mile lower slope; some associated channel;-side slumping: 212+20 to 213+00 and 210+90 to 211+60.
q. Major damage is observed offshore of the existing 2010 head location. This represents a total of 3038' of head loss from the 1942 head repair.

c. North Jetty Inspection

In 2010 the North jetty was inspected Sta 60+00 to the jetty head. During 2010 inspection, access to the north jetty was limited due to the WALDR dredged material pump ashore operation. There were some isolated areas of damage noted along the western-most area of the 2005 repairs (Sta 73, 82, & 85). In general, the area offshore of the 2005 repair area is in a severe state of disrepair. The deterioration is accelerating. The crest is narrow and jumbled; the peak of the crest is not coincident with the jetty axis, but, rather, varies location along the jetty axis. There are several areas of lower crest elevation than surrounding crest elevations.

In-shore of Sta 81+00, the 2005 repairs are performing very well. The repair area is in good condition with only a small number of minor damaged areas observed. The length of jetty inshore of the 2005 repair area has never been repaired and continues to show signs of deterioration. The crest width is narrow and jumbled. The channel-side slope is mild. The land-side slope is steep. Water freely passes through this section of the jetty to a backside embayment, which has been created from the erosion of the backside sand. The specific minor, moderate and major damage areas along the length of the jetty observed during the 2010 inspection are noted below. Areas shown in bold designate damage that has realized since the last jetty inspection in 2009:

Minor damage

a. Ocean-side steep upper slopes and mile low slopes: 84+50 to 85+20.
b. Ocean-side chute (stone missing along slot from water line to crest): 82+00 to 82+50
c. Missing toe stone channel-side: 81+60.
d. Ocean-side jumbled side slope; some cascading slope stone and non-interlocking stone: 72+50 to 73+30.

Moderate damage

a. Ocean-side lower crest elevation from side-slope sloughing. Channel-side narrower crest width due to slumping side slope, characterized by a mild low slope and steep upper slope at the crest stone. Channel-side sloughing slope, cascading crest stone, steep upper slope and mild lower slope: 92+40 to 96+30.
b. Jetty is in a varied state of deterioration resulting from no repair since original construction: 10+00 (shoreline) to 56+00.

Major damage

a. Jetty crest width is narrow with steep surrounding upper slopes to mild low slopes; the toe is wider at the base from cascading or moving toe stone: 98+00 to **99+74**
b. Large ocean-side scallop with more encroachment into the jetty stone towards the offshore side than the onshore side; nearly vertical faces at

the upper slope; toe stone has moved away from the jetty creating a low shelf of stone: 96+00 to 98+00.

c. Lower crest elevation (6'-8') than surrounding crest elevations with intermittent large armor stone left perched or sliding. Low slope has slid out from toe: 91+40 to 92+40.
d. Very narrow and meandering crest peak (1 stone diameter wide). Both sides' exhibit signs of slope sloughing, some perched stone near the crest; many smaller stone comprise the remaining stone near crest (1'-2' and 3'-5'): 88+20 to 91+40.
e. Lower crest elevation by **10'** with slope sloughing on both sides: 87+60 to 88+20.
f. Very narrow crest width (1 stone diameter) with steep slopes on both sides: 86+70 to 87+60.
g. Major damage is observed offshore of the existing 2010 head location. This represents a total of 993' of head loss from the 1965 head rehabilitation.

6. Conclusions. The jetty system at MCR is subject to annual stormy weather conditions and large wave activity. The entrance to the Columbia River is also subject to large tidal currents superposed on large river currents. The combination of all these factors makes for a challenging environment in which to sustain protective structures that can maintain stability through strong climatic events.

Both the North and South Jetties have undergone repairs along specific reaches within the last 3 years. Recently repaired areas of both jetties are already showing signs of minor to moderate damage, at isolated locations. The 2005 North Jetty repair and the 2007 South Jetty repair are exhibiting signs of minor-moderate damage in 2010. Areas of each jetty that have not undergone recent repair are experience continued deterioration.

The South Jetty, although suffering no additional loss in length from 2009, has many locations of varying degrees of damage that have formed since 2009. Other damage areas are expanding in along and through the jetty cross-section. Some of these damage areas encroach well into the jetty crest, leaving as little as a 10' wide crest before a breach will occur. The nominal crest width should be 30 ft. In addition, some of these same damage areas are exhibiting crest lowering and channel-side damages (due to wave overtopping and re-distribution of armor stone). This type of damage is occurring both offshore and inshore of the recent repair areas. The area of the jetty inshore of Sta. 182+00 consists of a narrow crest width and more jumbled stone than what is visible offshore of this point. This area is typically within the breaking wave region of the surf zone and exposed to the energy breaking waves frequently. Near the beach between Sta. 160+00 and 164+00, over topping waves and storm surge has eroded sediment to the point that the water passes freely through the jetty stone at higher water levels, allowing access to the backside sand dunes, where more sand is eroded by the water. This location has been monitored for several years, and should continue to be monitored closely for damage advancement of the erosion line. A foredune that intersects the south jetty root near Sta

155+00 serves to prevent overland surge from the ocean that would otherwise lead to breaching of Clatsop Spit between Trestle Bay (estuary) and the ocean. The south jetty foredune is currently in a threatened condition; more than 2/3's of the foredune has been eroded and the dunes' crest elevation has been reduced from +40 ft MLLW to +25. The progressive erosion of the foredune is being driven by a receding foreshore morphology, with storm waves and surge eroding the face along the ocean side toe. Abatement and remediation of the erosion along the south jetty foredune should be undertaken as soon as practicable.

The North Jetty sections offshore of the 2005 repair area appear to be in a severe state of disrepair. Much of this region consists of very narrow crest widths, with a meandering crest peak. Many locations have lower crest elevations than surrounding cross-sections. The narrow crest is fronted often by a low shelf of toe stone from sloughed or cascaded slope stone. Steep upper slopes leave many stones perched, if they have not cascaded down-slope already. The wave heights increase tremendously immediately offshore of the jetty head, as the submerged relic jetty stone causes abrupt changes in water depth. Waves frequently break on the jetty head stone and, when waves approach from the north, the ocean-side of the jetty undergoes significant wave attack.

The shortening of the jetty is believed to be directly responsible for the shoreline recession immediately north of the jetty (Benson Beach). For several years, dredge disposal has occurred in the Shallow Water Site (SWS) which extends offshore from the western tip of the North Jetty. Sediment is transported north from the SWS and transports or deposits naturally along the near-shore region. This process supplies sediment to the spit in an attempt to stabilize the beach and cause sand to accrete. A breach through the North Jetty trunk would potentially destabilize the jetty rapidly as well as the adjacent shoreline. Sand would be transported into the navigation channel causing additional shoreline recession and navigation hazards in an already dangerous navigation channel. This jetty should be monitored closely, as well, for further destabilizing damage.

Jetty 'A', though still performing well according to its purpose, is exhibiting signs of severe damage along its length. The head continues to recede, losing approximately 80 additional feet since the 2007 inspection. Various scallops are forming on both sides of the head, with the smaller, sub-material stone exposed in these areas. There was only one layer of armor stone placed when this section was constructed or repaired. Once the armor stone is removed, the sub-material is not interlocked sufficiently to prevent further erosion.

The mid-section of the jetty suffers from a narrow crest of jumbled stone and lower crest elevations. Several locations exhibit signs of jetty crest breaching to various degrees. In one location, the breach is clear down to the layer of sand. The stone remaining in this breach is low in elevation, potentially underwater during extreme high water level events. During the inspection, the water level was approximately 5.7' MLLW and was approximately 2.0' below the top of stone through the breach. If this continues to grow, or any of the other breaches continue to deteriorate, flow may be allowed to pass through the jetty, further destabilizing the jetty and surrounding regions (e.g. the Ilwaco, WA channel that it serves to protect). If further breaches are allowed to form or deteriorate, the jetty will not be effective in re-directing the river flow towards the south jetty. The result of this would be potential destabilization of the North Jetty, as the river current will be allowed to scour the adjacent toe sediment.

The ongoing MCR Major Rehabilitation Study will attempt to look at all consequences of various repair strategies. The objective is to produce the most holistic, cost-effective, long-term maintenance and repair plan for the MCR jetty system.

MCR Jetty System Major Rehabilitation Evaluation Report

Historical MCR Morphology Change

Appendix A5

Bathymetry Surfaces

This appendix contains thirteen bathymetric surfaces created from bathymetry and shoreline data sets. Bathymetric surfaces were created using a TIN model that incorporated high-water shoreline positions as landward boundaries for bathymetry. Three-dimensional perspectives also are provided for each surface.

MCR Jetty System Major Rehabilitation Evaluation Report

Appendix B

Geotechnical Studies

Appendix B - Geotechnical Studies

Table of Contents

List of Tables and Figures

Appendix B - Geotechnical Studies

1. BACKGROUND

The jetties adjacent to the mouth of the Columbia River (MCR) at Astoria, Oregon are under study for a major rehabilitation action to repair them back to a 50-year design life. All three jetties have been experiencing damage from winter storms and each has lost significant amounts of material from the head and trunk sections over the past several years. Designs resulting from numerical and physical modeling require very large amounts of jettystone to be placed on the relict stone base as well as the adjacent sand foundation.

Project Description

The North and South jetties at MCR are located at the mouth of the Columbia River in northern Oregon and southern Washington. Jetty A is located at approximate river mile 3 and extends south from Cape Disappointment towards the navigation channel. All jetties were built on sand foundations. The North Jetty was constructed to a length of 12,408 feet from 1913-1917. It has had four repairs to the outer trunk and head section culminating with interim repairs to the trunk section in 2005. The first 22,440 feet of the South Jetty was constructed from 1885-1896. It was repaired and extended by 12,514 to the currently authorized length from 1903-1914. The South Jetty has had eight repairs to the head and trunk section since it was extended, with the last interim repair occurring in 2006-2007. Jetty A was constructed in 1939 to a length of 10,000 feet and was repaired four times before a repair and 3,806 foot extension in 1958. The last repair occurred to the trunk and outer end in 1961. All three jetties have experienced significant damage to the trunk and head sections in the last several years.

2. GEOLOGICAL FRAMEWORK

The coastal area of Oregon has been influenced by a combination of tectonic forces and glacial effects during the past few million years. Regional uplift, coupled with a fluctuating sea level, are shown by marine terraces up to 100 feet above present sea level and Astoria Canyon, more than 300 feet below sea level. Beneath deposits of recent sands are rocks up to 40 million years old. These are mostly marine deposits with volcanic outcrops forming such features as North Head, Tongue Point, and Tillamook Head. About 20 million years ago these rocks were uplifted and deformed into a “trough” along the course of the present river. Erosion as uplift occurred produced massive sedimentary deposits that were subsequently partially eroded and overlain by younger deposits. Volcanic activity associated with the uplift produced submarine basalt deposits and intrusions intermingled with the sedimentary deposits.

Beginning about 2 million years ago, glacially-induced sea level fluctuations were superimposed upon the continued regional uplift. At the maximum extent of the continental glaciers sea level was as much as 400 feet below present and the MCR was up to 10 miles offshore. During this time a series of shelf-edge canyons were formed, including Astoria Canyon, which channeled sediments into deeper water. Delta-like features formed from massive amounts of sediments, estimated up to 10 times present volumes (Nelson 1968). The Astoria fan is one such feature, shown on Figure B-1. As the glaciers retreated, sea level rose up to 100 feet above its present elevation. Coastal forces extensively reworked unconsolidated sediments and formed marine terraces during relative still-stands. The last episode of glacial retreat began less than 20,000 years ago with sea level rising rapidly until 5,000 to 6,000 years ago. Estuaries at the MCR and elsewhere are "drowned" river valleys, and coastal features such as extensive sand spits and dune complexes resulted from marine forces reworking sediments relict from earlier times.

Figure B-1. Columbia River Drainage Basin and Adjacent Pacific Ocean Floor

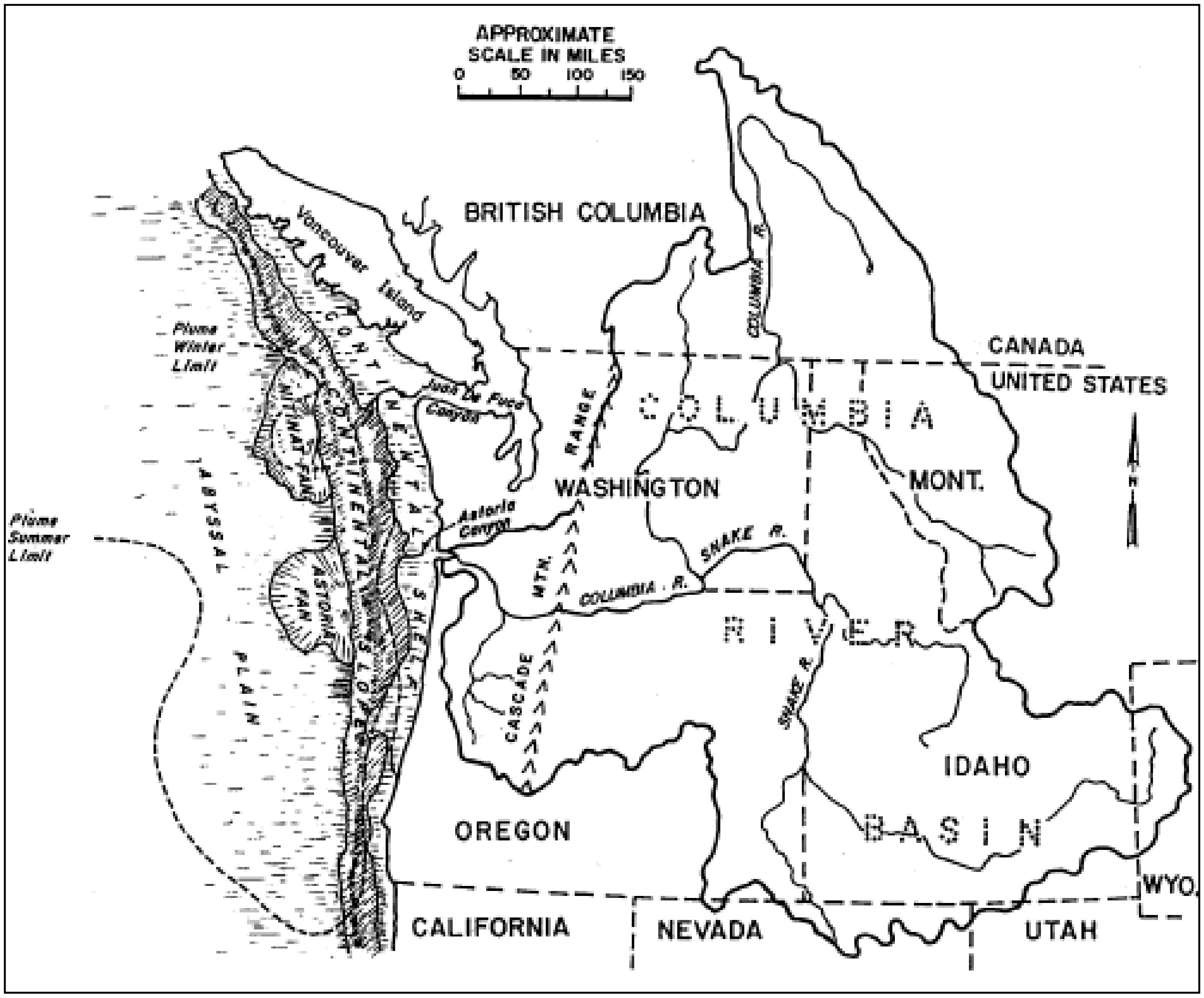

Figure B-2 shows the general geology of the area around the MCR. Upland areas are mostly older sedimentary rocks that are intercalated basalt flows that are folded and faulted. Overlying these rocks are occasional remnants of once extensive Pleistocene marine terraces. Filling the valley bottoms and the estuary are modern river sediments. These sediments grade into marine sands near the river mouth that continue offshore. Extensive coastal dunes and beaches have been formed in modern times by wind forces acting upon river/marine sands. Figure B-3 presents two cross sections of the study area based upon onshore drilling. These sections are displayed on Figure B-2. Section A-A runs north-south along Clatsop Spit and Section B-B runs perpendicular to the shoreline near Gearhart. These sections demonstrate the extent of the sediment layer above bedrock, averaging 100 feet near Gearhart and thickening to over 200 feet at the MCR.

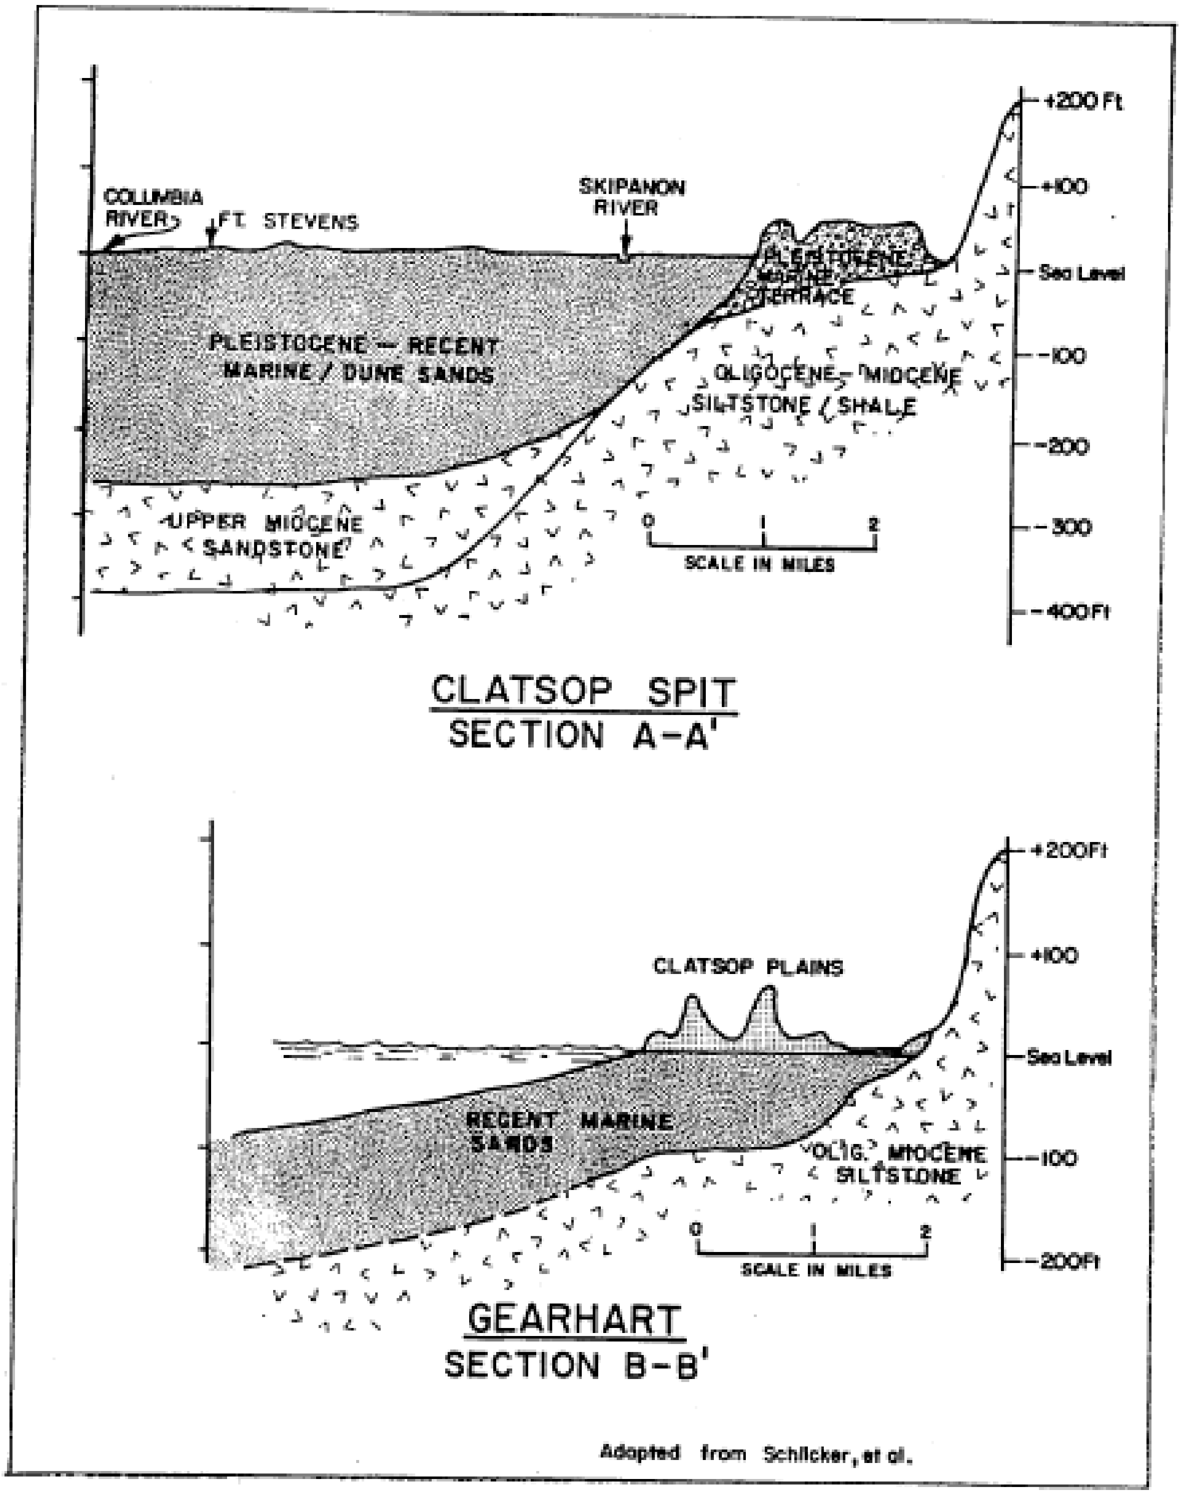
Figure B-3. Cross-sections of Coastal Areas near the MCR (sections are shown in Figure B-2)



Geologic Units beneath the MCR Study Area

No bedrock outcrops were found during USACE investigations within the MCR study area. Snavely and Wells (1996) indicate that Pleistocene and Holocene sediments extend across the entire continental slope and are exposed on the sea floor only on large banks such as Heceta and Nehalem, which are south of the study area. By projection of bedrock units mapped in the Astoria 15' Quadrangle by Schlicker and others (1972), it appears that the study area is underlain by an undifferentiated sequence of sedimentary rocks of Oligocene to middle Miocene age. These beds are estimated to be approximately 5,000 feet thick and consist of thin-bedded to massive tuffaceous siltstone and clay stone with lesser amounts of sandstone and shale locally. These beds are mildly deformed, typically dipping 40 degrees or less. No known faults mapped on land project into the study area. A west-trending strike slip fault through the Columbia River mouth and extending offshore is known from either aeromagnetic data or seismic reflection profiling. It occurs in the older rocks, being concealed by the younger strata.

Several wells have been drilled in the Clatsop plains area south of the South Jetty within a few miles of the study area (Frank 1970). Near the surface, these wells encountered a variety of unconsolidated dune, beach, and shallow marine sands interbedded with alluvium, all of Pleistocene and Holocene age. These young deposits extend to depths of between 250 and 300 feet below sea level and rest unconformably on a sandy unit that extends to depths of approximately 400 feet below sea level. This second unit was tentatively identified as Astoria Formation by Frank (1970), but has subsequently been called Upper Miocene Sandstone by Schlicker and others (1972). This unit is typically buff-colored, medium- to coarse-grained, semi-consolidated sandstone of marine origin. The Oligo-Miocene beds that are part of the Astoria Formation underlie the Upper Miocene Sandstone.

Seismic Conditions

The site is located within the Cascadia Subduction Zone where very large magnitude earthquakes are expected to occur. Earthquakes between magnitude 8 and 9+ occur on average about once for 450 to 500 years. The last event occurred 311 years ago and was at least a magnitude 9. A subduction zone earthquake will result in at least a one to three foot subsidence of the sea floor and jetty, liquefaction and lateral spreading of loose sediments, and a large tsunami (a series of long wave length, 20 to 50 foot waves) that will overtop the jetties.

Recent Geophysical Investigations

Geophysical investigations consisting of side scan sonar and sub-bottom profiling, have been conducted for the USACE at the mouth and offshore of Columbia River since at least 1982 (Northern Technical Services). This initial investigation provided information related to sub-bottom conditions present in the entrance and lower navigation channel, including the identification of potential areas of harder dredging related to an early study to deepen the navigation channel in this area. Subsequent vibracoring operations (L.R. Squier 1984 and Dames & Moore 1986) in these potential harder areas identified the material types and properties up to 20 feet and 30 feet respectively, beneath the existing channel bottom.

The study of the Columbia River mouth area in 1985 by Earth Sciences Associates and Geo Recon International utilized both side scan and sub-bottom profiling techniques. Figure B-4 shows a geologic map of the 1985 study area produced by side-scan sonograph records. The sub-bottom data, such as that shown in Figure B-5, provided a clear differentiation between the unconsolidated fine to medium sand of the present sea bottom and underlying semi-consolidated to consolidated material beneath.

The top layer of sediment defined between the base of the water column and the first sub-bottom reflector has a variable thickness averaging from 20 to 40 feet thick. This material is of Holocene age with the upper part consisting of the sediment currently being deposited by the Columbia River and subsequently redistributed by oceanic currents. The basal reflector of this unit is very irregular, suggesting that the underlying unit might be large scale sand waves or dunes. This unit averages 90-120 feet thick and is thought to consist of unconsolidated and semi-consolidated sand with minor silt and clay. This correlation is based solely on depth and geometry of these contacts with those found in nearby wells. The lowermost unit identified on the profile represents the Upper Miocene Sandstone Formation which is one of the bedrock formations found in the area. Side scan data from 1985 revealed a general uniformity of the sea floor, which appears to be composed of silty sand to sandy silt. No rock outcrop exposures were found in the area surveyed. Small east-west trending ripple marks were consistently apparent over the entire area surveyed, decreasing somewhat north of the river mouth. The extreme northern portion of the study area showed a notable increase in bottom debris and bottom growth. At and south of the river mouth there was a marked absence of typical sea floor growth and debris. Sand waves were noted south of the active disposal site A. Long period sand waves with wave lengths of up to 500 feet, crest to crest, and heights of up to five feet, trough to crest, were noted on the fathometer records and located where indicated on the side scan map. The wave crests parallel the east-west axis of the local grid. These long-period sand waves were practically invisible on the side scan records due to their long wave length and small wave height.

Side scan data from 1996 (Northwest Geophysical Associates) was collected from areas not covered by the 1985 survey. Data from the combined surveys provides fairly complete coverage out to about 5 miles from the river mouth with overlap noted primarily in the river mouth area (Figure B-6). Figure B-7 shows the majority of the material in the 1996 coverage area is interpreted to be sand/silt which is equivalent to the fine to medium sand identified in the earlier survey. A large area between the jetties and immediately offshore shows numerous sand waves. Beyond that is a large area described as possible scour/ submerged rock, however, rock is not likely to be found within the study area. A few large unidentifiable objects were found on the bottom. None of these targets exhibited a shadow indicating there was little bottom relief. These are located in a table on Figure B-7.

Figure B-6. 1996 Side Scan Plan Map Compared with 1985 Coverage

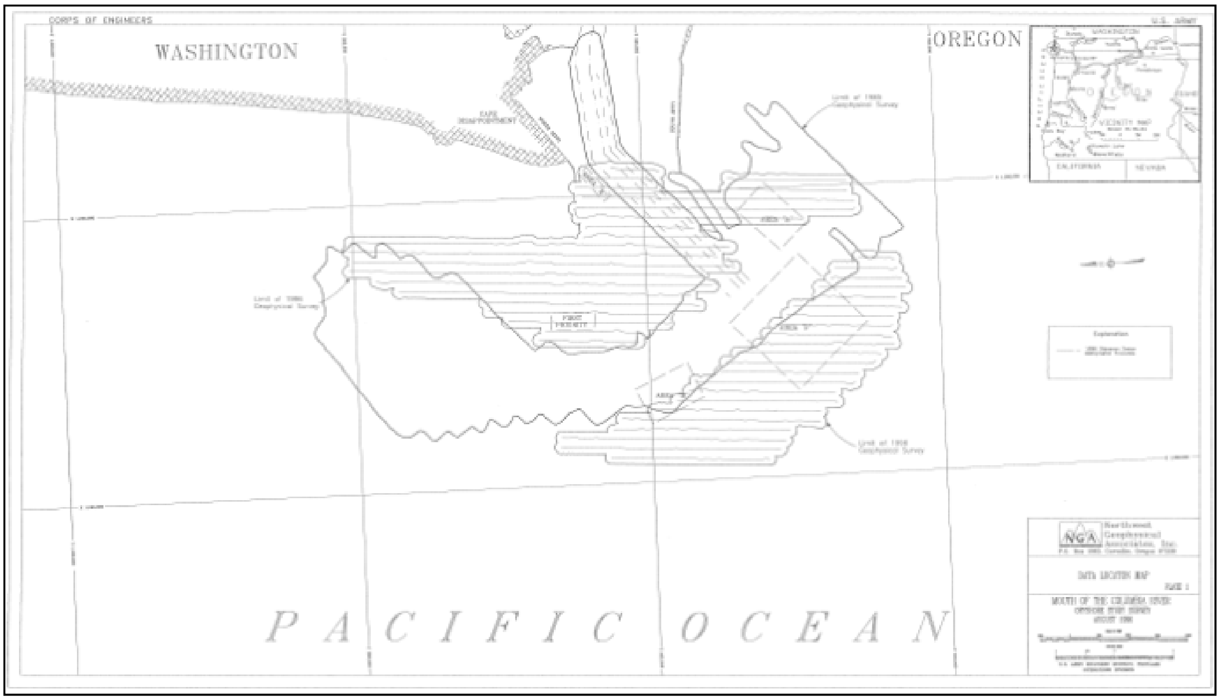

Figure B-7. 1996 Side Scan Survey Results

Bottom Changes Noted between the 1996 and 1985 Surveys

Most of the area of overlap between the 1985 and 1996 surveys appears to be unchanged. The major differences found between the two studies are as follows:

- Sand waves are no longer present in Area “F.”

- Less scour was observed in the channel between the jetties and was replaced by sand waves.
- More scour was observed west of approximately X=1,090,000. Bathymetric changes show the removal of one to two feet of material in the scoured areas.
- Five "other submerged targets" were detected at the mouth of the jetties and do not appear in the 1985 study.
- Three objects shown in the 1985 study as "shipwreck or other large object on sea floor" were not detected by the 1996 survey.
- Significant amounts of material have been added to Areas "B", "F", and "A." Area "B" appears to be as much as 25 feet shallower in 1996 than in 1985.

Other Studies

A side scan sonar survey with accompanying seismic reflection, along with a surface sediment sampling program was undertaken by the USGS in 2000 (Twichell et.al.) to map the distribution of Recent sediment in the Columbia River littoral cell. The study also identified the surficial geology of the inner continental shelf area of southwestern Washington, including the area around the mouth of the Columbia River and adjacent to the north and south jetties. This study confirmed that the inner shelf and lower beach face in the study area around the Columbia River mouth is comprised of between 10 and 50 meters of Holocene sediments with no rock outcrops present anywhere within the study area. Surface sediments were shown to be comprised of fine sand in water depths less than 15 meters depth grading to very fine sand in water depths of 15 to 25 meters.

Information obtained from a Sediment Trend Analysis (STA®) and Acoustic Bottom Classification (ABC) conducted in 2000 (McLaren and Hill) was used to develop an understanding of the mechanisms of sediment transport and inter-relationships among sediment sources and sinks associated with the Columbia River mouth, primarily related to offshore disposal sites. The study, through the tracking of relative changes in grain-size distribution of the bottom sediments, was able to identify areas of net erosion, net accretion, or dynamic equilibrium. Information from the sediment sampling program and acoustic data used with STA technique identified sediment transport pathways in the study area including adjacent to the north and south jetties. Results indicate that net erosion is occurring near both the north and south jetty; however, dynamic equilibrium is present along the inner portion of both the north side of the south jetty and the south side of the north jetty. Seismic reflection lines were run in 2003 in the area between the North Jetty and Jetty A to identify subsurface materials adjacent to the North Jetty for use as a possible sump location for dredged material for eventual distribution onto Benson Beach (David Evans and Associates 2003). Comparing records with vibracore samples taken shortly after the survey (Kaminsky 2003) showed that the entire area was comprised of very fine to medium grained sands with little or no internal structure evident. The top of bedrock dropping away from Cape Disappointment was also identified in the records, and detectable to an elevation of -175 feet MLLW at a distance of almost ½ mile west of the headland.

The lower 6 miles of the MCR and the adjacent offshore dredged material disposal sites were mapped in 2005 as part of a detailed study. The maps created by these multibeam investigations accurately produced bathymetric imagery with contours, along with backscatter imagery (Global Remote Sensing 2005). The resulting bathymetry was used to create an accurate depiction of bottom conditions for numerical models related to this rehab study. The maps created from these investigations have not been compared with the 1996 surveys to identify changes that may have occurred since that time.

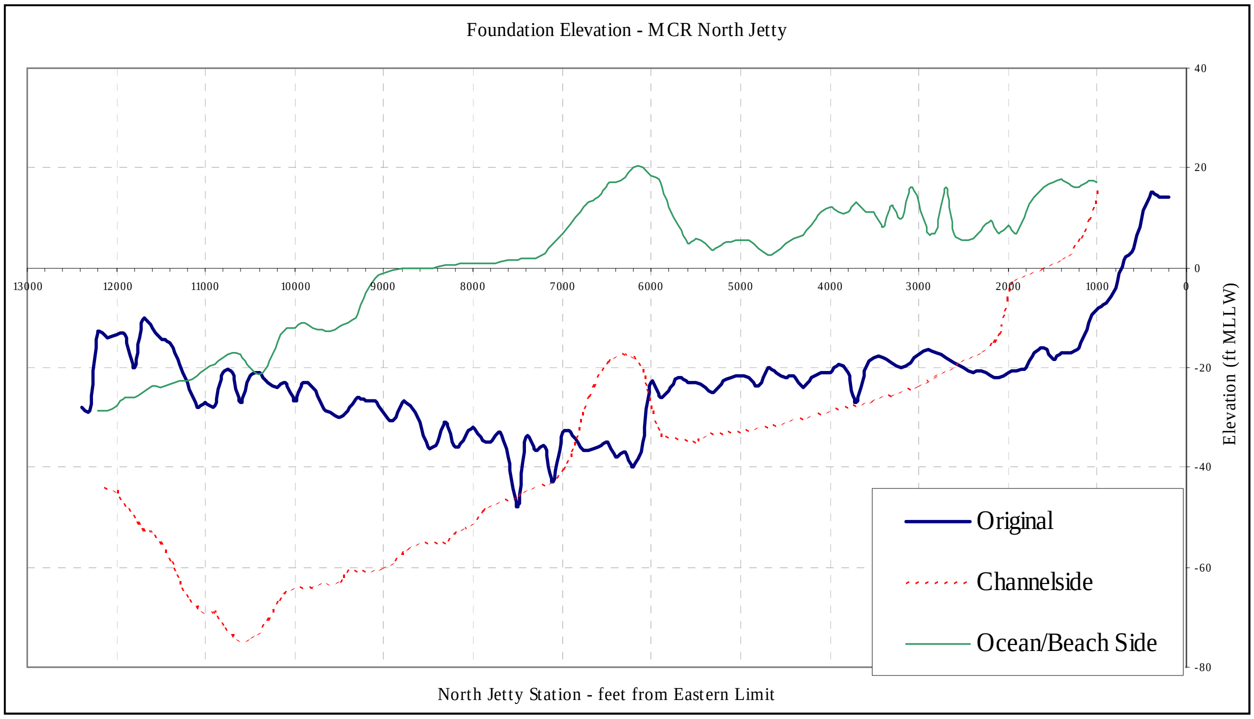
3. FOUNDATION CONDITIONS

No known subsurface explorations have been conducted by the USACE in conjunction with jetty construction. Vibracoring operations have been conducted, however, adjacent to the jetties (Kaminsky and others 2005) for the purpose of evaluating a proposed dredged material re-handling area adjacent to the North Jetty. Information from these cores as well as from cores obtained near the South Jetty during the same study has provided a look at the subsurface materials present adjacent to each jetty. The foundations for original construction of both the North and South jetties consisted primarily of recently deposited fine sand with some mud/sand interbeds. Bedrock is anticipated to occur at depth and is not believed to have been encountered during original construction. Conditions within the current footprint have been interpreted from analyzing multibeam fathometer surveys completed in 1999. The conditions surrounding each jetty foundation are discussed below.

North Jetty

The North Jetty is anchored to the western side of Cape Disappointment, which is a hard, basaltic headland. Bedrock quickly drops beneath the ocean floor and was not encountered during construction. Figure B-8 shows that stone placement during original construction encountered the ocean floor at approximately El. –20 feet MLLW over the majority of the area from Sta. 12+00 to Sta. 60+00. Stone placed at Sta. 60+00 drops to near El. –40 MLLW, then transitions gradually back to near El. –20 by Sta. 108+00. It is not known how much stone settlement has taken place after initial placement, but Figure B-8 indicates that the toe of the jetty is now up to 10 feet deeper than it was during original construction. This is most likely to have occurred from stone displaced from the jetty side slopes and crest having settled along the margins of the jetty slope, rather than from actual settlement from the jetty. Vibracores taken adjacent to the North Jetty indicate that the foundation is primarily well-sorted very fine to fine grained sand with only thin interbeds of laminated mud, silt and sand, interpreted to having been deposited during floods. Radiocarbon dating indicates that the sediment pre-dates jetty construction by at least hundreds of years, indicating that any settlement of the layers had likely taken place long before jetty construction. As a result, this material is less susceptible to compaction upon loading and was shown during vibracoring operations to be dense and hard to penetrate, especially along the inner portion of the jetty.

Figure B-8. North Jetty Foundation Grade during Original Construction

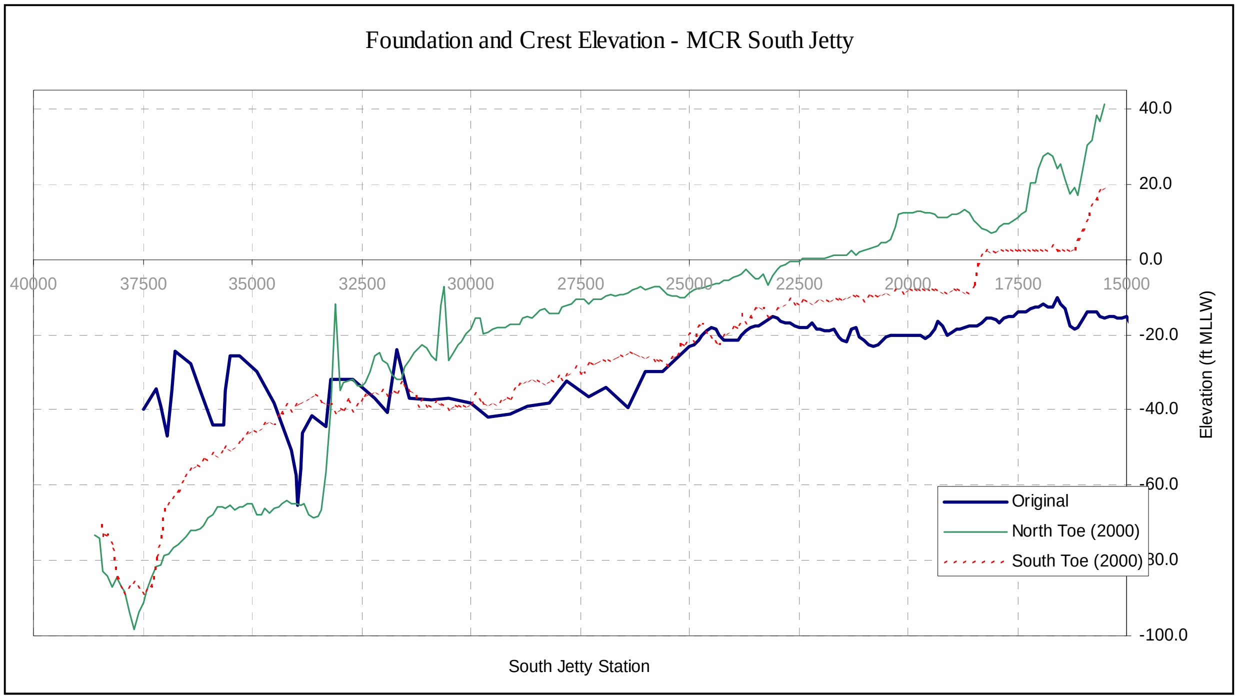


Much of the area within this study has not been repaired since original construction ended in 1917. Stone was dumped from railway cars from the jetty tramway and placement was mostly random. Migration of the channel northward and adjacent to the North Jetty caused undercutting of the stone base, and resulted in side slope failures along a significant portion of the reach under study. The outer edge of exposed rock on the channel side is fairly consistently located approximately 90 feet from the centerline of the jetty between Sta. 40+00 and Sta. 59+00 at an elevation of -30 feet MLLW. Shoaling occurs adjacent to the jetty between Sta. 59+00 and Sta. 70+00. In this area, the exposed edge of the rock side slope disappears beneath the sand approximately 60 feet from jetty centerline at an elevation of about -6 feet MLLW. Side slopes below MLLW are a fairly consistent 1V on 2H from Sta. 40+00 to Sta. 70+00, and then increase to approximately 3V on 4H to Sta. 80+00. Small, localized areas of steepening up to 1V on 1H are present throughout the study area.

South Jetty

Construction of the South Jetty commenced in 1885 at Point Adams, near Ft. Stevens, which is comprised of recent sand deposits. No bedrock is present in the area, and is anticipated to occur at greater depth than the North Jetty. Construction was directed seaward across Clatsop Spit, which is an extension of Point Adams. Figure B-9 shows that the ocean floor was encountered between elevations of -10 and -15 feet MLLW from near the start of the jetty to Sta. 180+00. Between Sta. 180+00 and approximate Sta. 250+00, the ocean floor averaged El. -20 feet MLLW. Jettystone was placed to elevations averaging between –30 and –40 feet MLLW from Sta. 250+00 and Sta. 330+00 for this report. The remainder of jetty construction seaward of this section placed stone at elevations varying between -25 to over -60 feet MLLW. Figure B-5 shows that stone was originally placed at a depth shallower than bottom conditions encountered now from Sta. 330+00 seaward. Analysis of historical bathymetric data adjacent to the South Jetty (Kaminsky and others 2005) indicates that a deeper channel existed beneath the jetty just landward of the knuckle a few decades before jetty construction. Vibracores suggest that thicker mud deposits are present in these buried channels, and since they only predated construction by a few years, it has been hypothesized that dewatering of these mud deposits by loading from jetty construction may have contributed to settlement, translating to recurrent damage to the jetty at this point.

Figure B-9. South Jetty Foundation Grade during Original Construction

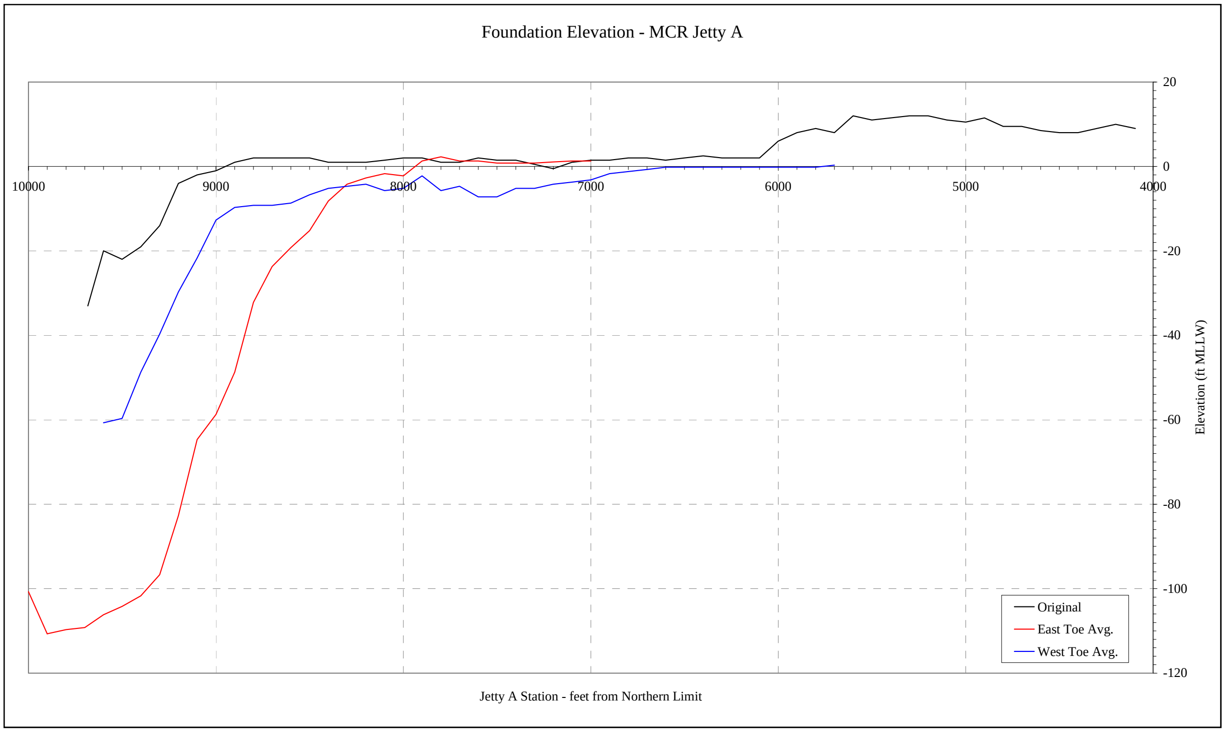


Repeated failures of the South Jetty have distributed a large quantity of stones primarily to the sea side of the jetty. The current jetty cross-section within the study area has been constructed on a relict stone base that has been dispersed between 150 feet to over 220 feet from jetty centerline. The outer edge of relict rock is not always obvious in the survey plots due to lack of data adjacent to the below water slope between the shoreline and Sta. 242+00. While settlement may have occurred along this and potentially other sections of the South Jetty, the numerous repairs provided stone for a substantial relict base and along with over 100 years of foundation loading having occurred, little to no additional settlement is expected along the jetty.

Jetty A

Construction of Jetty A commenced from the southeastern side of Cape Disappointment and was built on an existing sand spit that extended south into the Columbia River. The jetty is anchored to the basaltic headland and was initially constructed above the high tide mark for the first 6,000 feet. At this point, as Figure B-10 shows, the sand spit dropped to an approximate elevation of +2 feet MLLW that extended an additional 3,000 feet to the south. At this point, the sand spit ends and water depths increase dramatically to the south with the end of the jetty founded on sand at El. -30 MLLW.

Figure B-10. Jetty A Foundation Grade during Original Construction



The root of Jetty A remains landlocked on both sides from near the Coast Guard Station to approximate Sta. 50+00. From this point, the western, or sea side of the jetty is exposed to wave action, and the jetty toe has scoured below original foundation grade to an elevation averaging MLLW to approximate Sta. 67+00. The jetty toe beyond this point continues to scour below grade at a fairly consistent slope from MLLW to El. -10 to Sta. 90+00, which is beyond the current head of the jetty. A scour hole occurs just south of Sta. 90+00 on the west toe and drops off to an elevation greater than -60 feet MLLW. The eastern side of the jetty (Baker Bay side) has an above water berm extending from the shoreline to approximate Sta. 79+00. The height of this berm equates to the original jetty foundation grade through this area. Southward of this point, the same scour hole at the end of the jetty is encountered, achieving an elevation of approximately -110 feet MLLW.

No vibracoring operations have been conducted adjacent to Jetty A, however, a geophysical investigation consisting of acoustical sub-bottom profiling and side scan sonar investigation was accomplished in the adjacent Baker Bay channel in 1983 (Northern Technical Services). Results of seismic reflection sub-bottom profiling indicated that bedrock occurred at a depth greater than 150 to 200 feet below the channel bottom. Subsurface materials in the channel adjacent to the jetty section were interpreted to consist of 5 to 10 feet of fine sand overlying a uniform, thick sequence of medium-grained sand probably in excess of 70 feet. Side scan sonar provided data out to 300 feet on each side of the trackline and results also indicate a uniform surficial layer of sand adjacent to the jetty. No evidence of mud interbeds, although found in areas further inland of the jetty, were found in this reach. This indicates that Jetty A is likely founded on fine to medium-grained sand that would provide for a uniform, more solid base that is not susceptible to settlement.

Foundation Design Considerations

While no known foundation borings have been conducted by USACE in conjunction with construction of these jetties which began over 100 years ago, USACE does have a good understanding of the foundation in relation to jetty performance. The original foundation conditions are identified through repeated geophysical testing and subsequent vibracoring operations in the vicinity of the jetties as being comprised of a thick deposit of sands with some minor localized interbeds of mud. These original foundations have been modified and strengthened through the years as a result of jetty stone movement by waves from severe winter storms widening the foundation footprint and have been supplemented with additional material from several repairs to create a significant relict stone base beneath and around the jetties upon which most of these new repairs will be founded.

Repairs to the MCR jetties have occurred multiple times since original construction. Repairs have taken place along most reaches of the jetties with the exception of the root of the north jetty. All areas currently impacted by the most severe conditions have seen repairs. The result of these repairs has strengthened the foundation under and adjacent to the jetties multiple times through successive loading by not only added stone mass but also by land-based repair equipment delivering stone along the jetty to the repair area. Planned repairs to the MCR jetties are not occurring on new, unknown foundations. Foundation borings are not required, as would be performed if these were new foundations. These are existing performance-tested jetty structures with performance-tested foundations. The stability of the jetties were modeled and analyzed for a range of geometries and geotechnical parameters to identify the sensitivity of factors of safety against failure for each various parameter. The likely failure modes identified for these structures have been verified from observing over 100 years of jetty performance.

The predominant failure modes for the jetties, as identified from modeling and discussed in the sections below, have been stone movement due to wave loading and foundation scour impacting the jetty toes. Large waves from winter storms dislodge stones from the upper exposed portions of the jetty and move them down the slope to a more stable configuration. Holes created from dislodged stones effectively destabilize adjacent stones and make them and deeper stones in the slope vulnerable to hydraulic forces. Larger stone size utilization and higher degree of interlocking is seen as the solution to this problem. The scour of sediments at the toe of the side slope is seen as the other major failure mechanism. Lower submerged slopes are most susceptible to failure when they are steeper than 1.5H to 1V and have been subjected to 5 meters or more of scour. Most side slopes are flatter than this though due to dislodged slope stones present on the lower slopes. A short apron of stone placed at the base of the exposed slope would act as a preventative measure to support the slope in areas where accumulated stone at the base of the slope is not already present. Deep-seated foundation failure, such as noted in landslides, has not been observed over the lifetime of the jetties and is not considered a concern. This makes sense from a soil mechanics point of view: deep-seated foundation failures do not occur in granular, free-draining foundation materials that gain strength with increasing depth and effective stress. In addition, the proposed jetty repair sections are no higher in top elevation and no steeper in side slope than the existing jetty sections, which mean they will not produce higher-than-already-experienced shear stresses in the foundation. Results of the analysis presented in the Stone Stability Analysis section below recommends a design foundation shear strength of ϕ' = 34 degrees. Foundation design parameters are identified in Table B-1.

Existing Foundation Stone Stability

Stone present below MLLW throughout the original footprint of the jetties should be fairly well stabilized. Various sizes of rock material within the original footprint, along with sand infilling, have probably created a hard, sound base for future construction. This is based on tough digging conditions encountered during a rock removal project at the outer end of the Yaquina North Jetty at Newport, OR in 1999. That Contract removed rock that had wrapped back around the channel side of the jetty as a result of jetty destruction by waves from winter storms. This "wing" of rock extends below water and encroaches on the navigation channel providing a rougher wave climate in that area. The Contractor had difficulty removing these stones, especially as they proceeded deeper, and in many areas was unable to make the design grade established by that Contract.

Most stones comprising the relict base are fairly well-keyed in, will provide a sound and stable base, and will see little to no additional settlement upon reconstruction. The existence of a relict stone foundation can be verified during construction by "feeling" the bottom with the stone placement equipment. The North Jetty and Jetty A reconstruction will take place primarily on relict stone foundations. Some areas may be at the margin of the relict stone, and other areas may encounter sand overlying the relict base. The South Jetty reconstruction is anticipated to be entirely on the relict stone foundation on the south side of the jetty, with sand foundations occurring on the margins of the north side if flatter slopes are attained. Spur groins placed on the south side of the North Jetty and the north side of the South Jetty will likely encounter a sand foundation except where it ties to the jetty. While these structures are located entirely beneath the water surface and quite small in comparison to the main jetties, it is important that any area encountering sand be prepped with a bedding layer prior to placement of the armor stone to ensure a stable foundation exists.

Deep seated slip surface failures are not likely to occur at the MCR jetties. One main reason that this type of failure is not likely is based on past performance of the jetties, where catastrophic damage involving a significant portion of the side slope and crest has not been observed in over 100 years since original construction. This makes sense from a soil mechanics point of view: deep-seated foundation failures do not occur in granular, free-draining foundation materials that gain strength with increasing depth and effective stress. Damage has been noted to primarily progress through time from the outer slope inward to the center, typically involving a single armor layer at a time. A second reason this type of failure is unlikely is that the original sand foundation underlying the jetties is protected from undermining and subsequent failure by an armored outer slope created by jettystone displaced during failure of original and subsequently repaired sections of the jetty.

Stone Stability Analysis

Stability of the MCR jetties was analyzed for a range of geometries and geotechnical parameters presumed to be representative of existing jetty conditions. Parameters used are listed in Table B-1. For each parameter, minimum likely, most likely, and maximum likely values were developed. There is insufficient information to develop a standard deviation. The range of values developed is based on judgment. Because of the extensive nature of the jetties, there are numerous combinations of possible geometries and uncertainties in parameters; analyses were done with a range of values to determine the sensitive of the factor of safety against failure for various parameters.

A significant aspect of this analysis was to develop a reasonable estimate of the internal hydraulic pore pressures within the jetty mass; in particular, the excess pore pressure between the stones as the ocean wave recedes after impact. This pore pressure is required to do the computations. However, the pressure distribution during storm events within the jetty is unknown. To provide this required parameter, a transient seepage analysis was conducted using the finite element software product SeepW, developed by GEO-SLOPE. The model is shown in Figure B-11. This analysis used one-half of the height of a storm wave train measured offshore of the jetties and modified to convert wave velocity to equivalent pressure as input into the seepage model. The output results from this seepage model were examined, and the highest positive pressure differential between the pressure beneath representative jetty stones and the ocean was used as the maximum likely excess pore pressure. The most likely pore pressure was taken as one-half of this value and minimum likely pore pressure was taken as zero differential pressure.

Stability analyses were accomplished using SlopeW - a limit equilibrium slope stability program developed by GEO-SLOPE. Geometry of the model is shown in Figure B-12. The model considered the geometry of the slope; materials weight and shear strength, estimates transient excess pore water pressures due to wave impact, and recession. The model took into account partial submergence of the jetties. Seawater was modeled as a force acting normal to the surface of the jetty and seabed. This representation was done to eliminate problems associated with inter-slice forces when modeling water as a zero strength material.

The factor of safety against failure of the jetty was calculated for the most likely condition. In addition, the factor of safety was calculated for each case where only one parameter was changed to minimum and maximum likely values while holding the others unchanged from the most likely value where possible. A few cases where depth of seabed was changed required other changes in geometry as well. The results of the analyses are also shown in Table B-1. Sensitivity of the various parameters is shown in Figure B-13. The results suggest that the stability of the jetties is sensitive to three primary parameters. These are in order of importance: the internal pore pressures (effects of waves impact and recession), shear strength of the mass of stones (quality of stacking or construction), and amount of exposed sediments below the base of jetty due to scour.

Table B-1. Geometrical, Mechanical, and Hydraulic Parameters used in Analysis and Results

Parameter	**Description**	**Adopted Range of Values & Factor of Safety**		
		Minimum Likely (FS)	**Most Likely (FS)**	**Maximum Likely (FS)**
Jetty Slope	Most likely value represents design above water surface, 1V:1.25H represents oversteepened or eroded condition, 1V:1.75 H represents flattened slope below water and degraded slopes.	1V:1.25H **FS=0.87**	1V:1.5H **FS=1.06**	1V:1.75H **FS=1.28**
Jetty Stone Mass Weight	Most likely value is based on laboratory tests of typical basalt used in construction of the jetties (165 pcf ±5 pcf). Mass weight of the jetty was then adjusted to reflect that the most likely jetty mass is estimated to be 75% stone and 25% voids. For the low end lower stone weight (65%) and voids (35%) was used and for the high end heavier jetty stone weight (85%) and voids (15%) was used. Unsaturated weight above and saturated weights below ocean level were used. Jetties are partially submerged so that sea-water (1.026x fresh water) was represented using a hydrostatic force applied to seabed and jetty.	Unsaturated 17.8 kN/m^3 Saturated 20.9 kN/m^3 **FS=1.01**	Unsaturated 19.7 kN/m^3 Saturated 22.3 kN/m^3 **FS=1.06**	Unsaturated 21.6 kN/m^3 Saturated 23.7 kN/m^3 **FS=1.10**
Jetty Stone Mass Shear Strength	Shear strength of the mass jetty stone is based on judgment. Most likely value is assumed to be 45° with a range between minimum and maximum values of 30° and 60°. A low value of 30° would represent poorly stacked stone that would tend to slide easily. This value is slightly lower than typical natural angle of repose for dry granular material and maybe reasonable for submerged conditions. High end represents well-stacked stones interlocking that would stand as very steep walls.	30° **FS=0.63**	45° **FS=1.06**	60° **FS=1.53**
Base Depth of Jetty (Original Depth of Water)	Most likely value is assumed to be -8 m with a range between minimum and maximum values of 6 m. Thickness of jetty stones varies with original depth of water that jetty was built on. Jetty is thinner near shore and becomes thicker as progresses in deeper water further off shore. This parameter captures the effects along the length of jetty. There is some overlap with Depth to Seabed parameter. In this model, minimum likely value (high base of jetty) is similar to having 5 m of seabed scour.	-5 m **FS=0.82** **FS=1.26 w/ debris apron**	-8 m **FS=1.06**	-11 m **FS=1.10**

Table B-1 (continued). Geometrical, Mechanical, and Hydraulic Parameters used in Analysis and Results

Parameter	Description	Adopted Range of Values & Factor of Safety		
		Minimum Likely (FS)	**Most Likely (FS)**	**Maximum Likely (FS)**
Underlying Marine Sediments Mass Weight	Most likely value is assumed to be 19.7 kN/m^3 with a range of 0.9 kN/m^3 (125 ±5 pcf). Based on typical values for unconsolidated saturated sediments.	19.7 kN/m^3 **FS=1.05**	20.6 kN/m^3 **FS=1.06**	21.4 kN/m^3 **FS=1.06**
Underlying Marine Sediments Shear Strength	Based on judgment. Most likely value is assumed to be 32° with a range of 4° - typical value and range for unconsolidated silty fine sand. There should be a correlation between underlying marine sediments mass weight and shear strength. As the density of the sediment increases the shear strength would increase.	32° **FS=1.04±**	34° **FS=1.06**	36° **FS=1.08**
Ocean Surface (Tide Level)	Most likely value is taken as 0 m with a range of 2.4 m. Most likely value represents mean sea-level and the extremes represent high and low tide conditions.	-1.2 m **FS=1.04**	0 m **FS=1.06**	1.2 m **FS=1.10**
Depth to Seabed (Current Elevation)	Most likely value is 10 m and represents the depth to base of jetty. There is some overlap of this parameter and base depth of jetty. Depth of seabed becomes deeper as scour occurs and amount of the underlying marine sediments is exposed. This parameter captures the effects of seafloor scour at any given stationing.	-5 m **FS=1.07**	-10 m **FS=1.06**	-15 m **FS=0.95**
Impact of Storm Waves	Parameter represents hydraulic impact of storm waves on stability of jetty stones. Value is very uncertain and conceptually based on estimating the differential hydraulic pressure that develops within the jetty using a simplified seepage model that accounts for transient pressure flow conditions. Estimated peak positive differential pressure (acting outward) is 1.6 m. This occurs during rapid wave recession of water as it drains. Conceptually, greatest pressure may not correspond to highest wave but would occur during a rapid recession following a long period of high water such that may occur with two interfering wave patterns with two waves nearly coinciding in time. This could result in longer period of time to drive water into the jetty that fills more voids. This larger quantity of water cannot drain in the short period during a rapid recession and, thus, result in higher differential pressure.	0 m **FS=1.44** (Instant free-draining)	0.8 m **FS=1.06** (0.5 x estimated hydraulic pressure due to 32 foot maximum wave)	1.6 m **FS=0.53** (Estimated hydraulic differential pressure due to maximum wave)

Sensitivity Analysis

Figure 3

Transient internal hydraulic effects of wave impact may be the most important parameter in the stability of the jetties. However, it is the least certain of all of the parameters. Internal hydraulic pressures in jetties have not been measured. In addition, it is extremely difficult to model, as there is nothing to calibrate a model against. Intuitively, period of excess pore pressure acting outwards occur during the period of most rapid wave recession. Slower wave recession or smaller waves do not generate as large of excess pressures. Stability analysis indicates that the outer layer of stones is least stable (shallow failure planes) with factors of safety dropping significantly below one (below point of stable equilibrium). Even though a factor of stability of less than one indicates that a stone can move, other factors are involved such as interaction with neighboring stable stones. Once all of the conditions are met, a stone will begin to move. However, movement may be restricted to a short period when factor of safety is less than one and all other conditions are met. Consequently, because of the large mass and inertia of a stone, it may only move a small amount before it comes to rest. Therefore, failure may be more in the form of gradual "walking" of the stone out of position and slow degradation of the jetty during periods of intense wave activity. Once one stone is removed, the neighboring stones may become less stable and susceptible to movement. Stones would accumulate at the toe and, thus, flatten the lower submerged slope of the jetty. Once a stone or layer is removed then hydraulic forces will increase their effects on to the exposed deeper stones. This may lead to continued progressive erosion and degradation of the upper or exposed portion of the jetty.

The second major factor is the shear strength of the mass of jetty stones. This factor represents the stone shape and how well stones are placed. Zones of low mass shear strength can occur where individual stones may form a smooth outward sloping surface or internal plane due to the way stones were placed. Internal planes may result from placing stones on a previously eroded and repaired erosion surface with little interlocking between the new stones and the older mass. Failure again would probably be progressive with small incremental movements occurring during recession of storm waves. Conceptually, continued movement of stones will gradually flatten the slope, which would result in slowing and self-arresting of failure by this mechanism.

The third major factor is scour of the sediments at the toe of the jetty. Analyses suggest that 5 meters of scour will decrease factor of safety sufficiently to lead to failure of 1.5H to 1V slopes. However, most slopes below the water surface are flatter than this and, consequently, this may not be as important of a factor as the analyses suggest. Analyses suggest that the lower toe of the slope where sediments have been exposed are most susceptible. Failures tend to daylight at the toe of the slope. Hence, a short apron of stone placed as preventative measure or as the result of movement and accumulation of moved stones would reduce the risk of this failure mechanism.

4. STONE REQUIREMENTS

Stones to be utilized for repair for the MCR jetties will need to meet the Portland District's minimum requirements for jetty stone as shown in Table B-2. Supplemental test requirements that may be required by the Government based on visual analysis also are shown in the table. Laboratory test data, or service records from previous contracts, will be necessary for approval. The largest hurdles for quarries to pass for providing stones for this job will be the size of the stones required. Depending on the repair templates for various reaches on each of the jetties, stone gradation will range from 5 to over 40 tons. Due to increased wave climate realized along the coast since original construction, larger stones will be needed to provide the necessary stability factor. Few quarries are available to produce the stone size necessary for this job. The other hurdle is the sheer volume of material required to repair the jetties. Estimates range into the millions of tons of jetty stone needed to repair the jetties to the recommended design templates.

Table B-2. Portland District Minimum Lab Testing Requirements for Jetty Stone

PRIMARY TESTS	REQUIREMENT
a) Unit Weight	Minimum of 165 lb/ft^3 but may vary per job
b) Absorption	Not more than 5.0 percent
c) Abrasion-500 revolutions	Not more than 20.0 percent loss (by weight)
d) Magnesium Sulfate Soundness -5 cycles	Not more than 15.0 percent loss (by weight)
e) Accelerated Expansion	Not more than 15.0 percent breakdown (by weight) or piece count

SUPPLEMENTAL TESTS	REQUIREMENT
f) Wetting and Drying - 80 cycles	Not more than 15.0 percent loss (by weight)
g) Freezing/Thawing - 100 cycles	Not more than 15.0 percent loss (by weight)
h) Petrographic Examination	Absence of weakness or materials that could result in significant stone alteration and reduction in durability
i) X-Ray Analysis (Spectrographic and Diffraction)	Absence of deleterious clays or other minerals that could result in significant deterioration of rock quality

It has been observed that armor stone damage through time has not been an issue relating to jetty damage. Portland District has strict armor stone quality requirements that have been in place for more than 50 years which provide for a more durable stone in the coastal environment. The very nature of the stones, being volcanic and metamorphic, has been demonstrated through time on the jetties as not being susceptible to much wear or breakage. Most existing broken stones found on the jetties were damaged during original placement with very little additional damage noted in later years. Broken stones account for probably less than 1% of the total jetty volume and do not impact the overall structural integrity of the jetty. Wear depends on the particular stone used and where in the template it is used (lower slope vs. crest). Most stones conforming to the 50-year old test requirements show minor wear to the point that they don’t impact the interlocking or cohesive nature of the jetties. A large percentage of the stones used during the original construction of the MCR jetties conformed to these current quality standards and are still performing adequately to this date.

5. QUARRY MARKET SURVEY

A quarry market survey was undertaken to help identify potential quarries that could supply stone for the jetty repairs. The primary purpose of this study was to identify potential quarries that have the capability to produce large-sized jettystone for upcoming jetty rehab work. With a projected 1.3 million tons of stone required for both North and South jetties and Jetty A, significant investigations will be required by the Government to verify that sufficient quantities of stone exist and are capable of being mined for full stone repair alternatives. The survey consisted of contacting potential stone suppliers in the anticipated market from Oregon, Washington, northern California, and southern British Columbia, usually within 200 miles of the Pacific Coast as identified in Figure B-14. Owners were questioned about their rock sources concerning the size of stone able to be produced from the quarries, type of rock, laboratory testing done, size of quarry and potential minable reserves. A few of the larger potential quarries that had not been previously visited were then investigated for the potential to produce stones for these repairs. Based on the large amount of stone needed for the repairs, it is anticipated that no single quarry will be used for producing the amount of material we’ve identified, but more likely a combination of quarries over multiple years will be necessary to produce the stone required in the timeframe needed.

Stone Sources for Jetty Repairs

Given the large amount of stone required for rebuilding the jetties, it is conceivable that several quarries may be utilized to produce and deliver the amount of stone needed within the time frame required. The majority of stone may likely be supplied by sources in northwestern Washington or one or more of several potential sources that exist in Canada, on or adjacent to Vancouver Island in British Columbia. Smaller amounts of stone may also be supplied by any number of local sources in Oregon and Washington within 100 miles of the MCR jetties, and by quarries near Eureka in northern California. Only quarries actually investigated for this study, or visited by Portland District personnel in the past, are presented here. Locations of the quarries discussed in the following sections are shown on Figure B-15 and described in Table B-3.

Figure B-14. Potential Quarry Areas by Region

Northern Washington Stone Sources

Stone sources used for the project that are located west of the Cascade Mountains and north of Seattle would exist and be permitted quarries. It is also possible that permitted but undeveloped rock sources may be utilized for stone. This would come into play especially if a stone supply contract were awarded for multiple years to produce jetty stone. The Contractor may have an undeveloped stone source that he may develop especially for this work. Most of these quarries would likely be located within 50 miles of Puget Sound. Known quarries that have likely potential to supply stone for the repairs are listed below.

Beaver Lake Quarry. The Beaver Lake Quarry is located just east of Mt. Vernon in Skagit Co, WA. It is leased by Meridian Aggregate which primarily produces crushed aggregate for Forest Service access roads. This quarry was used by the USACE Contractor Kiewit in 2001 for the Yaquina North Jetty Repairs and produced approximately 33,700 tons of jetty stone for that Interim Repair Contract. Kiewit had approximately a 20% yield for usable material during these mining operations. The quarry is a rock monolith located in an outwash plain left from the last Ice Age, which ended around 10,000 years ago. Continental glaciers stripped off the overburden and any surrounding softer material, leaving only the more hard material in place. The rock was originally volcanic in origin, probably a pillow basalt, that was metamorphosed into a greenstone, or metabasalt. Rock conforms to all Portland District standards and has a unit weight of 180 lbs/ft^3. The rock monolith is quite massively jointed which tend to produce large sized material. There seems to be at least 3 main joint sets running through the rock body. These occur at intersecting angles, which tends to create stones with a blocky shape. Joint spacing appears to be quite variable, ranging from 3 feet to over 20 feet. Additional work, such as splitting, is required in many instances to obtain the sizes necessary.

As of 2006, the remaining intact rock body has approximate dimensions of 600 feet by 300 feet long through this base section and averages about 75 feet high above the ground surface. The waste rock from all mining operations has been pushed over the south and east faces of the rock body. Based on the dimensions of the remaining rock body, plus knowledge from the reclamation plan that mining will occur to one lift below the ground surface, estimated at 40 feet, total remaining in-place reserves are guesstimated to be 1.86 M tons. If the achieved 20% yield is applied, an estimated 370,000 tons of jettystones are still available for use from this quarry. Stones from this quarry that were utilized at Portland District jetties were hauled approximately 26 miles by truck to Anacortes where they were loaded on barges and shipped down the coastline.

Marblemount Quarry. The Marblemount Quarry is located approximately 5 miles west of the North Cascades National Park near Rockport, in Skagit County, WA. The existing quarry actually occurs in a talus slope at the base of a 400-foot high cliff. There is an estimated 800,000 cubic yards of material present at the base of the cliff. Many large sizes of rocks are present in the slope with occasional rocks to over 200 tons visible. Rocks tend to break big with many sizes greater than 10 tons present in the stockpile. Actual percentage of large sizes present in the talus slope is not known at this time, but it appears to be quite high. A small portion of the talus slope has been mined for the production of rip rap in years past. No estimate on how much material has been removed so far, but it has only made a small dent in the total amount. The rock cliff is near vertical and extends approximately 400 feet high from the base of the quarry floor. The cliff extends along the entire front of the 38 acre parcel which is calculated to be approximately 1300 feet long. The owner indicated a cat road has been built up to the top of the cliff from the west side, but little work has been done up there. No blasting has ever been conducted at the site, as more than enough material is present in the talus slope for current uses. Examination of the cliff face shows that the rock is massive and will tend to break into large sizes.

Petrographic analysis has not been performed on this material; however, the rock appears to be a metavolcanic breccia. The rock has a greenish color, due to alteration of feldspar minerals to the mineral chlorite. Some relict structure is still present. The rock is fresh and hard. Material from this quarry has been tested and passed all Portland District standards. Rocks have a unit weight of almost 190 lbs/ft^3. Stone from this quarry has never been used as jettystone, but was used at one time by local agencies for riprap along the Skagit River before it was classified as a Wild and Scenic River. Haul distance to the nearest barge on-loading site in Anacortes is about 67 miles one way.

Iron Mountain Quarry. The Iron Mountain Quarry is located just outside of Granite Falls, which is approximately 15 miles NE of Everett, WA. This is a large quarry that has been in operation since the1980s. The quarry owns part of the land and also has a lease with Weyerhaeuser for the remaining portion. The quarry is approximately 500 acres in size. The quarry is active and produces a variety of material sizes ranging from crushed aggregate through riprap. Larger stone sizes exceeding 15 tons are capable of being produced. The quarry is located on a large hill and contains multiple areas being mined. Jettystone sizes were observed in oversized stockpiles present on the top of the quarry. Rock consists of metamorphosed sedimentary rock with remnant bedding very visible in the quarry and mined stones. Variability of visible rock characteristics does exist within the quarry; however, stones appear to have similar engineering properties. The rock was tested to Portland District standards in 2005 and passed all tests. Stones weigh approximately 170 lbs/ft^3. This stone has been used by Seattle District for some of their projects and has performed satisfactorily. Minable reserves have been estimated to exceed 30 million tons. Stones would likely be trucked directly to the jetties, but may be on-loaded to a barge facility in the vicinity of Everett, WA, within 20 miles of the quarry.

Southern Washington Stone Sources

Rock sources in southern Washington would primarily be existing quarries with the possibility of permitted, but undeveloped rock sources being opened up to supply some of the large amount of stone necessary for construction. Stone sources would most likely be distributed east of I-5 closer to the Cascade Range, but selected deposits, especially intrusive bodies, may occur at any location within the region. Here again, most quarries will be west of the Cascade Range.

Columbia Granite Quarry. The Columbia Granite Quarry is located approximately 10 air miles southeast of Tenino, Washington. The quarry, located on Weyerhaeuser land, has a long history of use when it was known as the Skookumchuck Quarry, but had been inactive from the late 1940's until the late 1990's when it was purchased by private sources. Stones from this quarry have been used by Portland District on the Columbia River North Jetty, Jetty A, and Yaquina North Jetty, MCR North Jetty, and by Seattle District for rehabilitating the jetties at Westport, WA. This quarry has been developed in a large intrusive sill and consists of rock described as both a gabbro porphyry and a diorite. It is uniform medium-dark gray, medium crystalline, fresh, and hard. Little variation in composition or surface expression exists within the quarry. This quarry has massive jointing characteristics which give the capability to produce large stone sizes with a shape conducive to facilitate good interlocking. The stone tends to break in tabular shapes, due to the intersecting nature of the jointing. When specialized blasting techniques are applied, a very high yield can be achieved. This stone also has the characteristic of being able to resist abrasion, which creates a higher coefficient of friction on the surfaces, and also tends to hold the shape better in a marine environment through time. Rock from this quarry has been tested at approximately 168 lbs/ft^3 and meets all of the Portland District standards. Minable reserves have been estimated to be approximately 28 million tons, with adjacent properties containing even more amounts. Stones would be trucked directly to the jetties, or to a barge loading facility in Aberdeen, WA for transport down the coast.

Fisher Quarry. Fisher Quarry is located approximately 3 miles west of Camas, Washington, adjacent to the Columbia River. CEMEX USA owns the property. The quarry is presently active and produces a variety of crushed aggregate and riprap sizes. Stones from this large quarry have been used on many of Portland District's jetties, both during original construction and in subsequent repairs. Quarrying operations have continued continuously for over 100 years. The quarry is developed in a thick andesitic basalt lava flow and produces rock with a unit weight of around 168 lbs/ft^3. Stone quality is quite consistent in this quarry. Stone shape varies depending on where in the quarry the stone is mined. Some areas, especially near the volcanic vents present in the quarry are platier, which produces a more tabular shape, where other areas will produce stone with a more equidimensional shape.

Remaining reserves for this quarry have been estimated at 2 million tons. Quantities, however, are limited for large rock production, and this quarry is considered to only be able to produce a small portion of the overall quantity of stone necessary. Essentially, stone contained in the outer margins or the northern rim of the quarry comprise the remaining resources for most of the jettystone. Rock from this quarry meets all of the Portland District's quality standards. Fisher Quarry has a private barge loading facility located just across the highway from the quarry on the Columbia River, and is located approximately 116 river miles upstream from the MCR.

192nd Street Quarry. This quarry is located immediately east of the Fisher Quarry, approximately 3 miles west of Camas, WA. The property is now owned by Sierra Pacific Communities, which recently bought it from the State of Washington. It is currently the site of the new 192nd Street Interchange which has recently been built through the quarry. Prior to that, a lease agreement with the operators of the Fisher Quarry existed from the mid-1960's to 1986 during which time both quarries were operated collectively under the Fisher Quarry name. This quarry has produced jettystone for many of the jetties in the past while under the Fisher Quarry name. The quarry is developed in the same lava flow as the Fisher Quarry and the rock weighs approximately 168 lbs/ft^3. As with the Fisher Quarry, large jettystone production is limited to along the margins of the quarry. Stone shape is the same as for the Fisher Quarry, and varies depending on where in the quarry the stone is mined. The quarry is estimated to contain 5-7 million tons of reserves, however, only a portion of this is available for producing jettystones. Quarry Direct Stone Sales, Inc., the company hired to manage the mineral resources, has been directed to move a half million tons of material by the year 2011, and are interested in possibly supplying large stone for upcoming jetty jobs. No barge loading facilities are currently available to the operator. Either a deal would have to be made with Fisher Quarry to utilize their existing loading facility, or another facility would have to be found.

Phipps Quarry. The Phipps Quarry is located on Weyerhaeuser land in the Hollywood Gorge area east of Castle Rock, in Cowlitz County, WA. The quarry is leased by Tapani Underground, Inc., which acquired it for use on the MCR North Jetty repairs in 2005. The quarry appears to be founded in a large diabase sill on a logged off hillside. The sill is estimated to be at least 130 feet thick and has intruded pre-existing sedimentary rocks, some of which contain coal seams. The top contact of the rock body is exposed in some places. Very little overburden is present on much of the surface, but the thickness increases as you proceed into the hillside. The area encompasses several acres, and includes reserves estimated at 11 million tons. The stone is very hard in places, blocky and angular, except for the margins of the rock body where platy jointing is present. Variability in stone size exists within the quarry with some areas being able to produce stones larger than 20 tons. Some iron stained joints are present on mined stones, but this is primarily surficial and doesn't affect the overall quality of the stone. The stone has passed all Portland District standards and weighs approximately 167 lbs/ft^3. This stone has been used by Seattle District for the Ocean Shores jetties, and Portland District has used this source for repairs to the MCR North Jetty in 2005. Stone from this quarry would most likely be trucked the entire distance to the jetties, estimated to be approximately 75 miles.

Northern Oregon Sources

Northern Oregon stone sources would probably be existing active quarries. Few quarries with any substantial reserves located within 50 miles of the MCR jetties have the capability to produce large-sized stones that would be acceptable for use in jetty repairs. Many of these sources can produce a few large stones and these are usually incidental to their normal operations. Many times the quarries will temporarily set aside these stones to be broken up into more manageable sizes later. Due to the close proximity of the quarries to the repair sites, it may be economically feasible to transport these few existing stones from these quarries, as a way to supplement the total amount required. Some sources may also occur as far away as the Cascade Range. Stone sources at this distance may need to have a larger supply of existing large stone on hand to make it economical to move sorting and loading equipment on site. The following quarry is included as a potential source due to the close proximity to the MCR jetties.

Young's River Falls Quarry. The Young's River Falls or Drake Quarry is located adjacent to the upper end of Young's Bay, south of Astoria, OR. It is located on Weyerhaeuser property and is currently leased by Big River Excavating. The quarry is founded in a basaltic dike that is part of a ring dike structure found in the area. The quarry was originally opened in 1960 for repairs to the MCR South Jetty. It has also been used in 1976 for the Hammond Boat Basin breakwater and the interim repair contracts for the MCR North Jetty in 2005 and South Jetty in 2006 and 2007. The rock is a medium gray, medium to coarsely crystalline diabase. Jointing varies between 2 and 5 feet which tend to create stones that are long and slabby. Most stone surfaces are angular with the exception of those stones mined close to the weathered margins of the dike. Many stones have some iron stained surfaces that do not detract from the overall engineering properties of the rock. The rock has passed all Portland District lab tests for jettystone and weighs approximately 182 lbs/ft^3. This quarry is located about 20 miles from the MCR South Jetty.

Southern Oregon Sources

There is a smaller likelihood that stones may be utilized from this area for upcoming MCR jetty repairs. The reason for this is that most quarries in this area that can produce large stones are smaller quarries located at some distance away from jetty repair areas, as well as at larger distances from barge on-loading facilities. These stone sources are most likely to be active, permitted quarries with known capability of producing large stone. Many quarries that fall within this area are located near the coast; however, a few quarries are also present closer to the I-5 corridor. The quarries closer to I-5 are less attractive due to the large distance required to transport the stone to the MCR jetties. Quarries that have been visited by Portland District personnel that could potentially be included are identified below.

Baker Creek Quarry. The Baker Creek Quarry is located just west of the town of Powers, OR, about 70 miles southwest of Coos Bay. The quarry is owned and operated by the BLM, Coos Bay District. This quarry contains very dense and very hard metamorphic rock on the order of 200 lbs/ft^3. This quarry was utilized for the repair of the Coos Bay South Jetty in 1963-64. The quarry is currently permitted for utilizing stone for road base, but environmental assessments need to be completed and filed prior to any major mining. This quarry has the capability of providing large size stone. Jointing characteristics present in this quarry will produce stones of a more tabular shape. The stone is also very hard and durable, but is also hard on quarrying and handling equipment. Stone from this quarry would likely be hauled by truck to a potential barge loading facility in Coos Bay for further transport to the jetties. Reserve quantities are unknown at this time. Even though this quarry is small in nature and quite some distance from a barge on-loading facility, due to the high density of the stone, it could potentially be an important source of stone for the repairs.

Bankus Quarry. The Bankus Quarry is located approximately 7 miles east of Brookings, OR just north of the Chetco River. The quarry is owned by South Coast Lumber Co. and has been in operation since the late 1950s. The quarry has produced jettystone for the Chetco River Jetties in 1958, 1963, and 1995. Stones were also produced in 1981 or 1982 for use at the Crescent City, California jetties. The quarry operation is divided into 2 areas. The quarry is located in the remnant of an exposed knob of rock located on a hillside. Most of the knob exposed above ground has been excavated, with only the back portion of the present lift located within the hillside remaining. Overburden has been only partially removed along the back side of the remaining lift. The quarrying operation started on the east side of the rock body and has proceeded west. A stockpile area containing jettystones is located to the north of the quarry in an unprepared area just south of a creek. A large quarry floor is present to the east of the quarry face. The floor measures approximately 250 feet long and perhaps 200 feet wide. A fairly large stockpile area is associated with this quarry, located in an undeveloped area to the north of the quarry and extending to an east-flowing creek. Stones produced for various jobs have ranged in size from 10 to 25 tons. The quarry has the potential to produce additional stones within the range of 15 tons to over 25 tons, based on jointing observed in the quarry face.

The rock present in this quarry is a fine to medium crystalline metavolcanic rock that has been brecciated and subsequently healed with green mineral seams. The mineral seams do not control rock breakage. It is medium gray-green in color, primarily fine grained with coarser crystalline clasts visible. The rock is fresh, hard, dense, and pit quality. Abundant seams of quartz are present along joint seams. Also present are small amounts of calcite, pyrite, and muscovite. The rock mass is fairly uniform in composition but some variation does exist in color and grain size. Two distinct colors of rocks were mined from this quarry for the Chetco South Jetty repairs in 1995. Samples selected during this contract were found to be of two separate unit weights.

The quarry face has a somewhat blocky appearance due to the intersection of joint sets. Three primary joint sets are present in the quarry face; one parallel to the quarry face, one set vertical and perpendicular to the quarry face, and one set parallel to the quarry floor. Most of the joints are tight and fresh, but many have been opened as a result of blasting. Open joints exposed to water have a stained surface, primarily limited to less than 1/4 inch. Joint spacing is variable and ranges from 2 to 10 feet. The stones in the stockpile tend to be quite irregular to rhombic in shape. The axes of the stones are pretty much equidimensional as opposed to being elongated in one direction. Most stones have at least two sharp edges created by intersecting joints, with other edges being somewhat rounded.

Laboratory tests were run by the Northwestern Division Materials Laboratory in June of 1982. A lighter colored stone weighed out at approximately 183 lbs/cu ft. and a darker colored variety weighed out at 195 lbs/cu ft. Results of tests performed indicated specific gravity was 2.85 (177.6 pcf). The LA abrasion test resulted in a 9.2% loss at 500 revolutions. Absorption was 0.8%. Accelerated expansion by immersion in ethylene glycol gave no action.

An additional rock body was available for mining immediately adjacent to the Bankus Quarry. This rock body, indicated by a large, mostly vegetated hill approximately 200 feet in diameter and 100 feet high based on the present quarry floor elevation, is located just northwest of the existing quarry and just west of the stockpile area. A creek flows on the north side of the rock body. This additional source is not covered by the existing permit. The owners are going to go through the permitting process to have it included. A representative from DOGAMI has looked at this site and indicated that it should not be a problem to have it included. The rock body supposedly contains the same rock material as the Bankus Quarry. If all the above assumptions hold true, this would allow for additional reserves to be developed.

Reserve quantity estimates for this rock source are based on both the existing quarry exposures as well as the adjacent additional rock source. A conservative estimate of reserves in this quarry is 270,000 cubic yards of material. Material from this quarry would likely be trucked to a suitable barge loading facility, perhaps in Crescent City, for transport up the coastline to the MCR jetties. Even though this quarry is small in nature and quite some distance from a barge on-loading facility, due to the high density of the stone, it could potentially be an important source of stone for the repairs.

Northern California Sources

Stones produced from northern California quarries have been utilized for jetty repair on the northern Oregon coast in the past. Stones from these, as well as other quarries in the area are still being produced. The quarries to be utilized for this work are primarily permitted, existing quarries that have proven capability to produce large stone. Most of the known quarries that have produced large stone in this area are located near the coast within about 20 miles of Eureka. The only larger quarry visited by NWP personnel is listed below.

Liscom Hill Quarry. The Liscom Hill Quarry is located approximately 8 miles east of Arcata, California, north of Eureka. The quarry is near the top of a fairly steep grade and is owned by Simpson Timber Co. The quarry is presently leased by Mr. Art Tonkin of Tonkin Construction Co. Stones from this quarry were used in the 1991 repair of the Tillamook North Jetty. Haul distance from the quarry to the barge facility in Eureka, CA is about 18.5 miles. This quarry was last visited by Portland District personnel in 1993.

The quarry operation is divided into 2 areas. The quarry is located in the remnants of an exposed knob of rock located on a hillside near the top of a ridge. Most of the knob exposed above ground has been excavated, with only a small corner remaining. A stockpile area is located lower on the hillside, below and west of the quarry. A bench of tailings or waste rock is present between the quarry floor and the stockpile area. This bench is about 15 feet above the quarry floor and is approximately 300 feet long (from the stockpile East to the quarry floor) by 200 feet wide (parallel to the quarry face). The bench is presently used as a staging area for the quarrying operation. The quarry has been excavated in lifts with the back of the present quarry floor now below ground level. Overburden is still present on the back and side margins of the quarry. The hillside slopes bordering the quarry have been flattened to an approximate 1V on 1H slope. The boundary between the bench and the quarry floor is the approximate western boundary of the rock body. The quarry floor dimensions are approximately 300 feet long by 250 feet wide. Rock body dimensions at the quarry floor are approximately 300 feet in diameter.

The quarry face is located on the north side of the quarry floor in the remaining rock mass comprising the present lift. The quarry face is triangular in elevation view and is rectangular to somewhat convex-shaped in plan view, generally facing west and south. The quarry face dimensions are approximately 50 feet high by 50 feet long on a side. The intact rock body appears to extend only an additional 50 feet behind the quarry face. The quarry face has a blocky appearance due to the presence of 2 prominent joint sets. Overburden consists of residual soil from surrounding rocks which incorporates the pod. Overburden is present along the quarry margins adjacent to the hillside. Water is present on the quarry floor. This appears to be surface water collected into shallow ponds as no springs are evident in the quarry limits. Groundwater is probably present in the area, however, as a drainage ditch present on the north side of the quarry operations leading from the quarry floor area does contain a small amount of running water.

A large stockpile area is associated with this quarry, located lower on the hillside to the west of the quarry and is primarily built on waste rock from the quarrying operation. Stockpile dimensions are approximately 450 feet long by 200 feet wide. The western edge of the tailings bench forms the eastern side of the stockpile area.

The rock present in this quarry is a metavolcanic breccia. It is medium-dark gray-green in color, primarily fine grained with occasional medium grained clasts visible. The rock is fresh, hard, dense, and pit quality. A chlorite mineral is present on some joint surfaces. Open fractures are stained yellow-orange. Occasional quartz, feldspar, and blebs of pyrite are present. The rock mass is fairly uniform in composition but some variation does exist in color and grain size.

The quarry face has a somewhat blocky appearance due to the intersection of joint sets. Two prominent joint sets are present in the remaining lift. The surfaces of these joint sets range from fresh to stained, depending on tightness of the joints. Many of the tight joints opened by blasting or excavation have a coating of a chlorite mineral. Open joints exposed to water have a stained surface, generally limited to less than 1/4-inch. Joint spacing ranges from 1 foot to greater than 5 feet for each joint set. A few discontinuous, incipient joints are present, primarily opened by blasting and excavation.

The stones in the stockpile tend to be quite irregular to rhombic in shape. The axes of the stones are pretty much equidimensional as opposed to being elongated in one direction. At least one surface on

most stones has a stained weathered surface of an open joint or an opened joint containing a chlorite mineral.
Laboratory tests were run by the Northwestern Division Materials Laboratory in March 1991 for stone to be used on the Tillamook North Jetty repair. Tests indicated specific gravity was 2.87 (179 pcf). The LA abrasion test resulted in a 7.7% loss at 500 revolutions. Absorption was 0.4%. Accelerated expansion by immersion in ethylene glycol gave no action. The quarry has the capability to produce additional stones within the range of 15 tons to over 25 tons, based primarily on stones present in the stockpile. Recovery rate for large stones was estimated by Mr. Tonkin, who is presently leasing the quarry, to be 15%-20%.

Canadian Sources

Several sources have been identified in southwest British Columbia adjacent to Vancouver Island. Many quarries are present on smaller islands in the Straits of Georgia east of Vancouver Island and in the terrain east of Vancouver. These are all existing quarries that are currently operating and producing stone, primarily granitic in nature. These quarries predominantly have large reserves and have the potential to supply large stones. The following quarries were inspected by Portland District personnel in 2006. Other prospects have since been identified but as of yet, not been permitted or inspected.

Texada Island Quarry. The quarry is located approximately 2 miles north of Gillies Bay on the western side of Texada Island, BC, between the Canada mainland and Vancouver Island. The quarry is owned by Lafarge North America and is operated by Texada Quarrying Ltd. This quarry is one of the largest in Canada, supplying primarily limestone products to various markets. The property was originally developed as a limestone quarry with production beginning in 1945. The magnetite skarn mineralization was developed and mined starting in 1952 in the form of 4 mines. These started out as open pit mines but eventually went underground to go deeper. A headshaft was sunken 850 feet into granitics and the ore body has since been mined out. The limestone portion of the quarry is 325 acres and produces a variety of limestone grades, including a pure calcium form for cement production, chemical and agricultural grades, as well as crushed aggregate and riprap. There isn’t much market for the granitic rock at this time; however, the company is interested in developing the granite resource as well. The quarry property comprises a total of 2,500 acres. The granitic intrusion has an estimated 250 million tons of mineable reserves.

The granite portion of the quarry is located on the west side of Texada Island. The granite extends from the water level to the top of the hills adjacent to the shoreline in the vicinity of three of the four existing iron mine excavations in the area. To date there has been limited mining of the granite stone, primarily on the southern portion of the intrusion. Quarrying operations in the granite were mostly associated with the mining of the iron mines. In each instance, the iron mines have been excavated back in the hillside around the mine. The character of the rock in the excavated areas appears to be heavily fractured due to blasting of the ore body; however, some massive areas are present as well. Outcrops of rock both in the excavation as well as adjacent to the mining operations reveal a more massive appearance and are probably more characteristic of rock in the area. Based on observations of jointing in these outcrops, it appears that large stone sizes could be produced. It is known from mining operations that the granite body extends at least 850 feet below sea level. Adequate areas are present for stockpiling of stone as well as storage of waste rock. Overburden is very shallow in all areas.

The granitic rock present in this quarry is classified as either a granodiorite or quartz monzonite. The granite types tend to be a light gray to pinkish gray in color. All are predominantly fresh, hard, and dense. Diorite dikes found in the limestone quarry are light greenish- gray in color and are of medium crystallinity. It also is fresh, hard, and dense. All types of rock present seem to have similar engineering properties.

No stockpiles of granite stones were available to see what shapes were produced from quarrying operations. Intersecting joint sets observed in outcroppings indicates that blocky to tabular shapes would most likely be produced, but also irregular shaped stones would also be produced. Diorite dike stones present in the limestone quarry tended to have a blocky shape due to the intersecting joint sets, but there were also irregular shaped stones present as well.

The quarry has the capability to produce granitic stones within the gradation of 2 tons to over 40 tons in size, based primarily on jointing observed in outcrops and mine excavations. Jointing in the rock mass, as described above, indicates that the capability to produce stones greater than 30 tons exists. The quarry has never conducted blasting tests to determine what sizes or yield would be available if actually mining for large stones. True yield would be known only if blasting were carried out to create the larger sizes. The quarry is very large and has large resources available for production of granitic stone without impacting its current production levels. The quarry lacks equipment capable of efficiently handling large stones, but would be willing to acquire that equipment for stone production.

Specific laboratory tests have been run by the quarry reportedly to Portland District standards. The quarry’s laboratory is located onsite, and ran tests specifically on the granitic stones. The lab is not a USACE validated laboratory, so it is not known if actual modified ASTM tests used by Portland District were run. All required tests were run and the unit weight of the stone varied between 173.5 and 193 pcf. Samples will need to be taken of the various materials from this quarry and will be tested to Portland District standards to verify results.

The quarry is located immediately adjacent to water on the west side of Texada Island. Water is deep at this location and a deep draft barge loading facility is present on site. The quarry regularly loads and ships material on ocean-going barges. The granite body to be mined is located near shore as well, so minimal hauling of stone would be required to load onto a barge.

Stave Lakes Quarry. The quarry is located approximately 45 miles east of Vancouver, BC and about 6 miles north of the District of Mission. The quarry is owned by Barry Holmes, who permitted the quarry in 1992 and developed it shortly after. The quarry property is 72 acres in size, permitted for 67 million metric tons of material, and is all mineable except for 6 acres. The quarry is located on the north side of the Fraser River on the east flank of a series of north-south-trending hills. The quarry operation originally started at the base of the hill, immediately behind the existing scale shack. This had limited storage space, so mining operations were developed at the crest of the hill in a flatter bench area. Mining is currently taking place only in this area. The quarry occupies a space of approximately 5 acres where mining occurs on several faces and benches. Rock appears to be fairly massive in both locations and should have the capability to produce large jettystones with a decent yield. Development in the upper quarry area has proceeded to where the thin layer of overburden has been stripped and benches have been excavated starting at the top and working down, which will be developed back into the hillside. Rock in some of these areas is more massive in nature, but joints and fractures are present that tend to limit the sizes and amounts of large stones that can be produced. The quarry plan is to develop the upper portion back into the hillside as far as the permit boundary, then bench down to the level of the lower quarry floor. A berm must be left in place between the quarry and the road to the east, so residents will be less affected by quarrying operations. The only holes drilled in the quarry area were for water monitoring purposes. It is not known how deep those holes were drilled, or details of the rock properties, but granite was encountered to full depth.

The rock present in this quarry is variable in nature but is all granitic in character. Most types fall into a granite, granodiorite, quartz diorite or gabbro rock classification. Rock varies in color but most are predominantly light gray to pink. The quartz diorite and granite are coarsely crystalline while the gabbro and granodiorite are predominantly fine to medium crystalline. All are predominantly fresh, hard, and dense. All types of rock present seem to have similar engineering properties.

Jointing is variable within the quarry with some areas being more massive than others. Three main joint sets are present with the principle joints intersecting at near right angles to produce a blocky-shaped stone. There are also lesser joints of various angles with variable spacing that control the shape of stones and tend to limit sizes in many places. Sheeting joints, or areas of multiple close-spaced parallel jointing, are present in some places that are parallel to the ground surface and usually occur near the top of the rock body. Jointing varies in width but substantial areas exist with joint spacing exceeding 7 feet in width. Areas observed within the upper quarry that have this wider joint spacing occur in the western upper bench, as well as the lower eastern bench area. The lower quarry area at the bottom of the hill near the scale shack also appears to have a wider joint spacing. Exposed outcrops show that jointing can exceed an estimated 5 feet in width, which will help to produce larger stones. This indicates that there is the potential for wider joints through the entire mineable rock body. The joint surfaces appear to be primarily fresh and tight with no obvious signs of staining. The general exception occurs in those areas near the ground surface.

Two main stockpile areas are associated with this quarry. The lower quarry area near the scale shack is a temporary storage area where material produced from the upper quarry is transported and stored. The second, and larger stockpile area, is located at the top of the hill in the active portion of the quarry. These stockpile areas are used primarily for crushed aggregate. There is a temporary stockpile of riprap and larger sizes present in the southern portion of the quarry floor. Stones in the stockpile vary in size up to greater than 6 feet in diameter. No permanent stockpiles of large material, such as jettystone sizes are present in the quarry. Large jettystone sizes are produced incidental to the blasting operation that is designed for crushed aggregate. Approximately 20 or so stones in the 10 to 30 ton range were observed on the lower and upper benches in the upper quarry. The stones present in the temporary stockpile areas tend to have a blocky shape due to the intersecting joint sets. There are also irregular shaped stones as well. Most of the larger stones observed are massive and do not contain multiple joints that tend to control the breakage of stones into smaller sizes. Most stones break along the joints rather than through the fabric of the rock.

The quarry has the capability to produce some stones within the gradation of 2 tons to over 40 tons in size, based primarily on stones present in stockpiles. Jointing in the rock mass indicates that the majority of stones that can be produced will be in the smaller size range of 5 to 20 tons. The yield on large stones will be low, limited to those areas identified with wider joint spacing. Some stones larger than 40 tons would also be produced, but at a considerably lower yield. The quarry has never conducted blasting tests to determine what sizes or yield would be available if actually mining for large stones. True yield would be known only if blasting were carried out to create the larger sizes. The quarry has the potential to greatly expand its area of production and is considered capable of making large quantities of larger sized material. The quarry owner, Barry Holmes, indicated that the quarry could easily produce 200,000 tons of rock in an 8 month period, based on 1,000 tons a day working six, 12-hour days a week. The quarry currently has no equipment to efficiently handle very large stones.

Specific laboratory tests have been run to Portland District standards on samples taken from the quarry. Test results indicated specific gravity was 2.71 (169 pcf) and absorption was 0.2%. The LA abrasion test resulted in a 12.5% loss. The sodium sulfate soundness test had 1% loss. Accelerated expansion test also showed a 1% loss. Test results show that rock from this quarry meets all Portland District quality standards.

An existing 10-acre barge loading facility is located about 6 miles south of the quarry in the District of Mission. The facility is being improved for rock transport, including jettystone sizes, down the Fraser River. At this point in time, all stone is trucked to markets. When completed, 7,000 ton barges will be able to be light loaded to 4,000 tons then transported downstream to deeper water where they can be topped off. There are no work restrictions on the barging operations. They have the ability to work 24/7. A sandbar located downstream limits the draft of shipping traffic to 12 to 15 feet during normal water. The quarry is located approximately 45 miles from the mouth of the Fraser River.

Ekset Quarry. This quarry is located approximately 45 miles east of Vancouver, BC and 5 miles north of the District of Mission. It is located just a few miles east of the Stave Lake Quarry. The quarry property is approximately 36 acres in size with an estimated 30 acres still to be mined. A rough estimate of 10 million tons of material is present within the quarry, provided that mining extends only to the level of the current quarry floor. The quarry is located on the north side of the Fraser River on the west flank of a series of north-south-trending hills. The quarry operation started at the edge of the rock body a few hundred yards from the road. The quarry is confined by 2 creeks, one on each side of the quarry, so mining has taken place between the creeks straight back into the hillside. Rock appears to have some massive jointing in areas and should have the capability to produce large jettystones. The quarry has only a west-facing face and one intermediate bench. Above the intermediate bench at the top of the quarry face, the rock body seems to be fairly flat for some distance behind the face, with trees on top. The upper portion was not accessible at the time, so no evaluation was performed. Overburden appears to be very shallow. The quarry floor is currently used for stockpiling of crushed aggregate.

The rock present in this quarry is variable in nature but is all granitic in character. Most types fall into a granite, granodiorite, quartz diorite or gabbro rock classification. Rock varies in color but most are predominantly light gray to pink. The quartz diorite and granite are coarsely crystalline while the gabbro and granodiorite are predominantly fine to medium crystalline. All are predominantly fresh, hard, and dense. All types of rock present seem to have similar engineering properties.

The quarry face has limited exposures of in-place rock due to large talus piles on the lower slope. Talus is the result of pushing blasted material from the upper bench over the lower face for easy access to the crushing operation. The visible jointing on the lower face is variable with some areas being more massive than others. Three main joint sets are present with the principle joints intersecting at near right angles to produce a blocky-shaped stone. There are also lesser joints of various angles with variable spacing that control the shape of stones and tend to limit sizes in many places. Jointing varies in width but areas exist with joint spacing exceeding 5 feet. The upper bench was not observed due to time constraints. The joint surfaces appear to be primarily fresh and tight with no obvious signs of staining. The general exception comes from those areas near the ground surface.

No stockpiles of large material, such as riprap or jettystone sizes were present in the quarry. Larger stone sizes produced incidental to the blasting operation are supposedly crushed on a regular basis. Very few larger sizes were observed in the quarry.

The quarry has the capability to produce some stones within the gradation of 2 tons to over 20 tons in size with some larger sizes also available. This is based primarily on jointing observed in the quarry face, as well as eyewitness accounts by people familiar with the quarry operations. Jointing in the rock mass, as described above, indicates that the majority of stones that can be produced will be in the smaller size range of 5 to 20 tons. The yield on large stones will be low, limited to those areas identified with wider joint spacing. Some stones up to 40 tons may also be produced, but at a considerably lower yield. The quarry has never conducted blasting tests to determine what sizes or yield would be available if actually mining for large stones. True yield would be known only if blasting were carried out to create the larger sizes. The quarry has limited potential to expand its area of production except for back into the hillside. The quarry currently has no equipment to efficiently handle very large stones.

Specific laboratory tests have been run to Portland District standards on samples taken from the quarry. Test results indicated specific gravity was 2.76 (172.2 pcf) and absorption was 0.3%. The LA abrasion test resulted in a 13% loss. The sodium sulfate soundness test had 1% loss. Accelerated expansion test also showed a 1% loss. Test results show that rock from this quarry meets all Portland District quality standards.

An existing 10-acre barge loading facility is located about 5 miles south of the quarry in the District of Mission. The facility is being improved for rock transport, including jettystone sizes, down the Fraser River. At this point in time, all stone is trucked to markets. When completed, 7,000 ton barges will be able to be light loaded to 4,000 tons then transported downstream to deeper water where they can be topped off. There are no work restrictions on the barging operations. They have the ability to work 24/7. A sandbar located downstream limits the draft of shipping traffic to 12 to 15 feet during normal water. The quarry is located approximately 45 miles from the mouth of the Fraser River.

Cox Station Quarry. The quarry is located approximately 8 miles Northeast of Abbotsford, which is about 30 miles east of Vancouver, BC. The property was originally bought in 1979 and developed in 1986 as a sand and gravel operation. The mining operation hit bedrock in 1989 and the quarry has been developed as a hard rock quarry since. The quarry originally was 450 acres in size but MS&G recently purchased an additional 150 acres adjacent to the east side of the property in Government (Crown) land. The quarry is located on the north side of Sumas Mountain. The quarry operation appears to be divided into 2 areas. The older portion of the quarry is located on the western portion of the property with the lowest bench at an elevation close to river level. Rock in this area is highly fractured and appears to have a more weathered texture, and is probably not conducive to the production of jettystones. The newer portion of the quarry, that portion developed in the newly added 150 acres, is located in the eastern portion of the property near the top of the ridge. Development is going on to strip remaining overburden and produce benches starting at the top and working down, which will be developed back into the hillside. Rock in some of these areas is more massive in nature, however is still well jointed and fractured, which limits the sizes and amounts of large stones that can be produced.

Two separate quarry faces are present within this quarry. The older quarry face is located on the western portion of the property on the north side of the hill. It has multiple benches plus a haul road located on the outer portion of the benches. This area was the first portion developed in the original

450 acres. The height of this quarry face is on the order of around 200 feet and extends to the top of the hill, which appears to be a bench, lower than much of the surrounding area,

The second quarry face is located on the far eastern portion of the property on the more newly purchased 150 acres. The quarry face is substantially higher than the other and extends to the top of a west facing ridge. Multiple high working faces are established in benches along with steep grade access roads to the top of the quarry face. Development is presently underway to create access roads with less steep slopes. Presently material is mined at the top of the hill and pushed over the edge to the bench below. Successive shifts take that material and push it to lower benches yet. Overburden is very shallow and only exceeds a few feet along the tip of the hill. This is stripped and stored for later reclamation purposes and benches are being developed back into the hill for production down into the hill.

A very large stockpile area is associated with this quarry, located at the base of both quarry faces as well as a large area between the two faces. A large crushing operation is in place in this area and large stockpiles of varying sizes of crushed aggregate are in place. Much smaller stockpiles of riprap and smaller sized material are also present. Most of this stone is 2-feet in diameter or smaller and is used for specialty work. No permanent stockpiles of large material, such as jettystone sizes are present in the quarry. Large jettystone sizes are produced incidental to the blasting operation which is designed for crushed aggregate. Most of these stones are present on the production benches and are usually broken down into more manageable sizes for the crushing operation. Approximately 20 or so stones in the 10 to 20 ton range were observed on a production bench near the top of the east side quarry face.

The rock present in this quarry is variable in nature but is all granitic in character. Most types fall into a granite, granodiorite, or diorite. Rock varies in color but much of it takes on a pinkish color due to the presence of the feldspar orthoclase. Quartz, biotite and hornblende are also present. The rock is coarsely crystalline and is predominantly fresh, hard, and dense. All types of rock present seem to have similar engineering properties.

Jointing varies greatly within the two quarry faces. The western quarry face has multiple, close-spaced jointing. Joint spacing varies and is hard to distinguish in places due to heavy blasting that takes place to produce the small sizes for the crusher. The east quarry face has an overall wider joint spacing, but has more variability. There are specific areas that have been identified in the east quarry face that lend themselves to producing larger sizes. Major joint spacing in these areas can exceed 5 feet, but smaller, less prominent and somewhat incipient jointing occurs in many places between these larger joint sets. Joint sets are generally at near right angles to each other which tend to produce tabular and blocky shapes. Irregular shapes are produced as well. The joint surfaces appear to be primarily fresh and tight with no obvious signs of staining. The general exception comes from those areas near the ground surface. The stones present in the smaller riprap stockpiles tend to be blocky and tabular. This is due to the intersecting joint sets. There are also irregular shaped stones as well. Some of the larger stones contain multiple joints within the stone. These are mostly tight and hold together well. Most stones break along the joints rather than through the fabric of the rock.

Specific laboratory tests have been run by Portland District to current jettystone standards. Tests indicated specific gravity was 2.69 (167.9 pcf). The LA abrasion test resulted in a 9.4% loss at 500 revolutions. Absorption averaged around 0.5%. The sodium sulfate soundness test had 1.0% loss after 5 cycles. The accelerated expansion test had a 1% loss after 15 days. This stone passed all Portland District jettystone standards.

The quarry has the capability to produce some stones within the gradation of 2 tons to over 20 tons in size, based primarily on stones present in stockpiles. Jointing in the rock mass, as described above, indicates that the majority of stones that can be produced will be in the smaller size range of 5 to 20 tons. The yield on large stones will be low, limited to those areas identified with wider joint spacing. Some stones larger than 25 tons would also be produced, but at a considerably lower yield. The quarry has never conducted blasting tests to determine what sizes or yield would be available if actually mining for large stones. True yield would be known only if blasting were carried out to create the larger sizes. The quarry is very large, considered advantageous; however, mining for larger sizes should only be conducted in areas with wider joint spacing.

Reserves are estimated at between 100 and 200 million tons within the 600 acres currently permitted for the quarry. Mining is planned down to river level, providing for many years of quarry work. Additional Crown land is also available for future quarry expansion.

A barge loading facility is present on site, and is currently scheduled for improvements to lengthen and widen the ramp to allow heavier material, such as jettystones, to be delivered onto barges. The largest barge currently loaded there is 4,000 tons. Water is consistently 35 feet deep adjacent to the quarry, and can exceed 45 feet during spring freshets, but there is a sandbar downstream that limits the draft of shipping traffic to 12 to 15 feet during normal water. The river shallows dramatically upstream of the quarry and no barge traffic goes above that point. The quarry is located 47 miles from the mouth of the Fraser River. The Canadian National (CN) railroad also runs adjacent to the river and the quarry. MS&G loads their product into railway cars (65 at a time) but at this time, CN will only allow railroad use for their own purposes.

6. STONE TRANSPORTATION ROUTES

Stone sources located within 150 miles of the MCR jetties are likely to be transported by truck directly to the jetty. Sources located at further distances, especially if they are located near waterways, are likely to transport stones by truck to a barge on-loading facility, then transport them by tug and barge to either a Government-provided or commercial barge offloading site located nearby. With the rising cost of transportation, railway may also be an option for transporting stone, provided an on-loading site is convenient to the quarry. Most railroads follow main highway arterials, such as I-5. The closest railroad terminal to the South Jetty is at Tongue Point, east of Astoria, which is about 15 miles from the jetty. The nearest railroad terminal to MCR on the north side of the Columbia River is Longview, WA. Potential stone transportation routes are identified in Figures B-16 through B-20.

Quarry Development and Production Time

No stockpiles of any appreciable size for stone of the sizes required for this Project are available at any of the quarries listed above. The larger stone sizes required translate to lower yields at the quarry than for previous jetty contracts. This means that more material needs to be quarried to supply the stone quantities required. The percent yield for these size stones varies by quarry based on jointing characteristics and quarrying techniques. Utilizing more than one quarry could reduce production time, but that is entirely the Contractor’s option. The ideal situation for construction would be to award a separate stone procurement contract prior to construction, or to award the repair contract early, allowing sufficient time for stone production prior to the summer months’ when placement would take place.

7. CONCLUSIONS

The following items highlight the key elements necessary to consider for repair of the MCR jetties with jetty stone:

a. Jetty stone of the sizes and quantities identified as necessary for repairs to the MCR jetties are available within the combined known sources in Washington, Oregon, California, and Canada. Not all of the quarries or prospects are capable of producing the quantity of stones necessary for repairs; however, some sites or a combination of sites would be able to produce sufficient quantities for contracts over a number of years.

b. Stockpiles of existing stones in the necessary large sizes are very limited. The combined stockpiles of all quarries investigated do not have the quantities necessary for repairs at this time.

c. A greater lead-time for jettystone production than normal is evident based on these investigations. The lead-time after Contract award and notice to proceed to actual delivery of the stones at the Project should be greater than 6 months. The primary reasons for this are insufficient existing stockpiles, the need for quarry development, and the difficulty of producing large stones. A possible alternate solution may be to let separated stone procurement and delivery contracts to provide a sufficient stockpile of stones onsite prior to construction.

d. Repairs will primarily be accomplished on relict stone within the original footprint of the jetty. This will provide a sound base for repairing the jetty, with no settlement or foundation disturbance taking place. There may be areas outside the footprint, primarily if spur groins, flatter side slopes, or toe berms are used, that may be founded on sand deposits. These areas need to have a bedding layer of stone place prior to placement of the jettystones to help reduce the risk of settlement or scour.

Appendix C
MCR JETTIES MAJOR REHAB ECONOMIC ANALYSIS

1. INTRODUCTION

This appendix describes the Federal interest in the rehabilitation of the MCR Jetties, as well as the procedures used and the results of the economic analysis. The economics are one of the key considerations in the selection of the recommended plan. The Columbia River comprises the M-84 Corridor for the Marine Highway Program. It is noted by the US Department of Transportation as a truck bottleneck resulting in up to 750,000 truck delay hours and an area of major rail congestion. The marine highway serves to reduce the congestion

The procedures adopted for use in economic[1] cost analysis stem from national policy and the NED efficiency objective. Life-cycle cost analysis presents a method by which economic benefits can be compared against economic costs to derive a cost-benefit ratio and to compute net economic benefits. Benefits and costs are converted to average annual cost equivalent values that represent the stream of investments and benefits accrued from those investments over the period of analysis.

The method follows standard life-cycle cost accounting principles in that investments occurring intermittently over a fixed period of analysis are adjusted to account for the time value of money to create equivalent values at a common point in time. The common point in time for USACE planning purposes is designated as the base year, which is defined as the first year during which benefits of the project accrue. Investments and benefits that occur prior to the base year are escalated to the base and investments and benefits that occur after the base year are discounted to the base. The present worth equivalent values are then summed and amortized over the period of analysis to derive an average annual equivalent value. The rate that is used for discounting and amortizing is published annually and is provided by the U.S. Treasury for USACE investment and benefit calculations.

In order for various alternatives with differing investment strategies to be equitably compared, guidance requires that the same period of analysis be used for all alternative plans. The period of analysis is defined as the time horizon for project benefits, deferred installation costs, and operation, maintenance, repair, rehabilitation, and replacement (OMRR&R) costs. OMRR&R costs are the expected costs over the period of analysis for operation, maintenance, repair, rehabilitation, and replacement necessary to maintain the benefit stream and agreed-upon levels of mitigation of losses to fish and wildlife habitats. For USACE navigation projects, the period of analysis is typically 50 years.

Also an equitable comparison of alternatives requires that a common price level for costs be applied. Usually, comparative economic cost values are developed for planning level estimates of alternatives. Historical bid cost data, experience, and/or unit prices adjusted to expected project conditions are acceptable methods of developing project costs for these alternatives. The selected plan is then refined to create a Total Project Cost using the USACE-certified MCASES (MII) cost model in accordance with

[1] COE planners use economic cost information to make the basic efficiency decisions about alternative plans. NED costs are used to make these decisions. Once the efficiency decision has been reached, the COE uses financial costs for project implementation, also referenced as fully-funded costs. A fully-funded cost is a financial cost, not an economic cost.

guidance.[2] While economic costs are used for efficiency decisions, fully funded total project costs are used for budgeting and implementation.

2. Federal Interest

The guidance for major rehabilitation projects is cited in ER 1105-2-100 and in ER/EP 1130-2-500. During initial discussions, the PDT worked with the MSC to determine the appropriate approach for the evaluation. Given the expected nature of projected failures and the usual Portland District repair response, service disruption and economic consequences would be significantly limited. The PDT and MSC determined that there was an obvious Federal interest in this project, and it would be appropriate to use a basic comparison of least cost alternatives to construct and repair. ER 1105-2-100, Section X, Major Rehabilitation Studies, notes that for the majority of cases, the Federal interest in an existing project will be obvious, and that a reasonable argument showing that Federal interest should be provided in the report.

The MCR jetty serves as the gateway to the larger Columbia/Snake River navigation system, carrying about 42 million tons of cargo on an annual basis, with an estimated cargo value of $20 billion in 2009 (source: Pacific Northwest Waterways Association [PNWA] fact sheet). The Columbia/Snake River navigation system from the Pacific Ocean to Lewiston, Idaho is a vital transportation link for the states of Oregon, Washington, Idaho, and Montana, as well as for the Nation as a whole. Failure to maintain navigation through the MCR project would lead to inefficiencies in the navigation system. It could potentially shut down a main artery of commerce in the region and the nation.

The Columbia/Snake navigation system flows through Idaho and Washington and forms the southern border of Washington and the northern border of Oregon, serving multiple ports along the way. The system was developed in two segments. The first is the authorized 43-foot deep-draft channel for ocean-going vessels, which extends about 106 miles from the Pacific Ocean to Portland, Oregon, and Vancouver, Washington. The second is the 14-foot deep inland navigation channel with eight locks that extends from Vancouver to Lewiston, about 365 miles. Table C- 1 displays the cargo volume, vessel trips, and drafts of vessels traversing the entrance to the Columbia River over the period 2005-2009.

source: U.S. Army Corps of Engineers, Navigation Data Center, Waterborne Commerce of the United States, Part 4, Cargo and Trips by Waterways, CY 2009-2005

The U.S. Army Corps of Engineers, Portland and Walla Walla Districts, maintains the navigation channels and operates navigation locks at eight federal hydropower projects on the Columbia/Snake River system. The navigation channels and locks provide access to markets for producers throughout the United States, and are part of a just-in-time delivery system for this major international trade gateway. The elements of the Columbia/Snake navigation system include the deep-draft navigation channel, the inland navigation channel, and the jetties, anchorages, turning basins, and upriver locks necessary to accommodate increasingly larger ships and growing inland barge movements.

The inland navigation channel runs about 365 miles upstream from Portland/Vancouver to Lewiston, Idaho. The channel is 14-feet deep. PNWA indicates that about 10 million tons of cargo is barged annually, with an estimated value of $1.5 to $2 billion. The deep-draft navigation channel runs 110 miles downstream of Portland/Vancouver to the mouth of the Columbia River, the gateway to the Pacific Ocean. This channel is currently being deepened to 43 feet. PNWA indicates that the deep-draft channel carries about 40 million tons of cargo annually, with an estimated value of $17 billion in 2009.

The Columbia/Snake River navigation system is a critical regional and national gateway linking agricultural, mineral and goods production across the Northwest, Mountain, Midwest, and East Coast states to growing markets in the Pacific Rim (see Figure C- 1). The economies of many states rely on the trade and commerce that flows up and down this important navigation system. According to the Center for Economic Development and Research[3] (CEDER), the Columbia/Snake River navigation system is the leading gateway for the Nation's wheat and barley exports. It is also a primary paper/paper products export gateway, bulk minerals export gateway, and automobile import gateway for the West Coast.

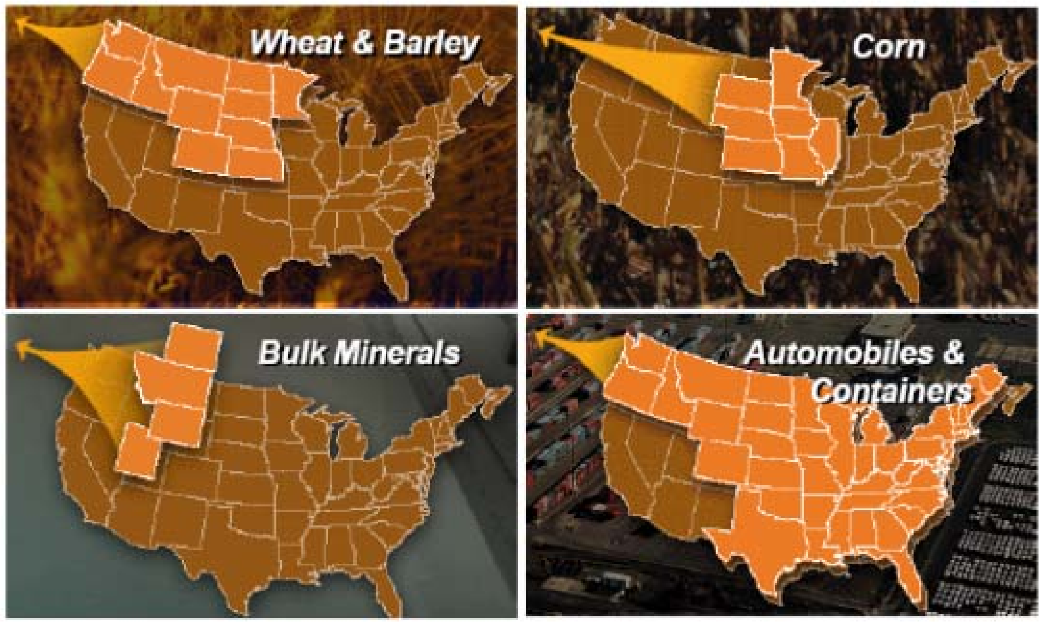

Figure C- 1. Regional and National Markets Served by the Columbia/Snake System

Each of the navigation components in the Columbia/Snake system contributes in valuable ways to the trade moving to, from, and through the region. The Columbia/Snake system provides a low-cost and energy-efficient means of transporting goods. The Columbia River Towboaters Association indicates that one 60,000-ton Panamax vessel is equivalent to a 4- to 5-barge tow, which is also equivalent to 600 rail cars, or to 2,400 semi-trucks.

The Texas Transportation Institute prepared a study[4] for the U.S. Department of Transportation Maritime Administration and the National Waterways Foundation, dated November 2007, showing the relative energy efficiency of barges over rail or truck. It showed the miles per gallon (mpg) carrying one ton of cargo for each of the modes: 155 mpg for trucks, 413 mpg for railroads, and 576 mpg for inland towing. It also provided a summary of emissions that showed that inland towing had the least emissions of the three modes.

a. Columbia River Entrance Fast Facts

- The mouth of the Columbia River is the opening point to the Columbia/Snake River navigation system.
- $20 billion in value each year moves on the Columbia-Snake system (PNWA).
- Nation's number one wheat gateway and number one barley export gateway (PNWA).
- 42 million tons of traffic (products) moves annually through the entrance, 90 percent of which is to or from foreign markets. (See Figure C- 2, WCUS data).
- About 1400 vessels with drafts 30 feet or greater use the entrance. (See Figure C- 3, WCUS data).

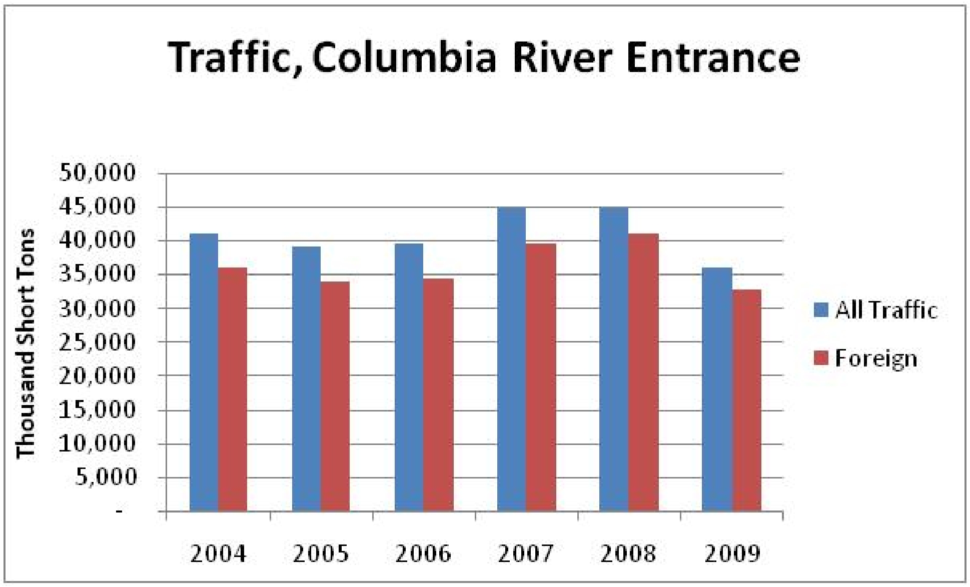

Figure C- 2. Annual Traffic at the Columbia River Entrance

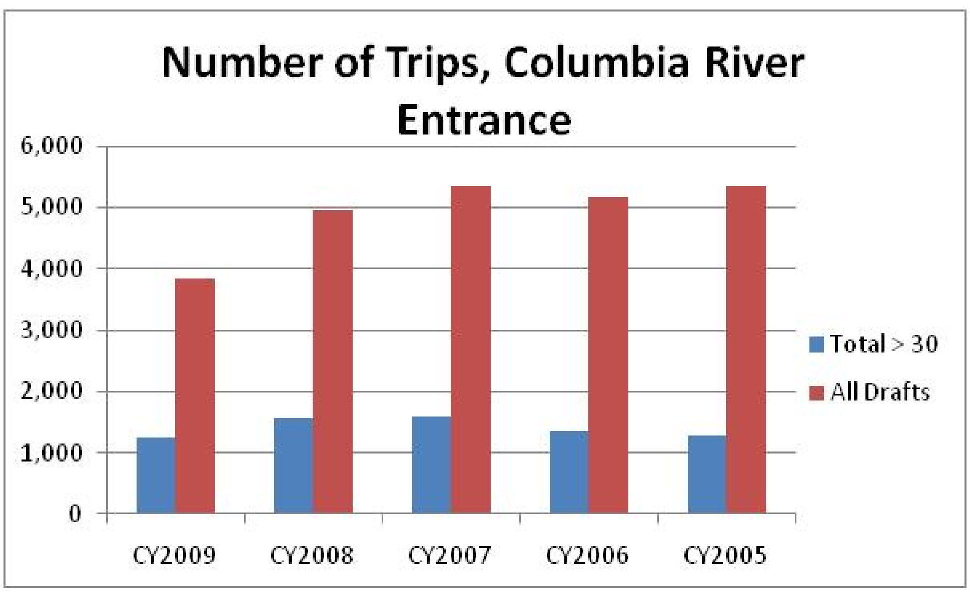

Figure C- 3. Annual Number of Traips at the Columbia River Entrance

In addition, the volume of passengers carried on cruise ships on the Columbia/Snake system has been growing dramatically. These vessels benefit from the same infrastructure maintenance and improvements as maritime cargo, and contribute economic benefits to the local communities located along the Columbia/Snake system. The Pacific Northwest Waterways Association (PNWA) indicates that 5/7 day cruise ship tours carry 6,000 passengers annually, and thousands of tour boat passengers take day trips and dinner cruises. These activities generate about $15 to $20 million in revenue annually for local economies. Additionally, the CEDER report, Appendix A, provides an indicator of Regional Economic Development impacts[5].

> *Direct impacts are the economic activities directly caused by the movement of cargo flows through the port, or the operations of port tenants and users. These activities represent the first round of spending, employment, and wages. Rounds of inter-industry purchases generate indirect and induced impacts. Indirect impacts represent purchases by the industry of goods and services, such as the payment for outside contractors or for accounting or legal services. Induced impacts refer to the household purchases based on the employment earnings from direct and indirect economic activities. As wages are paid out, workers' families spend their income on a wide array of goods and services, much of which are supplied by the local economy. Total impacts incorporate the sum of direct, indirect, and induced impacts. The Lower Columbia River region had over 15,000 direct and 40,000 total jobs in 2000 due to marine cargo activity. The direct payroll of port activity was estimated at $576 million. This generated an income of $1.8 billion, including direct, indirect and induced effects.*

3. Most Likely Future "Without Project" Base Condition

The Base Condition is the plan/scenario against which all other plans are measured. Several considerations need to be determined when developing the Base Condition: determining operating trends, current and projected reliability of all critical components, and planned maintenance on the project. These must all be provided throughout the entire study period.[6]

4. Future "With Project" Alternatives

The goal of implementing with-project alternatives is to maintain navigation within the Federal navigation channel and to avoid any negative impact to mission over the period of analysis. All with-project alternatives include monitoring and advance repairs (i.e., repairs that are intended to occur before potential breaches impact navigation). Detailed descriptions of the alternatives and the different repair strategies are shown in Main Report 3.8.2 and further detailed in Appendix A2.

These alternatives are listed in Table C- 4.

[6] U.S.Army Corps of Engineers, EC1110-2-6062, Engineering and Design, Risk and Reliability Engineering for Major Rehabilitation Studies, 5-5. Establishing the Base Condition and Alternative Without-Project Scenarios, 1 Feb 2011

5. Assumptions for the Life-Cycle Costing of MCR Jetties Alternatives

a. Benefits

The fundamental economic assumption of the MCR Jetties Major Rehabilitation Report is that the navigational or functional performance of the jetty system will be maintained throughout the period of analysis. In fact, in only in one instance during the history of the jetty system has navigational service been disrupted. This assumption implies that transportation service benefits from the jetty system are constant across any scenario or alternative considered. The "most likely" future without project condition maintains the functional integrity of the jetty system as do all alternatives considered throughout the period of analysis. Increasing structural resiliency is a goal of the alternative actions; however, this concept is not monetized as an economic benefit.

Therefore, with no expected variation in transportation service benefits and a lack of monetization of structural resiliency, the remaining economic consideration is the cost effectiveness of the alternatives considered with costs avoided being the remaining monetized benefit to the project.

Price Level, Period of Analysis, and Federal Interest Rate[7]

The costs applied in the life-cycle cost analysis are USACE-provided 2012 values. The period of analysis is 50 years, from beginning of year 2015 to end of year 2064. The project economic evaluation rate applied is the FY12 Federal interest rate of 4.0 percent. Prices used do not include inflation. End of year values were calculated for the life cycle cost analysis.

Base Year and Interest during Construction

Alternative plans can differ in their implementation timing, that is, not all plans or features have to be in place at the beginning of the period of analysis. As project on-line dates are varied, annual benefits and costs will often vary. In general, the more the benefits vary through time and the longer the time to implementation from the base year (first year of period of analysis), the stronger this effect will be. The best schedule for implementing project features shall be considered as an element in the formulation and evaluation of alternative plans.[8]

Table C- 4 lists the alternatives evaluated and the construction schedules of the alternatives that have rehab components for the three jetties in the Mouth of the Columbia River Jetty system: North Jetty, South Jetty, and Jetty A. All alternatives have an annual dredging component cost estimated which is not reflected in Table C- 4 but is incorporated into the life cycle cost analysis. Other repair costs occur intermittently over the period of analysis and are incorporated into the life cycle cost analysis also.

The base year was set at the beginning of implementation period in the year 2015 based on two factors:

1) The implementation periods are lengthy due to the large quantity of rock required to complete the work, seasonality of construction, the rock supply and storage activities; and,
2) Benefits will begin accruing with each implementation stage.

---

[7] U.S. Army Corps of Engineers ER 1105-2-100, Planning Guidance Notebook, Appendix D, Amendment #1, paragraph D-6, 30 June 2004.
[8] U.S. Army Corps of Engineers, ER 1105-2-100, Planning Guidance Notebook, paragraph 2-4 (o), 22April 2000.

This method is intended to produce a straight-forward and consistent comparison of alternatives. All alternative costs are discounted at the end of the year to the beginning of the base year 2015 using the stated Federal interest rate and amortized over the period of anlaysis to produce average annual equivalent values. This method will allow for the simple combination of alternatives among the three jetties to identify a combination least cost plan because all economic costs for all three jetties will be represented as equivalent costs.

Also due to the expectation of an immediate accrual of benefits, interest during construction (IDC) was not calculated. IDC is calculated typically when completion of construction is required before benefits are realized. For the MCR jetties rehabilitation alternatives, benefits are assumed to be realized immediately beginning with each activity for which costs are generated.

Also because the first year of construction is also the designated base year due to the expectation of an immediate accrual of benefits, no escalation of costs prior to the base year was necessary. Costs incurred over the period of analysis were discounted to the base year.

6. Life-Cycle Costing of MCR Jetties Alternatives

This life cycle cost analysis should not be confused with the derivation of total project costs which are financial in nature and take into consideration factors of implementation. The life cycle cost analysis presented represents a method by which alternatives can be compared equitably and decisions regarding economic efficiency can be made.

A life cycle cost analysis was performed over the 50-year project life for the alternatives listed in Table C- 17 with consideration, as appropriate, of project construction costs and associated operations and maintenance (O&M) and other costs over the period. Each alternative, with the exception of the “fix-as-fails” alternatives, was modeled allowing the jetty trunks to recede over the period of analysis and then again with holding the current jetty length constant.

a. Unit Cost Components of Alternatives

Repairs, rehabilitation, and dredging are projected throughout the period of analysis in response to scenarios developed with the SRB Model. USACE-provided 2012 cost variables contribute to the jetty alternatives cost estimates over the period of analysis and are assembled to reflect the activities that define each alternative’s repair strategy:

1. Repair activities: unit costs/ton of rock for expedited, base, and scheduled repairs, specific to jetty structure;
2. Rehabilitation activities: unit costs/ton of rock for a variety of scaled activities ranging from minimal to large;
3. Additional fixed costs of activities associated with rehabilitation for every year that rehabilitation occurs: mob/demob; jetty crest haul road construction; barge off-loading facility; mitigation costs; dredging costs; and offloating costs;
4. Jetty head capping: unit cost/ton of rock specific to each jetty;
5. Spur construction: fixed cost specific to each jetty; and
6. Normal dredging: unit cost/cy of sediment dredged specific for North Jetty, same unit cost for South Jetty and Jetty A.

All alternatives contain expedited repair activities and normal dredging activities. All alternatives contain O&M activities that are base repair, interim repair, or scheduled repair.

Table C- 4 presents the array of unit and fixed costs applied in the life cycle cost analysis. The derivation of these costs and their application is discussed in detail in Appendix E, MCASES Cost Estimates. Table C- 6 through Table C- 16 display the cost components specific to each of the alternatives considered for the three jetties in the Mouth of the Columbia River system. Alternatives that share the same unit and fixed costs are listed together in the displays.

b. Interface between the SRB Model and the Life Cycle Cost Analysis

The life cycle cost analysis is performed separately and subsequently to the SRB Model calculations. The execution of the SRB model results in calculations of jetty degradation and required repair (e.g. material quantities required to create a defined condition based on the alternative considered, described in Appendix A1). The output files containing quantities from this model analysis are then used as inputs to the cost analysis to estimate life-cycle costs and other parameters for each alternative. The cost analysis is performed via a set of Microsoft Excel spreadsheets. This section discusses the life cycle cost component of the analysis and the outputs of the SRB model which feed the life cycle cost analysis.

As shown in Table C- 2, the SRB model creates outputs that contain a set of mean values for seven types of activities—rehabilitation; expedited repair, emergency repair; interim repair, base repair, scheduled repair, and normal dredging. These output parameters are listed in the life cycle cost spreadsheets which have a consistent nomenclature, generally titled "MCR_LifeCycleCosts_{name of jetty}_{name of alternative}". These files are built automatically from a single template file “cost_template.xlsx” by calling MCR_COST script in Matlab. The script takes SRB Model CSV files from “output” folder for each alternative and converts them into Microsoft Excel files. The main CSV files are listed in Table C- 2 below.

Table C- 2. Output CSV Files Used to Populate Life Cycle Cost Analysis Spreadsheets

Output File	Description
OUTPUT_Repair_for_COST_MEAN_INNER.csv	Stone volumes for inner range of the jetty for emergency, expedited, fix-as-fail, interim and scheduled repairs.
OUTPUT_Repair_for_COST_MEAN_MIDDLE.csv	Stone volumes for middle range of the jetty for emergency, expedited, fix-as-fail, interim and scheduled repairs.
OUTPUT_Repair_for_COST_MEAN_OUTER.csv	Stone volumes for outer range of the jetty for emergency, expedited, fix-as-fail, interim and scheduled repairs.
OUTPUT_Rehab_for_COST_MEAN.csv	Stone volumes for minimum, small, moderate and large rehab templates and head capping.
OUTPUT_Dredging_for_COST_MEAN.csv	Maintenance dredging volumes.
OUTPUT_Head_Recession_Repair_COST_MEAN.csv	Repairs on North Jetty due to scour associated with Jetty “A” head recession.

Note: Emergency repairs were not used in the SRB Model for the MCR Jetties.
The cost for each activity is calculated in the MCR_LifeCycleCosts spreadsheets, based on actions and volumes projected by the SRB Model to which unit and fixed prices are applied. The unit prices are initially specified in “cost template” spreadsheet on the “Setup” sheet for all jetties and activities. The referencing of the unit costs within the spreadsheets allows for updating, modification, and adjustment, if necessary.

Only the values that occur during the period of analysis, 2015-2064, are considered in the life cycle cost analysis even though the SRB Model outputs a stream of volumes.

Project Life (Years)	Inner Cost/ton	Middle Cost/ton	Outer Cost/ton	Federal Discount Rate	Monthly Compound Interest Factor	Amortization factor, 50 yrs	Activity Index
50	$ 216.00	$ -	$ 241.50	4.00%	1.003274	0.046550	2

Alternative: NJ_fut1_base
Activity: Expedite Repair

Totals over Project Life 2015-2064

2029	15	2,834	-	380	$ 703,914.00	$ 390,858.46

Figure C- 4. Example of Life Cycle Cost Spreadsheet with Reference Unit Costs and Input Volumes from the SRB Model

In the above example, the cost for repair options is calculated in each "Repair" worksheet (Expedited Repair is shown), and unit costs are linked to the "Setup" sheet for named jetty. The present worth equivalent values for all activities associated with each alternative response scenario are totaled and accumulated into a summary spreadsheet, "Cost_Summary.xlsx," and then the present worth equivalent values are amortized over the period of anlaysis to create average annual equivalent values. Table C- 5 displays the results of the life cycle cost analyses for all the alternatives evaluated. Comparisons are made among the alternatives and the alternatives are ranked by net excess benefits.

7. Summary of Costs and Benefits

The most cost effective NED plans among the 71 alternatives are displayed in Table C- 3 below. The most cost effective alternatives are those that produce the greatest net excess benefits over costs. The full array of the alternatives are displayed in Table C- 6 through Table C- 16 and present the results of the life-cycle cost analysis, least cost ranking, benefit-cost ratio, and net excess benefits.

Table C- 3. Most Cost Effective NED Plans

Jetty	Most Cost Effective Alternative	Net Excess Average Annual Benefits	Average Annual Costs	Benefit to Cost Ratio
North Jetty	NJ fut=1 Scheduled Repair Hold	$251,729	$2,984,682	1.09
South Jetty	SJ fut=1_Base	$0	$9,566,691	1.0
Jetty A	JA fut=1 Scheduled Repair Hold	$383,847	$913,260	1.42

Please refer to the Engineering Appendix for a statistical description of variance, standard deviation, risk and uncertainty, etc., based on the model prepared by the Hydrologic, Coastal, and Riverine Section of the Hydraulics and Hydrology Branch. Also, refer to the Engineering Appendix for an explanation on the relationship and interaction between the cost streams related to Jetty A and the North Jetty.

REVISED CLEAN WATER ACT SECTION 404(b) (1) EVALUATION

For

MAJOR REHABILITATION OF THE JETTY SYSTEM AT THE MOUTH OF THE COLUMBIA RIVER
IN PACIFIC COUNTY, WASHINGTON AND CLATSOP COUNTY, OREGON

I. Introduction and Project Description

This 404(b) (1) evaluation describes unavoidable impacts to wetlands and other waters of the U.S. that could occur as a result of proposed actions related to the Major Rehabilitation of the Jetty System at the Mouth of the Columbia River. This action involves repair and rehabilitation at all three jetties in the system, North Jetty, Jetty A, and South Jetty. It also involves lagoon and wetland fill, as well as shoreline foredune stabilization, dredging, and rock placement activities. Further details are described in the proposed action.

Section 404 of the Clean Water Act (CWA) of 1977, as amended, requires that all projects involving the discharge of dredged or fill material into waters of the United States be evaluated for water quality and other effects prior to making the discharge. All dredge and fill materials associated with the major rehabilitation activities at the Mouth of the Columbia River (MCR) jetty system are activities undertaken by or at the direction of the Corps of Engineers. Federal regulations, at 33 CFR 336.1, provide that a Section 404 permit will not be issued for such fill material by the Corps to itself; however, the Corps shall apply the Section 404(b) (1) guidelines to the project. This evaluation assesses the effects of dredge and fill actions described below utilizing guidelines established by the U.S. Environmental Protection Agency (USEPA) in conjunction with the Secretary of the Army under the authority of Section 404(b)(1) of the Act. Guidelines for conducting a 404(b) (1) evaluation are described at 40 CFR 230.1-12.

II. Description of Proposed Action

a. <u>Location</u>

The North Jetty and Jetty A are located in Pacific County, Washington, near Ilwaco and Long Beach on the Long Beach Peninsula. The 2.3-mile long North Jetty was completed in 1917. Three repairs to the North Jetty have been made with the last one completed in 2005. To date, jetty rock placement totals approximately 3.4 million tons. Since initial construction, about 0.4 miles of the North Jetty head has eroded and is no longer functional. Jetty A, positioned on the south side of the North Jetty, was constructed in 1939 to a length of 1.1 miles and is located upstream of the North Jetty. Jetty A was constructed to direct river and tidal currents away from the North Jetty foundation.

The South Jetty is located in Clatsop County, Oregon near Warrenton/Hammond and Astoria. The South Jetty is about 6.6 miles long. The initial 4.5-mile section of the South Jetty was completed in 1896, with a 2.4-mile extension completed in 1914. Currently, approximately 3 miles of jetty extends seaward of the shoreline. To stabilize the jetty foundation, six groins perpendicular to the South Jetty were constructed with lengths from about 100 to 1,000 feet. Over 6,100 feet of head loss has occurred at the South Jetty. Nine repairs to the South Jetty have been completed with the latest one in 2007. To date, jetty rock placement at the South Jetty totals approximately 8.8 million tons.

b. Project Description

The Proposed Action is generally composed of four categories applicable to each jetty: **(1)** engineered designs elements and features of the physical structures; **(2)** construction measures and implementation activities; **(3)** proposed Clean Water Act (CWA) 404 mitigation actions for impacts to wetlands and waters of the US, and **(4)** proposed establishment of and coordination with an Adaptive Management Team (AMT) composed of representatives from the Corps and appropriate federal and state agencies. More detailed descriptions of the proposed action, base condition, effects, and discussions can be found in the 2012 revised Final Environmental Assessment as well as the associated Biological Assessments and Biological Opinions from the resource agencies.

The duration of the revised construction schedules is 8 years with a 50-year operational lifetime for the MCR jetty system. Therefore, an inherent level of uncertainty exists regarding dynamic environmental conditions and actual conditions of and at each of the jetties. For this reason, in all cases where areas, weights, and volumes (tons, acres, cubic yards, etc.) or other metrics are indicated, these are best professional estimates and may vary by greater or lesser amounts within a 20% range when final designs are completed. These amounts represent Corps' best professional judgment of what the range of variability could entail as the design is further developed and as on-the-ground conditions evolve over the 8-year construction schedule. The Corps maintains an active jetty monitoring and surveying program that will further inform the timing and design of the proposed action in order to facilitate efficient completion of the project and whenever possible to avoid emergency repair scenarios.

(1.) Design elements and structural features specific to each jetty include the following:

- North Jetty –Scheduled repairs addressing the existing loss of cross section and head stabilization to minimize future cross section instability are proposed. The cross-section repairs are primarily above MLLW, with a majority of stone placement not likely to extend beyond -5 feet below MLLW. To address the structural instability the jetty head (western-most section) would be stabilized with armoring of large stone, but to a lesser extent than capping that was previously proposed. The head stabilization measure at approximately station 101 would be placed on relic and jetty stone that is above MLLW. The shore-side measures that have been identified are culvert replacement and lagoon fill (STA 20-60). These actions are designed to stop the current ongoing erosion of the jetty root and are considered part of the base condition, along with interim repairs between stations 86-99.

The cross-section design from stations 20+00 to 99+00 would have a crest width of approximately 30 feet and would lie essentially within the existing jetty footprint based on the configuration of the original cross section, previous repair cross sections, and redistribution of jetty rock by wave action. About 429,000 tons (268,125 cy) of new rock (221,000 tons for

Major Rehabilitation; 65,000 tons for Major Repairs; and 109,000 for lagoon fill) and reworked rock will be placed on relic armor stone, with the majority of stone placement above MLLW. About three repair events were predicted over the next 50 years. Each repair action is expected to cover a length range of up to 1,500 feet and include stone volumes and rework in the range of 53,000 to 103,000 tons (~33,125-64,375 cy) per season.

Approximately 109,000 tons (~68,125 cy) of gravel and sand will be added to the jetty's beach side as lagoon fill to eliminate the tidal flow through the jetty that is destabilizing the foundation. A recent berm repair action now precludes lagoon inundation by tidal waters coming from the shoreline. Scouring has taken place on the north side of the North Jetty resulting in formation of a backwater area (lagoon) that was previously inundated both by tidal waters that come through the jetty and from the shoreline, and by freshwater that drains from the O'Neil Lake-McKenzie Head lagoon and wetland complex area through the accreted land to the north of the jetty and North Jetty Road. This area drains through a culvert under the road and provides some of the freshwater flow to the lagoon. The surrounding lagoon resembles a scoured-out tidal channel and is a non-vegetated (and non-wetland) area of bare sand comprising approximately 8.02 acres. These wetlands and waters will be filled to protect and stabilize the foundation of the North Jetty and to serve as a location for rock stockpiles and construction staging activities.

The aging culvert draining south from the wetland complex north of the roadway will be replaced, as it provides required drainage under the roadway. The design of the inlet, elevation, and culvert size will be determined so that hydrologic function in the adjacent wetland system is not negatively impacted. The outlet channel downstream of the culvert will not be filled. This area may provide an opportunity for minor stream and bank enhancement which will be evaluated when the culvert design is finalized, but this is uncertain until possible benefits can be further assessed. Under the proposed action, the existing channel will outlet to an engineered sump area comprised of newly placed lagoon fill material. In addition to infiltration through the jetty structure, this small portion of the creek currently connects the wetland to the lagoon and likely also receives some backwater flow from jetty infiltration.

- South Jetty – Under the base condition, interim repair scenario, the cross-section design from stations 167+00 to 258+00 would have a crest width of approximately 30 feet and would lie essentially within the existing jetty footprint based on the configuration of the original cross section, previous repair cross sections, and redistribution of jetty rock by wave action. The majority of the stone placement would be conducted above the MLLW. Each repair action is expected to cover a length up to 2,300feet and include stone volumes in the range of 50,261 to 130,353 tons per season (31,329 to 81,471 cy). Augmentation of the foredune at the western shoreline extending south from the jetty root has been included in the base condition, but is describe in detail under the selected plan. This action is intended to prevent the degradation of the jetty root and prevent the potential breaching of the fore dune.

About 40,000 to 70,000 cy of cobble is proposed at the South Jetty root in order to fortify the toe of the foredune and to improve the foreshore fronting to resist wave-induced erosion/recession (Figure 24). Maximum crest width of the template is estimated to extend 70 feet seaward from the seaward base of the present foredune. Construction of the foredune augmentation would require 2 to 6 weeks. To adequately protect the foredune during storm conditions, this requires that the top of the stone berm (crest) extend vertically to approximately 25 feet NAVD and have an alongshore application length of approximately 1,100 feet, extending southward from the South Jetty root. This is equivalent to about 3 acres. The constructed template crest would be 10 to 15 feet above the current beach grade and have a 1 vertical to 10 horizontal slope aspects from crest to existing grade. Cobble is not expected to extend below MHHW. A layer of sand may be placed over this berm or natural accretion may facilitate sand recruitment after construction of the adjacent spur groin.

Cobble material would be procured from upland sources and placed using haul trucks and dozers. The material would be transported on existing surface roads and through Fort Stevens State Park to a beach access point at the project site. There is an existing relic access road along the jetty root that will be refurbished and used to transport stone to the dune augmentation area.

The dune augmentation may require maintenance every 4 to 10 years (assume 40% replacement volume). Consideration will be given to development of revegetation plans which incorporate native dune grasses to supplement foredune stabilization in the augmentation area. This bioengineering component could help restore vegetated dune habitat and take advantage of natural plant rooting functions that provide greater protection from erosive forces.

• Jetty A – The cross-section design from stations 48+00 to 84+00 would have a crest width of approximately 40 feet and would lie mostly within the existing jetty footprint based on the configuration of the original cross section, previous repair cross sections, and redistribution of jetty rock by wave action. About 80,375 tons (~50,234 cy) of new rock would be placed on the existing jetty cross section and relic armor stone. Most of the work would occur above MLLW.

(2.) Construction measures and implementation activities for all three jetties include the following:

- Storage and staging areas for rock stockpiles and all associated construction and placement activities such as: roadways, parking areas, turn-outs, haul roads, weigh stations, yard area for sorting and staging actions, etc.
- Stone delivery from identified quarries either by barge or by truck. Possible transit routes have been identified. This also includes the construction and use of permanent barge offloading facilities and causeways with installation and removal of associated piles and dolphins.
- Stone placement either from land or water, which includes the construction, repair, and maintenance of a haul road on the jetty itself, crane set-up pads, and turnouts on jetty road. Placement by water could occur via the use of a jack-up barge on South Jetty, but will not occur by other means or on North Jetty to avoid impacts to crab and juvenile salmon migration.
- Regular dredging and disposal of infill at offloading facilities with frequency dependent on a combination of the evolving conditions at the site and expected construction scheduling and delivery. Disposal will occur at existing designated and evaluated approved in-water sites.

(3.) In addition, the Corps has identified specific and potential mitigation for impacts to CWA 404 wetlands and waters of the US. Wetland mitigation opportunities have been identified adjacent to the impacted wetlands at the North Jetty. Wetland mitigation for Jetty A would also be implemented at the North Jetty because space is unavailable at Jetty A. Mitigation for wetland impacts at the South Jetty would occur within the State Park but southwest of the impact area in a location south of Trestle Bay. The mitigation for the impacted wetlands would be creation of wetlands of similar type and function. Specific mitigation for impacts to waters other than wetlands has not been determined, but a suite of potential projects and examples has been identified. Depending on further development of both the project and potential mitigation alternatives and commensurate with final impacts, a specific mitigation project or combination of projects would be selected and constructed concurrently. Mitigation would provide environmental benefits to offset impacts as portions of the proposed action are completed over time. This EA has identified and quantified the maximum amount of impacts and mitigation likely under the Preferred Alternative, and further details and selection of specific appropriate mitigation actions for waters other than wetlands would be refined as the project moves forward. Depending on the method of project implementation, commensurate mitigation could also be reduced if impacts are avoided. Generally, possible mitigation measures could include but are not limited to an individual project or a combination of projects and actions such as the following list.

- Excavation and creation of tidal channel and wetlands to restore and improve hydrologic functions including water quality, flood storage, and salmonid refugia.
- Culvert and tide gate replacements or retrofits to restore or improve fish passage and access to important spawning, rearing, and resting habitat.
- Beneficial uses of dredged material from MCR hopper dredge to replenish littoral cells.
- Invasive species removal and control and revegetation of native plants to restore ecological and food web functions that benefit fisheries.

Mitigation meets compliance obligations under the Clean Water Act and would be commensurate with impacts from construction activities. It also complements Corps obligations to protect and restore critical habitat for ESA listed species. More specifics regarding mitigation are described in that section.

(4.) Due to the dynamic conditions at MCR and the long duration of the MCR Jetty Rehabilitation schedule, the Corps proposes formation of a modified interagency Adaptive Management Team (AMT). The Corps suggests annual meetings and more as needed to discuss relevant design and construction challenges and modifications, technical data, new species listings or critical habitat designations, evolving environmental conditions, and adaptive management practices as needed. The primary purpose of the proposed AMT and its implementation is to ensure construction, operation, and maintenance actions have no greater impacts than those described in the Biological Assessments and this Environmental Assessment, and that Corps obligations and terms and conditions are being met. This will also allow confirmation that any necessary construction or design refinements remain within the range and scope of effects described during Consultations and that compliance obligations are being met and efforts are being made to adjust mitigation once final impacts are fully understood. These adjustments could result in a reduction in mitigation based on actual impacts occurring. This forum would provide an opportunity for periodic evaluation as to whether or not the proposed actions, ESA listings, or environmental conditions result in any re-initiation triggers. It would also facilitate continued coordination and updating and allow the Corps to inform agency partners when unforeseen changes arise. Results regarding marine mammal and fish monitoring, mitigation monitoring, as well as water quality monitoring would be made available to the AMT in order to fulfill reporting requirements and to address any unexpected field observations. Results of jetty monitoring surveys would also inform the AMT of the repair schedule and design refinements that may become necessary as the system evolves over time. This venue would provide transparency and allow opportunities for additional agency input. Final selection and design of the mitigation proposal would be determined by the Corps and would be vetted through this forum to facilitate obtaining final environmental clearance documents for this component of the MCR proposed action. Potential principal partners include federal (National Marine Fisheries Service, U.S. Fish and Wildlife Service) and State (Washington and Oregon) resource management agencies.

c. Authority, Purpose, and Need

For the authorization for the actual construction of the MCR jetties, the present navigation channel and configuration of the inlet at the mouth of the Columbia River are the result of continuous improvement and maintenance efforts have been undertaken by the Corps Portland District since 1885. Congress has authorized the improvement of the MCR for navigation through the following legislation: Senate Executive Document 13, 47th Congress, 2nd Session (5 July 1884) authorized the Corps to construct the South Jetty (first 4.5 miles) for the purpose of attaining a 30-foot channel across the bar at the MCR; House Document 94, 56th Congress, 1st Session (3 March 1905) authorized the Corps to extend the South Jetty (to 6.62 miles) and construct a North Jetty (2.35 miles long) for the purpose of attaining a 40-foot channel (0.5 mile wide) across the bar at the MCR; House Document 249, 83rd Congress, 2nd Session (3 September 1954) authorized a bar channel of 48 feet in depth and a spur jetty ("B") on the north shore of the inlet. Funds for Jetty "B" construction were not appropriated. Public Law 98-63 (30 July 1983) authorized the deepening of the northern most 2,000 feet of the MCR channel to a depth of 55 feet below mean lower low water (MLLW). The MCR federal navigation project was originally authorized (in 1884) before formulation of local sponsor cost sharing agreements; therefore, all navigation maintenance and improvements at MCR are borne by the Federal Government.

The authority for maintenance of the MCR jetties comes from the original authority for construction of the project and then with Corps' policies for the operations, maintenance, and management of a Corps' project (Chapter 11 of EP 1165-2-1). For navigation, completed projects like the MCR have established that operations and maintenance (O&M) is solely a federal responsibility to be accomplished at federal cost.

When maintaining a Corps' project, there is regular O&M, major maintenance, and major rehabilitation. Major rehabilitation consists of either one or both of two mutually exclusive categories, reliability or efficiency improvements.

- Reliability. Rehabilitation of a major project feature that consists of structural work on a Corps operated and maintained facility to improve reliability of an existing structure, the result of which will be a deferral of capital expenditures to replace the structure. Rehabilitation will be considered as an alternative when it can significantly extend the physical life of the feature (such as a jetty) and can be economically justified by a benefit/cost relationship. Each year the budget EC delineates the dollar limits and construction seasons (usually two construction seasons).

- Efficiency Improvements. This category will enhance operational efficiency of major project components. Operational efficiency will increase outputs beyond the original project design.

Thus, the authority for maintenance of the MCR jetties comes from the authorization documents for the project and/or the authority to operate and maintain the structures.

The purpose of the proposed action is to perform modifications and repairs to the North and South jetties and Jetty A at the MCR that would strengthen the jetty structures, extend their functional life, and maintain deep-draft navigation.

Structural degradation of the +100-year old MCR jetty system has accelerated in recent years because of increased storm activity and loss of sand shoal material upon which the jetties are constructed. In addition, beaches on the ocean sides of the North and South jetties, which formed as a result of jetty construction, have been receding gradually over the years, exposing previously protected sections of the jetties at the beach line to storm waves. Taking no action to protect and to extend the functional life of the jetties will result in further deterioration of the jetties and the sand shoals upon which they rest, increasing the likelihood of a jetty breach. Recent jetty repairs have addressed immediate critical needs. Additional modifications and repairs to the jetties are necessary to address critical near- and long-term needs and to reduce the potential for emergency repairs, emergency dredging, and impacts to navigation.

d. General Description of Fill and Dredged Material

The repair and rehabilitation project would require placement of clean armor and fill stone. This would also be required for construction of barge offloading facilities. The material would come from an approved quarry. The Corps intends to use operating quarries rather than opening any new quarries. The Contractor and quarry owner/operator will be responsible for ensuring that quarries selected for use are appropriately permitted and in environmental compliance with all state and federal laws.

Depending on site-specific circumstances, barge offloading facilities may be partially removed and rebuilt, may be permanently removed, or may remain as permanent facilities upon project completion. Facility removal will depend on access needs, removal and mitigation costs, and evolving hydraulic, wave, and jetty cross-section conditions at each offloading locations.

Offloading facilities will range from approximately 200- to 500-feet long and 20- to 50-feet wide, which ranges from about 0.48 to 2.41 acres in total area. For initial construction of all four facilities combined, approximately up to 96 Z- or H-piles that are 12-16-inches in diameter could be installed as dolphins, and up to 373 sections of Z- or H-piles installed to retain rock fill. They will be located within 200-ft of the jetty structure. Facilities will have a 15-foot NGVD crest elevation and will be installed at channel depths between -20 and -30 feet NGVD. Because the sediments in the region are soft (sand), a vibratory hammer will be used for pile installation and only untreated wood or steel piles installed to a depth of approximately 15 to 25 feet below grade. Removal and replacement of the facilities could occur within the duration of the construction schedule. Volume and acreage of fill for these facilities are shown in below.

Rock Volume and Area of Barge Offloading Facilities and Causeways

Location	Approximate Length (ft)	Approximate Rock Volume (cy) Below 0 MLLW	Total Approximate Rock Volume (cy)	Approximate Square Feet	Acres
North Jetty	200	7,778	29,640 cy	21,000	0.48
Jetty A near head	200	7,778	29,640 cy	21,000	0.48
Jetty A mid-section causeway	5000	38,888	38,888	105,000	2.41
South Jetty Parking Area D	450	17,417	33,688 cy	47,250	1.08
South Jetty along jetty turn-out	200		18,640 cy	21,000	0.48

Dredging activities will entail the following. Transport of rock would most likely be done by ocean-going barges that require deeper draft (20-22 feet) and bottom clearance when fully loaded than river-going barges. Therefore, dredging will be required to develop each of the barge offloading facilities. Under-keel clearance should be no less than 2 feet. The elevation at barge offloading sites should have access to navigable waters and a dredge prism with a finish depth no higher than -25 feet MLLW, with advance maintenance and disturbance zone depths not to extend below -32 feet MLLW. These facilities should also provide for a maneuvering footprint of approximately 400 feet x 400 feet. The depth along the unloading sites would be maintained during the active period for which the rock barges will be unloaded. The volume of material to be dredged is shown; these estimates are based on current bed morphology and may change. Also, maintenance dredging to a finish depth of -25 feet MLLW will be needed before offloading during each year of construction. Dredging is likely to occur on a nearly annual basis for the duration of the project construction period, but this will be intermittent per jetty, depending on which one is scheduled for construction in a particular year.

Estimated Dredging Volumes for Barge Offloading Facilities

Location*	Estimated Dredging Volume (cy)		Approximate Acres
	Initial	Est. Maintenance**	
North Jetty	30,000	30,000	3.73
Jetty A	60,000	80,000	3.73
South Jetty	20,000	20,000	4.19
South Jetty - Parking Area D	20,000	20,000	4.19

* Some of the locations will not be used on an annual basis; it depends on the construction schedule for each jetty.
**All dredging will be based on surveys that indicate depths shallower than -25 feet MLLW.

Approximately 109,000 tons (~68,125 cy) of gravel and sand will be added to the North Jetty's beach side as lagoon fill to eliminate the tidal flow through the jetty that is destabilizing the foundation. This fill could be derived from dredge material, upland excavation, as well as quarry stone. The aging culvert draining south from the wetland complex north of the North Jetty Access roadway will also be replaced. At the South Jetty there will be some temporary fill in the lagoon and culverts will be installed in the marsh wetland to maintain hydraulic connectivity while allowing access up to the jetty and to areas identified for construction staging and stock piling. At the area identified for dune augmentation adjacent to and south of the root, cobble material would be procured from upland sources and placed using haul trucks and dozers. About

40,000 to 70,000 cy of cobble in the shape of angular or rounded graded stone is proposed, and could require periodic supplementation.

In order to place stones, a haul road will be constructed on the 30-foot crest width of each jetty to allow crane and construction vehicle access. Roads will consist of an additional 3 feet of top fill material, which could also entail an additional 2 feet of width spill-over. These roads would remain in place for the duration of construction. Due to ocean conditions and the wave environment, these roads would likely need yearly repair and replacement. They will not be removed upon completion. Ramps from the beach up to the jetty road will also be constructed to provide access at each jetty.

At approximately 1,000-foot intervals, turnouts to allow equipment access and passage will be constructed on the North and South jetties. These would consist of 50-foot long sections that are an additional 20-feet wide. Some of this stone for these facilities may encroach below MLLW. On the North Jetty, there will be approximately two turnouts. South Jetty could have approximately eight turnouts with two additional larger-sized turnouts. These larger turnouts will be in the range of 300-feet long with an additional 20-foot width. One of these larger turnouts will function as an offloading facility on South Jetty. At Jetty A, the causeway will function as the turnout facility.

Towards the head of each jetty, additional crane set up pads will be constructed at approximately 40-ft increment to allow crane operation during the placement of the larger armoring stones. Set-up pads will roughly entail the addition of 8 feet on each side of the crest for a length of about 50 feet. Some of this stone for these facilities may encroach below MLLW. Approximately five set-up pads will be required to construct each jetty head.

e. <u>Description of the Proposed Discharge Site</u>
A dredged material disposal site called the North Jetty Site is entirely within inland waters. It is located about 400 feet south of the North Jetty, occupies an area of 1,000 feet by 5,000 feet, and has an average water depth of 35-55 feet. This site was evaluated and established in 1999 under Section 404 of Clean Water Act to allow the placement of dredged material along the toe of the North Jetty to protect it from excessive waves and current scour. Use of the site is limited to disposal of MCR dredged material. From 1999-2008, about 4.4 million cubic yards (mcy) of dredged material was placed in the North Jetty site.

An ocean disposal site called the Shallow Water Site (SWS) lies within 2 miles offshore from the MCR and was evaluated and designated in 2005 by the U.S. Environmental Protection Agency (USEPA) under Section 102 of the Marine Protection, Research and Sanctuaries Act. The SWS occupies a trapezoidal area of 3,100- to 5,600 feet in width by 11,500 feet in length and lies within a water depth of 45-75 feet. The SWS is used for disposal of material dredged from either the MCR or the lower Columbia River. The SWS is dispersive, which means that material placed there is transported away from the site by waves and currents. Active monitoring and evaluation determined that 80% to 95% of the dredged sand annually placed at the SWS moves northward onto Peacock Spit. From 1997-2008, approximately 29 mcy of dredged sand has been placed in the SWS. The SWS is of strategic importance to the region; its continual use has supplemented Peacock Spit with sand, sustained the littoral sediment budget north of the MCR, protected the North Jetty from scour and wave attack, and stabilized the MCR inlet.

There is also an active deep water disposal site 7 miles off shoreline in Pacific Ocean, west of the Columbia R., as well as an active disposal site in the estuary at RM 7 called the Chinook Channel Area D, the latter of which receives materials from the Columbia and Lower Willamette reaches. There may also be potential future proposed dredge material disposal sites near both the North and South Jetties.

Two dredged material disposal sites, the Shallow Water Site and the North Jetty site, are the most likely sites to be used for disposal of dredged material. Modeling has showed that the potential changes to the two disposal sites from the proposed action would not inhibit their use as disposal sites. These sites have been previously vetted through the appropriate regulatory agencies, were evaluated for their effects, and were subsequently designated or approved after such review. The current proposed action and use of these disposals sites will maintain compliance with approved use.

These disposal sites would be used seasonally, likely between May and October, in order to maintain barge offloading facilities at the required depths. Depending on in-fill rates, dredging and disposal could occur one or more times per season. Any rock placement or road maintenance would also likely occur on a daily basis but be limited seasonally to the spring and summer months, as weather conditions at the jetties preclude safe working conditions in the winter and fall months. Localized turbidity in the immediate vicinity of the work or placement sites is also expected to occur on a seasonally limited daily basis during daylight hours. However, due to the nature of the materials and the conditions at the jetties, this is not expected to exceed background levels in any significant manner. Conditions of the State Water Quality Certifications will also likely include limited exceedence durations to protect aquatic life, with which the Corps and its contractor will comply. Lagoon fill, wetland fill, and foredune augmentation will all occur in a single season and will occur during a limited amount of time during daylight hours.

f. Description of the Disposal Method

Placement of armor stone and jetty rock on the MCR jetties would be accomplished by land or limited water-based equipment. Only clean stone will be used for rock placement, where appropriate and feasible. Where appropriate, there may also be some re-working and reuse of the existing relic and jetty prism stone. Fill for the jetty haul roads will not be cleaned prior to installation. Dropping armor stone from a height greater than 2 feet will be prohibited. During placement there is a very small chance of stone slippage down the slope of the jetty. However, this is unlikely to occur due to the size and cost of materials and placement.

Another approach to water-based rock placement would be via a jack-up barge. This would only be applicable at the South Jetty. For armor stone and rock placement at the head, a jack-up barge with crane could be used to serve as a stable work platform (Figure 36). Once into place, the jack-up barge would be jacked up on six legs so that the deck is at the same elevation as the jetty. The legs are designed to use high-pressure water spray from the end of the legs to agitate the sand and sink the legs under their own weight. The jacking process does not use any lubricants that contain oils, grease, and/or other hydrocarbons. The stone and rock will be barged to the jack-up barge and offloaded onto the jetty head. The jack-up barge will keep moving around the head of the jetty to complete the work. A jack-up barge would not be used on the North Jetty or Jetty A to avoid interference with navigation of fishing boats and crab and fish migrations.

For land-based rock placement, a crane or a large track-hoe excavator could be situated on top of the jetty. The placement operation would require construction of a haul road along the jetty crest within the proposed work area limits. The crane or excavator would use the haul road to move along the top of jetty. Rock would be supplied to the land-based placement operation by land and/or marine-based rock delivery. For marine-based rock, the land-based crane or excavator would pick up rock directly from the barge or from a site on the jetty where rock was previously offloaded and stockpiled, and then place the rock within the work area. For land-based rock, the crane or excavator would supply rock via a truck that transports rock from the stockpile area. The crane or excavator would advance along the top of the jetty via the haul road as the work is completed.

A clamshell dredge would likely be used for all dredging, although there is a small chance that a pipeline dredge could be used. The material to be dredged is medium to fine-grained sand, typical of MCR marine sands. Disposal of material would occur in-water at an existing previously evaluated and designated approved disposal site. Clamshell dredging is done using a bucket operated from a crane or derrick that is mounted on a barge or operated from shore. Sediment removed from the bucket is generally placed on a barge before disposal. This type of dredge is typically used in shallow-water areas.

The following overall impact minimization practices and best management practices (BMPs) will be used for all maintenance dredging for offloading facilities.

1. To reduce the potential for entrainment of juvenile salmon or green sturgeon, the cutter-heads on pipeline dredges will remain on the bottom to the greatest extent possible and only be raised 3 feet off the bottom when necessary for dredge operations.

2. To reduce turbidity, if a clamshell bucket is used, all digging passes shall be completed without any material, once in the bucket, being returned to the wetted area. Not dumping of partial or half-full buckets of material back into the project area will be allowed. No dredging of holes or sumps below minimum depth and subsequent redistribution of sediment by dredging dragging or other means will be allowed. All turbidity monitoring will comply with State 401 Water Quality Certification Conditions.

3. If the Captain or crew operating the dredges observes any kind of sheen or other indication of contaminants, he/she will immediately stop dredging and notify the Corps' environmental staff to determine appropriate action.

4. If routine or other sediment sampling determines that dredged material is not acceptable for unconfined, in-water placement, then a suitable alternative disposal plan will be developed in cooperation with the NMFS, EPA, Oregon Department of Environmental Quality (ODEQ), Washington Department of Ecology (WDOE), and other agencies.

A vibratory hammer will be used to install pilings for offloading facilities. At the South Jetty, cobble material would be procured from upland sources and placed using haul trucks and dozers. At the North Jetty, lagoon fill will also be placed using haul trucks and dozers or pump ashore.

III. Alternatives

The Preferred Alternative for repair and rehabilitation of the MCR jetties has been developed and refined to take advantage of opportunities to avoid and minimize, to the maximum extent practicable, the proposed project's ecological impacts to wetland, aquatic habitats, and species per requirements under the Clean Water Act and Executive Order (EO) No. 11990. Efforts were made to reduce the project footprint and to locate staging areas away from wetland and waters areas. However, there would be unavoidable effects to wetlands and waters as aquatic habitat would be filled and converted as a result of the project. The process used to determine mitigation was to first maximize avoidance of the impacts. However, some impacts to wetlands and waters remained unavoidable. Mitigation for unavoidable impacts was then based on the extent and quality of the habitat affected.

The discharge of dredge and fill materials to wetlands and other waters of the U.S. will occur via the following project activities: stone placement for the jetty structures and associated engineering features; lagoon fill for jetty root stabilization and construction staging and access; stone placement and pile installation for barge offloading facilities; fill of wetlands for construction staging, rock stockpiles, and sorting; and discharge during inwater construction activities and dredge disposal actions. The Corps has evaluated and taken advantage of all practicable alternatives as well as minimization measures to avoid significant adverse environmental consequences. Some of these actions are water dependent or require proximity to special aquatic sites. These circumstances are described for each of the actions.

Stone placement for the jetty structures and associated engineering features: Various jetty rehabilitation and repair design alternatives have been considered. These are described further in the associated June 2012 *Revised Final Environmental Assessment for the Major Rehabilitation of the MCR Jetty System*, which is incorporated herein. Alternatives considered for jetty design included variations in the timing, sequencing, and extent of cross-section repairs and rehabilitation actions at each of the jetties, as well as variations with type and size of stone, slope, spur groin size and locations, head capping and armoring, etc.

The "no action" alternative was considered in the alternatives analysis and was determined to be unacceptable due to the risk of jeopardizing the long-term functional integrity of the jetty system, possible effects to navigation, and possible loss of interdependent landforms. To allow the jetties to continue to deteriorate could eventually lead to breaching and sediment transport into the estuary and navigation channel, which could increase offshore shoaling outside of the channel entrance and result in loss of beach areas and accreted habitat. As the jetties continue to deteriorate, waves are predicted to move further into the inner harbor adding to the difficulty of maintaining a reliable, year-round navigation channel, particularly one that accommodates larger, ocean-going vessels. There could also be a resulting increase boating hazards and necessary dredging actions. Repair and rehabilitation of the jetty system will facilitate maintenance of the current river entrance location and navigational function, as well as the accreted landforms, habitats, and recreational uses that have developed along the shoreline.

Should the condition of the jetty worsen to the point an emergency is declared (which becomes much more likely under a “no action” scenario), repairs and dredging would commence as soon as possible. Environmental documentation would follow, if was not completed prior to emergency construction.

However, this emergency situation is unlikely as the final selected plan addresses these functional issues and minimizes the amount of fill material because it has the smallest footprint practicable. Additionally, this fill is unavoidable because this is a project to maintain the jetty system at its current location at the river’s mouth, which also preserves accessibility for navigation at the MCR. Therefore these actions are by nature water-dependent. The purpose of the project could not be achieved without the level of stone fill to meet the repair and rehabilitation goals and needs.

The method of stone placement does reduce the amount of fill to some degree, as placement by land reduces the need for additional pilings and mooring facilities. When placement by water does occur, it will happen via a jack-up barge, which provides a stable platform without the addition of other facilities.

Lagoon fill for jetty root stabilization and construction staging and access: Lagoon fill will occur at both the North and South Jetty. At the North Jetty, this fill is required to arrest the scour that is undermining the jetty root at the lagoon, which could contribute to its structural deterioration. As a structural component in each of the repair and rehabilitation alternatives, it is a water-dependent feature that is identified as a critical component in any of the alternatives carried forward to maintain the North Jetty.

Partial fill of the lagoon is necessary at the South Jetty because it allows access to the jetty itself for the necessary construction activities. Some logistical staging and preparation activities require proximity to the jetty access road. Additionally, an access road is necessary to ramp up to the jetty itself, and this best occurs in the proximity of the lagoon and marsh inlet area. The farther out on the jetty on the seaward side that the access road can be constructed prior to ramping-up to the jetty, the more resilient and lower its cost. A longer road on the jetty (which would be the case if ramping-up nearer inland) is less feasible, more costly because of the additional fill material needed, and requires more maintenance and repairs because of exposure to wave action. To minimize impacts to waters, the road will be constructed immediately adjacent to the jetty to avoid any marsh channels or wetlands as much as possible. Additionally, a culvert or series of culverts will be installed in the access road as necessary to maintain hydrologic connectivity into the marsh wetland system.

Stone placement and pile installation for barge offloading facilities: Barge offloading facilities will likely be necessary for the transport and delivery of large stones, particularly those used for jetty head stabilization. Logistically and feasibly, the size of stone that could be used may in some cases preclude efficient or safe transport of stone by land. Offloading facilities also benefit from being in proximity to the jetties, because this reduces the redundancy of re-handling and moving the stones prior to placement. Besides increasing efficiency, this reduces the likelihood of stone breakage, which can be very costly.

Though private offloading facilities exist locally, there is no guarantee that these facilities will be available during the timing and in the duration that would be required to efficiently complete the entire project. Areas selected for facilities were chosen because of their proximity to the jetties, their likelihood for safer sea conditions, and their proximity to deeper waters to reduce maintenance dredging. Additionally, in the case of Jetty A, the transportation network to the jetty itself may preclude safe passage of vehicles sized to carry the specified tonnage of rock necessary to complete the project. At the North Jetty, the facility was placed in an area that is presumed to have feasible sea conditions and deeper bathymetry to allow safe offloading. This is the same for the facility located along the South Jetty. At the South Jetty, Parking Area D was selected over the Social Security Beach area also under consideration because it provides some additional shelter from ocean conditions while reducing the footprint and impacts to shallow water.

Finally, in order to maintain appropriate side-slopes, to reduce the in-water footprint of the facilities, and to provide a location for barges to tie-up, the installation of sheet pile and dolphins will be required in conjunction with these facilities. In summary, these facilities ensure availability to feasible offloading sites that allow efficient delivery alternatives, which in the case of large stones may be the only existing technological option to delivery very large stones.

Fill in wetlands for construction staging, rock stockpiles, and sorting: Variations regarding locations for construction staging and rock stockpiling were considered in order to avoid and minimize potential impacts from wetland fill. The current proposed plan reduces these impacts to the maximum extent practicable.

In order to efficiently sequence work, purchase and sort stones, and efficiently place rock each season, it was determined that a maximum two-year supply of stones would be required at each site. This amount was then translated into an acreage that included a minimum area needed to meet basic construction staging needs for things like scales, parking, equipment preparation and storage, etc. Proximity of these activities to the jetty structures is required for feasibility of project execution so that stone is near the placement site for the purposes of proper sorting, stone sizing and selection, minimization of stone breakage, minimization of re-handling stone, and efficient work flows.

Official wetland delineations were completed at all jetties to determine wetland locations that could be avoided. At Jetty A, there is little available space to access the jetty itself, so adequate desired staging and stockpiling is already unavailable. The location of the wetlands in the middle of the site, the isolation and steep topography of the site, the somewhat limited large-vehicle access, and the use of the site by the Coast Guard further preclude availability of staging and storage areas as practicable alternatives to avoid these wetlands.

At North Jetty, the structural lagoon fill is also likely to affect adjacent wetlands, as will also occur to a smaller degree with the culvert replacement. In order to concentrate effects and reduce impacts to additional higher-value wetlands in the complex north of the North Jetty

Access Road, this fill area south of the road was selected to serve the dual purpose of structural fill as well as staging and stockpiling. Most of the wetlands were avoided north of the road, and areas were selected that preserved adequate conserved wetland and shoreline buffers while also providing adequate space necessary for efficient and feasible construction activities.

At the South Jetty, staging and stockpile areas were required to be in proximity to the jetty and the second barge offloading site near Parking Area D. This allows efficient offloading, sizing, and sorting that is necessary prior to placement at the jetty. Parts of a relic access road were included to minimize any new impacts, and several of these areas have been used during previous repairs. Stone sizes are very large, and are easily broken. To reduce re-handling, to minimize interference with construction traffic flows, and to avoid interactions between construction vehicles and park visitors, staging areas closer to the work site are required. The amount and size of the stone and the need for several available sizes during placement precludes the feasibility of staging areas located off-site from the jetties and offloading structures.

However, adequate areas available for stockpiling and staging were constrained to the north by the recent development of the Oregon Parks and Recreation Snowy Plover Habitat Conservation Plan. The project area abuts and overlaps with the southern boundary of this area, but manages to avoid a majority of the designated HCP area. Wetlands and mudflats on the Trestle Bay side, the need to maintain an adequate shoreline dune buffer on the western side, and park recreation activities are also constraints for locating construction staging and stockpiles.

In the current configuration, the marsh wetland will be crossed, but culverts will maintain hydrologic connectivity between the wetland complexes. By allowing this crossing, there is a chance that portions of the park may be able to remain open to the public while certain stages of construction are occurring. Otherwise, additional closures may be necessary which could be more disruptive to park visitors. The selected configuration also allows a safer and more efficient flow of construction traffic that reduces interactions between construction and visitor traffic while somewhat reducing travel time for stone delivery between the jetty, stockpiles, and offloading sites.

The areas around the neck of the Spit and to the south would have provided less available space and would have resulted in a larger park closure. Environmental and wetland impacts for this area were not assessed. Staging and stockpiling any further away from the jetty structure would not be feasible.

Overall, wetland impacts were avoided and minimized to the maximum extent practicable, including providing adequate buffers for conserved wetlands. However, some wetland fill was unavoidable to achieve an adequate and contiguous construction area that allowed access and proximity to implement the project. For the reasons described in the discussion above, no other practicable alternatives allowed full avoidance of wetland impacts.

Wetland mitigation has been identified at both the North Jetty and in proximity to the South Jetty in Trestle Bay to offset these impacts. This is discussed further under the section: *Aquatic Ecosystems and Organism Determination*.

Dredging of barge offloading facilities: Maintaining the functionality of the offloading facilities may require regular dredging when they are seasonally in use. Barges delivering jetty stones are likely to be larger, ocean-going vessels that require under-keel clearances in excess of depths that are likely currently available and self-maintainable at the offloading sites. Dredging and in-water disposal will be required to maintain adequate depths that avoid bottom collisions and allow safe offloading in sometimes rough and unforeseen channel, ocean, wind, and wave conditions. This dredged material will be placed at a pre-approved designated Ocean Dredge Material Disposal Site for which the Corps through its Annual Use Plan will seek permission for use from the EPA prior to any dredge or disposal activities.

Discharge during inwater construction activities: During stone placement, pile installation, and dredging activities, there is likely to be some level of discharge and associated turbidity levels. However, this is unavoidable and will likely be minimal. The size of the stones and the sandy substrate ensure that any suspended sediments are likely to be negligible and to settle out quickly. Additionally, BMPs have been described that will further avoid and minimize any runoff, spill, or discharge potential. Turbidity monitoring and Conditions of the State Water Quality Certification will also be protective of species and will limit the duration of any such discharge. Conserved wetlands will be adequately buffered to avoid and unintended discharge.

IV. Factual Determinations (40 CFR § 230.11)

The actions evaluated in this analysis and the associated EA include South Jetty dune augmentation, actions at the North Jetty described in the *North Jetty Major Maintenance Report* (MMR), May 2011, and actions described in the Major Rehabilitation Report (MRR) (*MCR Jetty System Major Rehabilitation Evaluation Report*, June 2012). Though these actions will be funded as separate projects, they were analyzed together. The following mitigation is required as a result of their associated cumulative effects. The breakdown of effects from fill are indicated in the table below and then described in further detail.

Area Affected	Impacted Acreage	Mitigation Acreage	Comment
North Jetty			
Wetland	1.14	2.28	Base Condition: Major Maintenance Report
404 Waters Lagoon	8.02	12.03	Base Condition: Major Maintenance Report
Other 404 Waters	4.36	6.54	
South Jetty			
Wetlands	2.65	5.30	
404 Waters	13.84	20.76	
Jetty A			
Wetlands	0.91	1.82	
404 Waters	6.60	9.90	

Impacts associated with wetlands had a known and quantified footprint and were the same under all the construction alternatives. Specific wetland mitigation sites and methods were identified and developed. The exact extent of impacts to 404 waters of the US remained unknown because they were contingent upon the delivery method of the rock which would be determined during contract bidding. Therefore, the extent of mitigation for impacts to 404 waters remained uncertain and variable based on the mode of stone delivery and placement. Impacts would be greater if the contractor chooses to use offloading facilities; hence, the maximum potential effects were evaluated in this EA (and in the BAs). Because of this, maximum mitigation requirements were also assumed for 404 waters. Mitigation requirements would be further coordinated with the AMT and may be reduced if offloading facilities are not constructed.

Staging and rock stockpile areas are required to work with the large stone and to construct the repairs. A balance was struck to provide and locate such staging areas that allowed project completion in an efficient and timely manner while minimizing both the areal and temporal extent of project impacts to wetlands and waters. This also includes siting offloading facilities in areas that minimize the extent of dredging and impacts to critical shallow water habitat. To avoid and reduce shallow-water impacts, the Corps determined that offloading facilities would avoid locations within Baker Bay as well as in the small bay area along the north shore of Clatsop Spit. Further, by potentially utilizing barging operations to supply and place the large-sized and large volume of stone, this both reduces the impacts of traffic and somewhat avoids and reduces safety issues with large trucks entering and exiting the Coast Guard and State Park facilities, respectively.

It is assumed all wetlands are expected to be impacted for more than 1 year. Impacts to 404 waters of the US would also occur for more than one year with maintenance dredging and continuous use. Facilities may be removed or left in as permanent fixtures depending on hydraulic conditions at the offloading sites and along the adjacent jetties. For these reasons, this analysis assumed a worst-case scenario so the impacts were considered permanent. Mitigation would be commensurate with the project footprint, which may be reduced further depending on whether or not the final implementation requires barge offloading facilities.

a. <u>Physical Substrate Determinations</u>

Rock placement will occur on an annual basis starting in the late spring through the late to early fall seasons. Fill will be comprised mostly of mostly clean, large armor stones. Placement may occur at more than one jetty per season and will occur regularly throughout the duration of the construction schedule. Some permanent habitat conversion and modification will occur as a result of stone placement for repair and rehabilitation of jetty features. Along specific portions of North and South jetties and along the entire length of Jetty A, substrate will be converted to rocky sub and intertidal habitat, and associated benthic communities will be covered. In addition, crane set-up pads and turnouts will require placement of rock that could extend slightly off the current centerline of the jetty trunk. However, this total area is a relatively small percentage of the existing jetty structures, and conversion is mostly limited to the spur groin locations. Some crushed roadway fill will be placed to form a road on the jetty. This will be mostly above the MHHW mark to avoid deterioration of the roadway.

Generally, effects to in-water habitat could include the following: sub-tidal and intertidal habitat conversion from sandy to rocky substrate and potential unforeseen indirect far-field effects from hydraulic influence (slight, localized changes to accretion, currents, velocities, etc). However, relatively little habitat conversion and footprint expansion will occur because a majority of the stone placement for construction of the jetty head, trunk, and root features will occur on existing relic jetty stone and within the existing structural prism. Moreover, aquatic species would experience limited exposure since stone placement for cross-section repair and rehabilitation actions occurs mostly above the MHHW elevation.

Indirect disturbance effects due to placement activities will be localized and occur mostly during daylight hours in the summer months. Disturbance effects are expected to be of limited duration and minimal, since a majority of the placement is above MHHW and on existing relic stone. There may be temporary disturbance to species using the jetty structure in the vicinity of placement activities. However, the Corps does not expect long-term negative effects from these actions. Finally, the selected plans include cross-sections that avoid and minimize additional habitat conversion that would have resulted from a larger selected cross section.

Dredging will be needed for construction and maintenance of barge offloading facilities and is likely during early summer prior to rock delivery; it may not occur at all facilities annually. If all facilities were dredged, this would total about 16 acres near the jetties. However, it is likely only one or two facilities would be used seasonally for short durations and would be dredged on a periodic basis as needed. The effects of dredging on physical habitat features include modification of bottom topography, which in the vicinity of the jetties is extremely dynamic. Dredging may convert intertidal habitats to subtidal, or shallow subtidal habitats to deeper subtidal. Such conversions may affect plant and animal assemblages uniquely adapted to the particular site conditions these habitats offer. However, the dredge prisms would be very small as a relative percentage of the ~19,575 acres of shallow-water habitat available within a 3-mile proximity to the MCR. The proposed dredging of offloading facilities would affect bottom topography, but is unlikely to cause large-scale or long-term effects to habitat features. Dredging activities will also have some contribution to increased acoustic disturbance that could occur for a limited duration while dredging is underway. These effects are expected to attenuate rapidly such that they return to background levels within a short distance from the source.

Disposal is likely to occur on an annual basis originating from one or more of the offloading facilities. The duration of disposal will be limited and will likely occur earlier in the construction season prior to use of offloading facilities. All disposal of dredged material will be placed in previously evaluated and USEPA-approved ODMDS or Clean Water Act disposal sites. No new or different impacts to species or habitats than those previously evaluated by USEPA or other resource agencies for disposal approval are expected from these actions. Per USEPA guidelines, the ODMDS have a Site Management and Monitoring Plan that is aimed at assuring that disposal activities will not unreasonably degrade or endanger the marine environment. This involves regulating the time, quantity, and physical/chemical characteristics of dredged material that is placed in the site; establishing disposal controls; and monitoring the site environs to verify that unanticipated or significant adverse effects are not occurring from past or continued use of the site and that permit terms are met. The relative quantities, characteristics, and effects of the proposed action would not be expected to have different or significant negative impacts to these sites.

The effects of disposal on physical habitat features include modification of bottom topography. In some cases, disposal may result in the mounding of sediments on the bed of the disposal site. Such conversions may affect plant and animal assemblages uniquely adapted to the particular site conditions these habitats offer. However, the area impacted by disposal would be relatively small and would occur in deeper habitat offshore, in the littoral cell, or near the North Jetty vicinity. The proposed disposal is unlikely to cause large-scale or long-term effects to habitat features.

b. Water Circulation, Fluctuation and Salinity Determinations

Water quality characteristics such as salinity, water chemistry, clarity, color, odor, taste, dissolved gas levels and nutrients are not likely to be affected. Hydraulic features such as current patterns, water circulation, velocity and salinity would remain unchanged.

The USGS and ERDC conducted numerical modeling to evaluate changes in circulation and velocity, salinity, and sediment transport at the MCR for various rehabilitation design scenarios for the MCR jetty system. A 2007 USGS model evaluation assessed the functional performance for rebuilding the jetty lengths in order to aid in the assessment of potential impacts to fish from the rebuilt lengths. Ultimately, even in the larger rebuild scenario only negligible and insignificant changes were predicted to the overall hydraulic and hydrological process at the MCR.

For the proposed action addressed in the current EA, rebuilding of the jetty lengths is not included. However, model results under the larger jetty length rebuild scenario are still relevant for comparing and evaluating potential changes to the MCR system as a whole. This earlier modeling work also remains valid because the current proposed action in this EA holds the jetties at their present lengths, which is essentially the same length as the "base condition" used in the models.

Modeling by the USGS was performed for two time periods, August-September and October-November. Existing conditions were established using actual data collected in August-September 2005. The October-November model period was established for engineering purposes as this time period represents extreme conditions at the MCR. Plots were produced to show existing and post-rehabilitation conditions for the following parameters: residual (average for all tides) velocity and current direction for bed and near surface, residual bed load transport, residual total load transport (bed load + suspended load), and mean salinity for bed and near surface.

The ERDC analyzed the impacts of the presence of spur groins at the MCR in 2007. This analysis was done independently of the USGS modeling and was conducted with the coastal modeling system (CMS) and other models that operate within the surface water modeling system (SMS). A regional circulation model (ADCIRC) provided the tidal and wind forcing for the boundaries of project-and local-scale wave, current, sediment transport, and morphology change calculated by the CMS. The half-plane version of the wave transformation model, STWAVE, was coupled with two-dimensional and three-dimensional versions of the CMS, which calculates current, sediment transport, and morphology change. These models were coupled to provide wave forcing and update calculated bathymetry used in both models at regular intervals (Connell and Rosati 2007).

In summary, the 2007 modeling work and assessment remains valid because the current proposed action holds the jetties at their present lengths, which is essentially the same length as the "base condition" used in the 2007 modeling. Modeling results showed that the changes to velocities, currents, salinity, plume dynamics, and bed morphology would be small to negligible under the larger jetty length rebuild scenario with spur groins. Any small changes to the system would be even less unlikely under the current proposed action because it does not involve rebuilding the length of the jetties. Therefore, no significant overall changes to the hydraulics or hydrology of the MCR system are anticipated under the current proposed action. Additionally, relative to earlier plans which restored the length of the jetties and capped the heads at a significantly longer restored length, the current revised plan selection further reduces any potential impacts to currents, velocities, or bathymetry.

c. Suspended Particulate/Turbidity Determinations

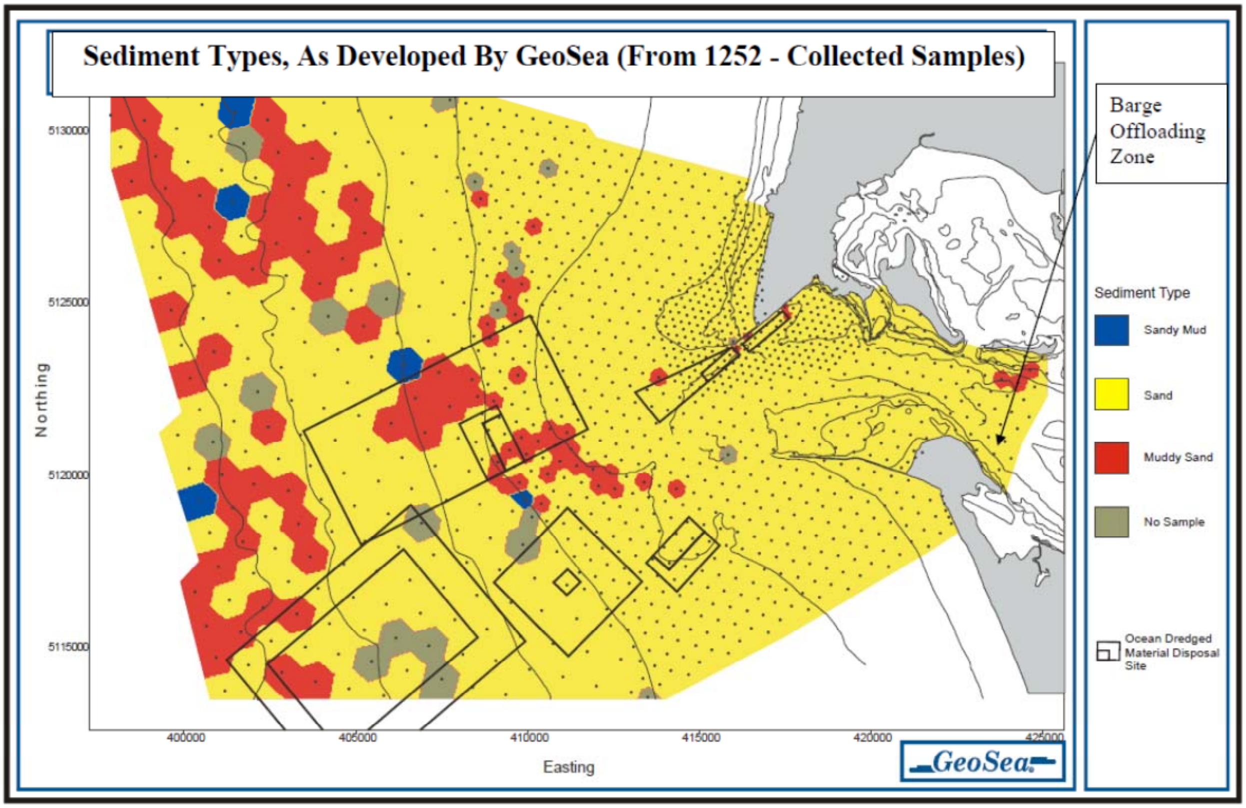
An unavoidable but minimal increase in suspended sediments in the water column is expected during the construction period; however, this impact is expected to stay within acceptable levels for fish and wildlife species of concern. Short-term turbidity is expected to occur with the placement of the temporary dolphins, offloading facilities, and dredging. Long-term adverse impacts are not anticipated.

In 2000, a sediment trend analysis was conducted in the MCR and surrounding off-shore locations by GeoSea Consulting, under contract to the Corps (McLaren and Hill 2000, Corps 2005). Over twelve hundred (1,252) samples were collected. Physical analyses of the samples surrounding the area (6 samples selected) indicated that the sediments consisted of +99% sand. Select samples from study in the MCR area were analyzed for physical and chemical contamination. Results indicated that no contaminates were detected at or near the screening levels in the *Dredge Material Evaluation Framework for the Lower Columbia River Management Area* (DMEF 1998). For a complete report on chemical results, see http://www.nwp.usace.army.mil/docs/d_sediment/Reports/Mcr/mouth00.pdf

In 2005, the Corps conducted a Tier I evaluation near the proposed the South Jetty barge offloading site following procedures set forth in the Inland Testing Manual and the Upland Testing Manual (Corps October 2005). The methodologies used were those adopted for use in the 1998 DMEF and its update, the *Northwest Regional Sediment Evaluation Framework, Interim Final* (SEF 2006). This Tier I evaluation of the proposed dredged material showed that the material was acceptable for both unconfined in-water and upland placement. No significant, adverse ecological impacts in terms of sediment toxicity were expected from disposal.

In 2008 using USEPA's *OSV Bold*, 10 sediment grab samples were collected from sites previously sampled in the 2000 sediment trend analysis (Corps 2008). In 2008, percent sand averaged 98.45% with a range of 99.3% to 97.0% and percent silt and clay averaged 1.59% (range from 3.0% to 0.7%). Per the Project Review Group approved Sediment Analysis Plan, no chemical analyses were conducted. Physical results for the 2000 and 2008 sampling events were compared. The mean percent sand for all samples in September 2000 was 98.11% and for June 2008 was 98.45%. In both data sets, sediments towards the outer portion of the mouth are finer than sediments towards the center of the mouth.

Sediment Trend Analysis in the MCR Area



Placement of rock by heavy equipment, jetty access road construction, dredging, disposal, and pile installation and removal could all cause temporary and local increases in suspended sediment. This is expected to have minimal and limited effects on the environment. Previous tests have confirmed that material to be dredged will be primarily sand with little or no fines, which does not stay suspended in the water column for a significant length of time. During infrequent and limited duration dredging and disposal, suspended sediments may increase locally for a short time. However, light attenuation and water quality effects from increased suspended sediments are expected to be minimal and fleeting. Pile driving is also expected to occur in sand and therefore have similar transient and minimal effects to water quality. Jetty roads could also contribute suspended sediments that would create turbidity, but since they are above MHHW this will likely be an infrequent occurrence. Increases in turbidity from construction activities on the jetties will likely occur on a nearly daily basis but will be of limited extent and duration, as rock placement will involve clean fill. Wave and current conditions in the action area naturally contribute to higher background turbidity levels; and such conditions also preclude the effective use of isolating measures to minimize turbidity. Effects from potential stormwater runoff will be avoided by implementation of an Erosion and Sediment Control Plan or Stormwater Pollution Prevention Plan that avoids and minimizes runoff and pollutant loading associated with upland construction activities. Therefore, impact from suspended sediments should be insignificant.

Temporally, effects to water quality from suspended sediment and turbidity could occur on a daily basis, but are not expected to be continuous throughout the day. Turbidity levels and durations will be limited to conditions required in the State Water Quality Certifications which include exceedence windows that are protective of beneficial uses such as salmonids and other aquatic life. Spills or leaks are expected to be infrequent and unlikely. Although the repetition of disturbance may be greater, it is still expected to remain within safe ranges that would not have long-term or significant effects. Furthermore, effects are expected to be geographically limited, short term, and minor.

Effects of the proposed action to water quality could occur by increasing suspended sediments, increasing the potential occurrence of spills and leaks, and increasing the potential for contamination. However, most of the discharged material will be large stone and coarser materials like sand. The Corps is also requiring a spill prevention and response plan along with additional BMPs and stormwater control measures that reduce the potential for leak or runoff exposure. Therefore, the Corps does not expect these effects to be likely or significant.

d. Contaminant Determinations

The Corps will require the contractor to provide a spill prevention and management plan that will include measures to avoid and minimize the potential for spills and leaks and to respond quickly to minimize damages should spills occur. Good construction practices, proper equipment maintenance, appropriate staging set-backs, and use of a fast fueling system would further reduce the likelihood of leak and spill potential and exposure extent and its associated effects.

Test results on dredge material described earlier further indicated that materials in the area are approved for unconfined in-water disposal and do not contain contaminants in concentrations harmful to organisms occupying the action area. The prohibition of treated wood will also avoid contamination from the migration of creosote and its components (e.g., copper and PAHs) from treated wood in the lotic environments.

e. Aquatic Ecosystems and Organism Determination

Fill and Removal in 404 Waters of the U.S. The Corps does not anticipate significant affects to the aquatic ecosystem. Some short-term loss of microhabitat will occur during the construction period but will be replaced by the completion of the proposed action. Avoidance of the area may occur throughout the construction period as a result of the increased activities and noise, but all species would be expected to return following project completion. Construction is expected to occur year-round. Some work would occur during appropriate in-water work periods determined by fishery agencies to minimize impacts to fish, wildlife and habitat; however, most of the work would occur outside these periods due to weather constraints. The Corps received a Biological Opinion from National Marine Fisheries Service (NMFS). The Opinion evaluated former proposed actions of the same nature that resulted in a larger temporal and geographic footprint than that associated with the current proposed action. Therefore, the Biological Assessments and resulting Opinion and Letter of Concurrence remain relevant for the scope of effects expected from the smaller project footprint. The Services concluded the previous proposed action was not likely to adversely affect any of the listed species in the action area, with the exception of eulachon, Stellar sea lions, and humpback whales. For these species, NMFS determined that Corps actions would not result in jeopardy to the species. The U.S. Fish and Wildlife Service (USFW) also concurred with the Corps' determination that its proposed actions would have no effect or were not likely to adversely affect any of the listed species under their jurisdiction in the action area.

In-water habitats (below MHHW), both shallow intertidal and deeper sub-tidal areas would also be affected by the project. These waters are also considered "waters of the US" as defined by the Clean Water Act. Habitat conversions and impact to 404 waters would occur from lagoon fill, maintenance dredging, jetty cross-sections, turnouts, barge offloading facilities, and causeways. Effects to waters and the aquatic resources residing there would occur on a temporal and spatial scale. Though dredged areas may refill over time and some facilities and fill may be removed, there would still be repeated and chronic site disturbance in these waters over the duration of the project. There would also be permanent lagoon fill at the North Jetty root and temporary, partial lagoon fill at the South Jetty for construction access. Fill would be in place for several years. Barge offloading facilities are a potential method of delivery for stone and other construction materials. If barge offloading facilities are used, this would create the largest impacts to 404 waters of the US and associated aquatic habitat. Therefore, the associated fill acreages and volumes represent the worst-case scenario for spatial and temporal effects.

The calculated extents of impacts were strictly based on the area of habitat that was converted by fill or removal. They did not include value or functional assignments regarding the significance of the conversion, whether it was a beneficial, neutral, or detrimental effect to specific species, nor if conversions created unforeseen, indirect far-field effects. For example, acreage of conversion for shallow sandy sub-tidal habitat to rocky sub-tidal habitat was calculated in the same manner as conversion from shallow intertidal habitat to shallow sub-tidal habitat. Multiple aquatic species utilize these waters, including macro-invertebrates like crabs, benthic organisms, marine mammals, and various other fish and wildlife species. It is also notable that impacts to 404 waters of the US would occur in an area that is listed as Essential Fish Habitat (EFH) for various species as well as in Critical Habitat for several listed ESA species. This impact was described in the 404 (b) (1) analysis.

In WA at MCR, the CWA beneficial use designations for fresh waters by Water Resource Inventory Area (WRIA) include the following general and specific uses: Aquatic Life Uses - Spawning/Rearing; Recreation Uses; Water Supply Uses; Misc. Uses - Wildlife Habitat, Harvesting, Commerce/Navigation, Boating, and Aesthetics. In OR, the following list of beneficial uses were identified: Anadromous Fish Passage; Drinking Water; Resident Fish and Aquatic Life; Estuarine Water; Shellfish Growing; Human Health; and Water Contact Recreation. These designated beneficial uses also include specific water quality criteria to protect the most sensitive uses, which includes use by salmonids for rearing and migration. For this reason, mitigation under the CWA also complements protections and conservation measures under the ESA for salmon and steelhead.

Without drawing a distinction between depths or tidal elevations, initial acreage estimates for all in-water impacts and habitat conversions in 404 waters of the US include:

- North Jetty ~12.38 acres (8.02 lagoon fill – this would occur during Major Maintenance; 0.63. barge offloading facilities, crane set-up pads, and turnouts; 3.73 dredging at offloading facility – the latter actions would occur during the Major Rehabilitation scenario.)
- South Jetty ~13.84 acres (3.5 lagoon fill; 0.4 crane set-up pads, and turnouts; 1.56 barge offloading facilities; 8.38 dredging at offloading facilities – all actions would occur during the Major Rehabilitation scenario.)
- Jetty A ~ 6.62 acres (2.89 barge offloading facility and causeway; 3.73 dredging at offloading facility– all actions would occur during the Major Rehabilitation scenario.)

This results in an estimated total of ~ 32.84 acres of potential in-water conversions and effects to 404 waters of the US other than wetlands.

Shallow-water habitat is especially important to several species in the estuary; thus, specific initial estimates were calculated regarding shallow-water habitat (shallow here defined as -20-feet or -23-feet below MLLW). About 21 acres at these depths would be affected by maintenance dredging and construction of the causeways and barge offloading facilities. About 12 acres would be affected by lagoon fill. However, this estimate does NOT include any expansion of the jetty's existing footprint or overwater structures from barge offloading facilities. For this analysis, there was no distinction drawn between periodically exposed intertidal habitat and shallow-water sandflat habitat. These approximations would be updated as project designs are refined and as additional surveys are completed to quantify changes in jetty and dune cross sections. However, these shallow-water footprints are very small as a relative percentage of the ~19,575 acres of shallow-water habitat available within a 3-mile proximity to the MCR.

Because of these impacts, the Corps has proposed mitigation actions at a ratio of 1.5:1 to offset temporal and spatial impacts to 404 waters and associated aquatic resources. This ratio was determined with input from the resource agencies considering several factors including: beneficial use listings that involve species with EFH and critical habitat designations in the impacted areas, the duration of the construction period, the number of different beneficial uses in the area impacted by the project, and the temporal and spatial extent of the actions. These actions are not proposed to directly mitigate or compensate for any project-related impacts to ESA-listed species but will mitigate for effects to CWA 404 waters of the US. However, the 404 mitigation actions would also complement but are not driven by Conservation Recommendations in the NMFS BiOp for recovery of ESA-listed salmonid habitats and ecosystem functions and processes.

Mitigation features would be commensurate with impacts and would be designed to create or improve aquatic habitat. In-kind mitigation opportunities for impacts to 404 waters were investigated specifically tidal marsh, swamp, and shallow water and flats habitat. Though a specific site or action has yet to be determined for mitigation of impacts to waters other than wetlands, if possible fish access to these mitigation features would be an important consideration.

From the list of possible mitigation features, one or a combination of actions would be selected for further development and implementation in order to offset actions affecting 404 waters. Selection would occur by the Corps with input from the AMT regarding appropriate design and completion of supplementary compliance documentation, and work is anticipated to be completed concurrent with jetty repair actions.

Impacts of fill and discharge to the structure and function of the aquatic ecosystem and organisms are expected to be minor, in that the disposal would temporarily disrupt feeding and food sources of organisms present within the site. Aquatic ecosystem functions would essentially remain unchanged within the high-energy environments of the site. Some organisms would be buried or temporarily displaced by the fill and discharge. It is expected that benthic organisms would rapidly reestablish at the sites within a short time following disposal and rock placement.

Specific opportunities were investigated in the Columbia River estuary and Youngs Bay and several are under consideration to mitigate for impacted aquatic functions in 404 waters of the US. Depending on further development and determination of appropriate mitigation siting for final impacts to 404 waters, a specific project or combination of projects would be designed and constructed concurrently as the proposed repair and rehabilitation options are completed over time. Proposed projects are subject to further analysis, and unforeseen circumstances may preclude further development of any specific project. In all cases, final selection, design, and completion of specific mitigation features is contingent on evolving factors and further analyses including: potential reduction in estimated impact acreage due to alterations in project implementation, hydraulic and hydrologic conditions, cultural resource issues, etc. For this reason a suite of potential proposals has been identified and subsequent selection of one or some combination of these or other projects and designs would occur during continued discussion with resource agencies participating on the AMT. The Corps would make a decision regarding the specific mitigation proposal for waters other than wetlands and then would vet the final designs through the AMT in order to obtain any potential additional clearances, if necessary.

Actions considered and investigated to provide mitigation for in-water habitat impacts include levee breaches, inlet improvements, or tide gate retrofits. However, mitigation efforts must consider in-kind mitigation and are constrained by the project's O&M authority, which precludes acquisition of private property and does not authorize breaches of federal levees. Additional associated actions that were investigated and may be implemented with the wetland mitigation include: excavation in sand dunes and uplands to specified design elevations in order to create additional intertidal shallow-water habitat with dendritic channels and mud flats, and excavation for potential expansion of the floodplain terraces. Though conceptually considered, other specific opportunities for mitigation projects such as the following were not identified but warrant further investigation if none of the projects in the list is determined to be feasible: removal of overwater structures and fill in the estuary; removal of relic pile-dike fields; removal of fill from Trestle Bay or elsewhere; removal of shoreline erosion control structures and replacement with bioengineering features; beneficial use of dredge material to create shallow water habitat features; and restoration of eelgrass beds. Certain pile fields and engineering features may be providing current habitat benefits that could be lost with removal, and such actions would require appropriate hydraulic analysis coordination with engineers and resource agencies.

For potential mitigation projects located in Trestle Bay, there is additional monitoring and assessment opportunity. A separate hydraulic/engineering study under a different project authority could investigate whether or not an expansion of low-energy, intertidal habitat near Swash Lake could effectively provide additional storage capacity and affect circulation in the bay such that erosive pressure at neck of Clatsop Spit could be reduced. This would not be covered under the existing project authority. A previous Section 1135 action that breached a section of the relic jetty structure is speculated to have been the cause of increased circulation and erosion. It would be worth evaluating whether or not projects that expand floodplain and intertidal areas in Trestle Bay provide demonstrable energy dissipation and additional low-energy storage capacity to offset or redirect erosive pressures. Alternatively, if other mitigation concepts are pursued that include removal of additional piles or creation of additional inlets, it would be worth investigating whether these actions could have indirect positive impacts that further reduce concern with erosion at the neck. Evaluating actions in this light would provide valuable information and insight regarding possible solutions and concerns for erosion and breaching at the neck area of Clatsop Spit on Trestle Bay.

Fill in 404 Wetlands. Some wetland fill will be required in order to conduct construction staging, storage, and rock stockpiling activities. Selection of appropriate sites has greatly avoided and reduced the amount wetland fill proposed. After avoidance and minimization measures, the following impacts will be appropriately mitigated per State and Federal requirements:

Wetlands near North Jetty.
All wetlands as well as the lagoon area south of the North Jetty Access Road will be impacted and filled in order to allow construction staging and to reduce processes eroding and undermining the jetty root, to which the lagoon also contributes. Additionally, a few small wetlands north of the roadway will be impacted in order to provide the necessary space for adequate rock storage (enough for 2 years-worth of rock placement) and efficient construction, staging, and access areas. The location of these staging and stockpiling areas have been selected in order to minimize impacts to the higher quality, more extensive wetland complex north of the North Jetty Access Road. There will also be some wetland impacts during replacement of the damaged culvert crossing under the North Jetty Access Road. After avoidance and minimization measures, including implementation of an 80-ft buffer around conserved wetlands north of the roadway and a 200-ft shoreline buffer beyond the Highest High Tide, unavoidable total wetland impacts come to about 1.14 acres out of the 31 acres identified for construction actions, and impacts to other waters of the U.S. via the lagoon equals about 8.02 acres.

Of the wetlands impacted, 0.11 acres are part of a wetland mosaic complex which rated as Category IV Interdunal, Depressional wetlands. 0.65 acres are part of a wetland mosaic complex which rated as Category III Interdunal, Depressional wetlands. 0.25 acres rated as Category II Interdunal Riverine wetlands; and 0.13 acres rated as Category 1 Estuarine, Freshwater Tidal Fringe.

These wetlands all will be mitigated onsite, in an area north of the North Jetty Access Road adjacent to the conserved wetland fringe that extends further north. At a 2:1 mitigation ratio, this equals about 2.28 acres of wetland mitigation, plus the required buffer. This amount of upland area is available, and wetland creation via excavation to appropriate depths, appropriate native plantings, invasive species removal, and buffer requirements will offset impacts to wetland within the same vicinity in which they are proposed. This 2:1 ratio also aligns with mitigation requirements in WA that were developed in partnership with WA Department of Ecology, EPA, and the Corps (WADOE 2006). According to this guidance, estuarine ratios are developed on a case-by-case basis (WADOE 2006). Given the ample rainfall and close proximity to higher functioning wetlands, the likelihood of successful wetland establishment further supports the proposed amount of compensatory wetland mitigation. Though these buffers, ratios, and acreages are likely close to the final amounts, they are subject to change depending on review by WA Department of Ecology and receipt of Conditions in the WA State Clean Water Act 401 Water Quality Certification and the determination of Coastal Zone Management Act Consistency.

Wetlands near South Jetty (on Clatsop Spit).
In order to acquire the 44 acres needed for staging and rock stockpiles, 2.65 acres of unavoidable wetland impacts will occur at the South Jetty. However, by slightly revising locations, maintaining hydrologic connections at wetland crossings, and by maintaining a 50-ft wetland, shoreline, and riparian buffer for preserved areas whenever possible, these impacts have been greatly reduced and minimized relative to initial conservative impact estimates. This includes limiting the roads required to cross wetlands to a 20-ft width and requiring culverts to maintain hydrologic connectivity at crossings. In addition to wetlands, about 3.5 of the existing 5.2 acres of other waters of the US will be impacted in the form of fill in a lagoon area adjacent to and along the jetty. There will be a road and crossing over these waters, which will be culverted in order to maintain flows into and out of the marsh wetland complex; and the 40-ft wide causeway/jetty access roadway will be constructed immediately adjacent to the jetty in order to minimize interference with and impacts to the inlet of the marsh complex.

According to the Cowardin Classification system (1979), of the wetlands impacted, approximately: 0.77 acres are classified as Estuarine-Intertidal-Emergent-Persistent; 0.66 acres are classified as Palustrine-Forested-Needled-leaved-Evergreen; 0.75 are classified as Palustrine-Emergent-Non-persistent; and, 0.47 acres are classified as Palustrine-Forested-Broad-leaved-Deciduous.

Wetlands were scored for grouped service functions as define by the 2010 Oregon Rapid Wetland Assessment Protocol (ORWAP), and the categories depressional and estuarine were identified.

Following this method in determining the types of wetland impacts, this brings the totals under the ORWAP categories to 1.15 acres of impacts to depressional wetlands at the South Jetty, which were ranked relatively as follows: low for hydrologic function and fish support group; and high for water quality, carbon sequestration, aquatic support, and terrestrial support. Alternatively, the relative scores for the grouped service values were: low for hydrologic function, terrestrial support, and public use and recognition; equal for provisioning services, and high for water quality, fish support, and aquatic support. The wetlands also ranked relatively high for ecological condition and sensitivity, and low for stressors.

In comparison to State wetland scores for grouped service functions as define by ORWAP (2010), 1.49 acres of impacts would affect estuarine wetlands at the South Jetty which are ranked relatively as follows: low for hydrologic function, aquatic support, and terrestrial support; and high for water quality, carbon sequestration, and fish support group. Alternatively, the relative scores for the grouped service values were: low for hydrologic function, aquatic support, terrestrial support, and public use and recognition; equal for provisioning services, and high for water quality and fish support. The wetlands also ranked relatively high for ecological condition, and low for stressors and sensitivity.

These wetlands will be mitigated near the impact site in an area identified in Trestle Bay near the channel entrance to Swash Lake. At a 2:1 mitigation ratio, this equals about 5.3 acres of wetland mitigation. Anecdotally, it is thought that the uplands in this area are the result of previous historic fill from the dredging the adjacent channel, so that excavation of uplands would result in restoration of wetland that are likely to be intertidal. There is also a former ODOT mitigation site that the Corps will likely abut. This is an appropriate mitigation site because it is within the same subwatershed (HUC 7), and per the ORWAP scoring and Cowardin classification, the adjacent areas have wetland types similar to those being impacted.

In comparison to State wetland scores for grouped service functions as define by ORWAP (2010), depressional wetlands at the South Jetty mitigation area are ranked relatively as follows: low for hydrologic function, carbon sequestration, fish support group, and aquatic support; and high for terrestrial support; and equal for water quality. Alternatively, the relative scores for the grouped service values were: low for hydrologic function, aquatic support, terrestrial support, and public use and recognition; equal for provisioning services, and high for water quality and fish support. The wetlands also ranked relatively high for ecological condition and sensitivity, and low for stressors.

In comparison to State wetland scores for grouped service functions as define by ORWAP (2010), estuarine wetlands at the South Jetty mitigation area are ranked relatively as follows: low for hydrologic function and water quality; and high for carbon sequestration, fish support group, aquatic support, and terrestrial support. Alternatively, the relative scores for the grouped service values were: low for hydrologic function, aquatic support, terrestrial support, and public use and recognition; equal for provisioning services, and high for water quality and fish support. The wetlands also ranked relatively high for ecological condition and stressors, and low for sensitivity.

Proximity of the uplands to existing wetlands from both classes that had similar ORWAP scores at the mitigation site, in addition to tidal and precipitation hydrology should serve as reasonable indicators for potential success of the mitigation site. For all proposed mitigation, detailed designs, plans, and specifications will be further determined in the next stages of project development and will be constructed concurrent with wetland impacts.

Wetlands near Jetty A.
A total of about 0.91 acres of wetland at Jetty A will also be filled due to rock storage and construction staging activities. Unfortunately, these wetlands cannot be avoided, but impacts to adjacent water of the U.S. will be minimized by implementing a 100-ft buffer beyond the Highest High Tide elevation, which is consistent with the setbacks required for lands designated by Pacific County as Conservancy. Of the wetlands impacted, 0.74 acres rated as a Category III Interdunal, Depressional wetlands with scores under 26. 0.17 acres rated as Category 1 Estuarine, Freshwater Tidal Fringe wetlands.

Because of onsite space constraints and site conditions, these wetlands will be mitigated in the same vicinity as the mitigation area identified at the North Jetty, north of the North Jetty Access Road. At a 2:1 mitigation ratio, this equals about 1.82 acres of wetland mitigation, plus the required buffer. These requirements were determined as described for the North Jetty and align with WADOE guidance (2006). Wetland creation will occur in conjunction with and in addition to the area and process described for compensatory mitigation at the North Jetty. Reduced disturbance coupled with improved potential hydrology and adjacent functioning wetlands at North Jetty compared to at Jetty A make the success of wetland creations more likely at the location at the North Jetty compared to any creation at Jetty A. The total compensatory mitigation acreage at the North Jetty is 4.1 acres, and this area is available as described. As with the North Jetty, though these mitigation ratios and acreages are likely close to the final amounts, they are subject to change depending on review by WA Department of Ecology and receipt of Conditions in the WA State Clean Water Act 401 Water Quality Certification and the determination of Coastal Zone Management Act Consistency.

Wetland fills and culvert installations at all jetties will occur once and could happen during anytime in the construction season depending on weather. Sequentially, these actions will be required prior to several of the other features of the proposed action. Subsequent removal of construction-related culverts would be likely to occur once and could also happen during anytime in the construction season depending on weather and construction needs. Periodic culvert maintenance may be required during construction. Temporally, this limits the repetition of disturbance activities to single event and season on separate jetties.

Where possible, the construction, access, and staging areas at all jetties have been planned so that the footprint would minimize impacts to wetlands and higher value habitat features. Protections and BMPs will be implemented for the identified rare and ranked vegetative communities within the area. Strategic use of uplands and lower quality wetlands for rock storage would be undertaken to the most practical extent in order to avoid and minimize these impacts. However, permanent and temporary wetland fill would occur as a result of construction staging, storage, and rock stockpiles at all three jetties. Fill used to protect the North Jetty root would also affect wetlands. Long-term direct and indirect impacts to wetlands could include permanent wetland fill, potential fragmentation of and between existing wetlands, soil compaction, loss of vegetation, altered hydrology, conversion to upland, and loss of ecosystem functions (water quality, flood storage, nitrogen cycling, habitat, etc.). However, it is expected that effects from wetland impacts and lagoon fill would be insignificant on river functions, as the wetlands are not within the channel prism of the Columbia River. Although these wetlands are connected hydrologically to the Columbia River, wetland fill impacts would not be likely to negatively alter groundwater-stream exchange or hyporheic flow because the wetlands are on accreted land that has formed on stabilized sand shoals behind the jetties. Wetland hydrology is mostly elevation and rainfall dependent, and fill impacts would be relatively insignificant to the Columbia channel. Culverts will be installed to maintain wetland hydrology and connectivity with permanent replacement at the North Jetty and when temporary construction roadways cross wetlands.

The current culvert under the North Jetty Access Road is perched and the regularly disconnected nature of the lagoon system does not appear to support anadromous fish use. Fish surveys were not completed for the stream inlet leading into this wetland complex and creek. An initial sampling survey will be conducted during peak juvenile salmon outmigration to determine whether or not fish salvage and fish exclusion efforts for ESA-listed species is warranted. The Corps will coordinate with NMFS if listed species are identified. Redesign of this system may provide an opportunity to accommodate improved hydrology to newly created wetlands excavated adjacent to the existing wetland complex, and will be further investigated during the hydraulic/hydrologic design analysis.

Though there is an existing razor clam bed adjacent to the vicinity of the proposed dune augmentation, species impacts are not expected because all of the stone placement will occur above MHHW, and haul traffic will be precluded from using Parking Lot B and from driving on the beach during material delivery. Excavator and bulldozer work will be mostly confined to the dry sand areas to further avoid negative species effects.

Because vibratory hammers will be implemented in areas with velocities greater than 1.6 feet per second, the need for hydroacoustic attenuation is not an anticipated issue. Piling will be fitted with pointed caps to prevent perching by piscivorous birds to minimize opportunities for avian predation on listed species. Some of the pilings and offloading facilities will be removed at the end of the construction period.

As mentioned, wetlands at Jetty A and North Jetty would be mitigated immediately north of the North Jetty Road adjacent to the project site. This is an appropriate location for the North Jetty impacts because mitigation remains as near the impact area as possible and compensates for mostly the same wetland types, of which the majority are interdunal depressional. For Jetty A, space is unavailable near the jetty, and the likelihood of successful creation is higher in the North Jetty location due to the land use requirements and disturbance from Coast Guard activities at Jetty A. Based on adjacent reference wetlands at the North Jetty of the same type, appropriate elevations would be determined, and existing uplands would be cleared of invasive species and excavated and graded to the appropriate depths and contours.

Materials removed from impacted wetlands would be reused in the created wetlands as appropriate to take advantage of the existing wetland seed bank and hydrologic soils constituents. Plantings, revegetation, and invasive species removal would also be implemented, including the required buffer around the new wetland area. It is anticipated that upland material removed during wetland creation would be placed as part of the lagoon fill. With ample precipitation, functioning adjacent reference sites, and appropriate plantings, the likelihood of successful wetland establishment is reasonably high.

At the South Jetty, wetland mitigation would take place adjacent to an existing mitigation site further southwest of the impact area at the bottom of Trestle Bay such that there are reference elevations and hydrophytic species to facilitate design planning and vegetation establishment, respectively. The mitigation location near Swash Lake is not as close to the area of impacts as the site at the North Jetty, but the proposed location is further away from areas experiencing heavy recreation and all-terrain vehicle (ATV) use such as is occurring in the existing wetlands on Clatsop Spit. Therefore, the likelihood of successful wetland establishment is greater in the proposed location.

The process for creating the wetlands at the South Jetty site would be similar to that at the North Jetty, but an additional dendritic channel may also be included as appropriate such that newly created wetlands experience an estuarine connection like those that are being impacted by the project. This would also involve excavation to create hydrologic conditions based on tidal and reference site elevations

Monitoring of all mitigation sites is expected to occur prior to, during, and for three years after mitigation implementation. For wetlands, sample reference plots would be established along with a photo point, and success criteria would be based on achievement similar or better functions and values scores relative to those indicated by the delineations for those impacted by the project. Monitoring components would likely include the following elements, which may be modified as further mitigation development details are available: percent survival; percent cover; percent of native vs. non-native species; and achievement of appropriate hydrology. Hydrologic indicators would include establishment of topography and contouring/geomorphology that is similar to adjacent representative sites, and in the case of South Jetty, achievement of regular tidal inundation. Appropriate monitoring criteria would also be developed for the mitigation to waters other than wetlands.

Refinement and implementation of this overall mitigation plan would help protect species and habitats while restoring wetland, inwater, and upland functions affected by the proposed action. Monitoring and maintenance of mitigation will be required to ensure successful establishment of mitigation goals and satisfactory return on investment. These mitigation actions and monitoring results would also be recorded on the Corps mitigation website at: https://sam-db01mob.sam.ds.usace.army.mil:4443/pls/apex/f?p=107:1:1390572094248259. Regular coordination with the AMT would further facilitate implementation of appropriate mitigation for impacts to wetlands and waters that appropriately offset affected habitat and are complementary to the framework for successful protection and preservation of aquatic resources, ESA listed species, and high-value habitat.

No significant or long-term adverse affects on any listed/candidate threatened or endangered species are anticipated. More thorough effects analyses can be found in the associated Biological Assessments and the subsequent Biological Opinion from NMFS and Letter of Concurrence from USFW, herein incorporated.

f. Proposed Disposal Site Determinations

The effects of disposal on physical habitat features include modification of bottom topography. In some cases, disposal may result in the mounding of sediments on the bed of the disposal site. Such conversions may affect plant and animal assemblages uniquely adapted to the particular site conditions these habitats offer. However, the area impacted by disposal would be relatively small and would occur in deeper habitat offshore, in the littoral cell, or near the North Jetty vicinity. The proposed disposal is unlikely to cause large-scale or long-term effects to habitat features.

Disposal is likely to occur on an annual basis originating from one or more of the offloading facilities. The duration of disposal will be limited and will likely occur earlier in the construction season prior to use of offloading facilities. All disposal of dredged material will be placed in previously evaluated and USEPA-approved ODMDS or Clean Water Act disposal sites. No new or different impacts to species or habitats than those previously evaluated by USEPA or other resource agencies for disposal approval are expected from these actions. Per USEPA guidelines, the ODMDS have a Site Management and Monitoring Plan that is aimed at assuring that disposal activities will not unreasonably degrade or endanger the marine environment. This involves regulating the time, quantity, and physical/chemical characteristics of dredged material that is placed in the site; establishing disposal controls; and monitoring the site environs to verify that unanticipated or significant adverse effects are not occurring from past or continued use of the site and that permit terms are met. The relative quantities, characteristics, and effects of the proposed action would not be expected to have different or significant negative impacts to these sites.

Determination of Compliance with Applicable Water Quality Standards

Oregon and Washington have classified the lower Columbia River as water quality-limited and placed it on the Clean Water Act Section 303(d) list for the following parameters: RM 0 to 35.2 for temperature and polychlorinated biphenyls (PCBs); RM 35.2 to 98 for arsenic, dichlorodiphenyl trichloroethane (DDT), PCBs, and temperature; and RM 98 to 142 for temperature, arsenic, DDT, PCBs, and polynuclear aromatic hydrocarbons (PAHs). In Washington, the river also is on the Section 303(d) list for dichloro-diphenyl-dichloroethane, Alpha BHC (a pesticide), mercury, dissolved gas, dieldrin, chlordane, aldrin, dichloro-diphenyl-dichloroethylene, fecal coliforms, and sediment bioassay. In addition, the entire river is subject to an USEPA total maximum daily load for dioxin.

The proposed action is not anticipated to contribute to the pollutant load or degradation of any of these listed water quality parameters. Effects to turbidity have been further described elsewhere and will remain in compliance with forthcoming State 401 Water Quality Certification Conditions. Therefore, the proposed actions are expected to be in compliance with all State and Federal water quality standards.

Potential Effects on Human Use Characteristics

Municipal and Private Water Supplies: There are no municipal or private water supply intakes in the vicinity of the disposal areas.

Recreational and Commercial Fisheries: Crab fishermen generally crab in the area adjacent to the North Jetty. There will be an impact to recreational fisheries along the channel sides of the jetties as a result of barge traffic to and from the barge off-loading platforms. The recreational crab fisherman will be notified as to when the construction activities will take place and they will need to limit their crab pots in the area to accommodate barge traffic.

Water-related recreation:
The proposed action would have minor adverse impacts to recreationists at Cape Disappointment State Park and Fort Stevens State Park, those participating in water-sports and beach activities near the jetties, and those using the jetty structures for fishing and crabbing. Heavy equipment using park roads and parking lots will delay or inconvenience park visitors and water sport and beach recreationists. Park visitors and recreationists are likely to be disturbed by construction noise. A number of restrictions would be in place near the construction zones at each jetty to protect park visitors, water sport and beach recreationists, and the public. Some park roads and parking lots would likely be closed at times during construction. Access to the jetties and nearby beaches would be closed periodically at different times during construction of the individual jetties, which would impact water sport and beach recreationists and anglers. However, large portions of the parks and beaches will remain open and accessible to the public, and the bulk of the construction activities are likely to be seasonally concentrated. The long-term reduction in the levels of recreational activity could also affect the local economy of the Long Beach peninsula and the Warrenton/Hammond area, which are highly dependent on tourism. However, the recreation and local economy impacts are not expected to be significant.

Rehabilitation of the MCR jetty system is expected to have a long-term, positive effect on recreational vessel safety. Maintenance of the shoreline at Clatsop Spit and Benson Beach is also expected, which preserves these areas for recreational opportunities mentioned above. The proposed action would have no effect on utilities and public services in the area. The MCR is the gateway to the Columbia-Snake River system, accommodating commercial traffic with an approximate annual value of $20 billion dollars a year. The proposed action would have a long-term, positive effect on maintaining this vital transportation link and associated economy for the states of Oregon, Washington, Idaho, and Montana, as well as for the Nation as a whole.

Aesthetics: No impacts to aesthetics are anticipated.

Parks, etc: Impacts to both Cape Disappointment State Park and Fort Canby State Park will involve the placement of jetty stone, construction traffic, temporary beach and road closures, and temporary staging areas for construction equipment. The impact will be repaired and any placement of construction material will be removed and the site restored to its pre-construction state. The Corps will coordinate with both Parks to avoid and minimize recreational effects as much as feasible while still accommodating an efficient completion of the project actions.

g. Determination of Cumulative and Secondary Effects on the Aquatic Ecosystem

For a determination of cumulative effects, the effects of the proposed activity have to be viewed in the context of past, present and reasonably foreseeable future actions that may impact environmental resources in the vicinity of the work. The cumulative effects of basin-wide actions are addressed in detail in the 2012 *Revised Final EA for the Major Rehabilitation of the Columbia River Jetty System*.

There have been significant impacts to the Lower Columbia River and MCR from historic actions such as the Federal Columbia River Power System which has greatly modified flow patterns of the Columbia River, the jetty system at the MCR which has altered ocean currents and wave patterns in the vicinity of the proposed activity, and dredging which has prevented meandering of the channel as would be expected in a more natural, dynamic river system. Because the current proposed impacts are intermittent and in a small area relative to the overall size of the MCR and adjacent beaches, this proposed activity will have only a small temporary impact on the aquatic ecosystem in the MCR.

Cumulative effects are defined as, “The impact on the environment which results from the incremental impact of an action when added to other past, present, and reasonably foreseeable future actions regardless of what agency (federal or non-federal) or person undertakes such other actions” (Code of Federal Regulations Title 40, Section 1508.7). Cumulative impacts can result from individually minor, but collectively significant actions taking place over a period of time. The past actions that have occurred in and near the MCR jetties are identified below. Together, these actions have resulted in the existing conditions in the vicinity of the MCR jetties (see Section 2).

- European settlement and associated modifications in the vicinity of the MCR.
- Residential, commercial, and industrial development that occurred in upland areas.
- Original construction of the MCR jetty system and subsequent rehabilitation and repairs.
- Development and recreational use of Fort Stevens and Cape Disappointment State Parks.
- Operation and maintenance of the Columbia River federal navigation channel including navigational structures, periodic dredging and disposal, surveying, etc.
- Designation and use of dredge material disposal sites. Several active and historic disposal sites occur in the vicinity of the MCR. A North Jetty site was established in 1999 to allow placement of dredged material along the jetty toe to protect it from excessive waves and current scour. Its use is limited to disposal of MCR dredged material. From 1999-2008, about 4.4 mcy of dredged material was placed in this site. The shallow water ocean disposal site (SWS) was designated in 2005 by USEPA and lies about 2 miles offshore from the MCR. The SWS is used for disposal of material dredged from the MCR and is of strategic importance to the region; its continual use has supplemented Peacock Spit with sand, sustained the littoral sediment budget north of the MCR, protected the North Jetty from scour and wave attack, and stabilized the MCR inlet. There is a deep water ocean disposal site further offshore from the MCR and a proposed dredge material disposal site near the South Jetty.
- Disposal of dredged material (marine sand) at Benson Beach.
- Deepening of the Columbia River federal navigation channel.

The reasonably foreseeable future actions under consideration in this analysis are identified below. The listing includes relevant foreseeable actions in and near the MCR including those by the Corps, other federal agencies, state and local agencies, and private/commercial entities.

- Mitigation associated with the proposed action.
- Operation and maintenance of the federal navigation channel for authorized project purposes.
- Protection and restoration of existing natural areas and potential acquisition, restoration and protection of natural areas in the vicinity of the MCR by federal, state, and local agencies.
- Operation and maintenance of existing recreational facilities in Fort Stevens and Cape Disappointment State Parks.
- Continued use and development in upland areas for residential, commercial and industrial use in proportion to future increases in population throughout the area.
- Water quality improvements with implementation of more stringent non-point source pollution standards, such as total maximum daily loads (TMDLs).
- The Corps has recently proposed designation of three dredge disposal areas that would provide potential benefit in restoring a sediment budget to the littoral cells in the vicinity of MCR. These sites include: South Jetty Nearshore site (sub-tidal), Benson Beach Intertidal site, and the North Head Nearshore site (sub-tidal). As with the existing North Jetty 404 Site, these additional sites could also help to alleviate some to the scour occurring at the jetty structures.

  The proposed sites are somewhat removed from the immediate geographic vicinity of the jetty Major Rehabilitation proposed actions. These beneficial use sites could also help rebuild the sand shoals at the North and South Jetty foundations. However, it is uncertain in what priority, frequency, and timeframe these new disposal sites would be implemented. Currently, the South Jetty Nearshore site is top priority, followed by Benson Beach, and then the North Head site. The specifics for these sites have been described and evaluated in the Corps' April 2012 *Draft EA for Proposed Nearshore Disposal Locations at the Mouth of the Columbia River Federal Navigation Project, Oregon and Washington*.

The potential cumulative effects associated with the proposed Major Rehabilitation actions were evaluated with respect to each of the resource evaluation categories in this Environmental Assessment. For the proposed action, water quality impacts (suspended sediment and turbidity increases) are expected to be temporary and localized, and BMPs would further reduce effects. Water quality impacts from the proposed action are not expected to be cumulatively significant. Stricter controls placed on foreseeable future projects would reduce short-term, adverse impacts and are anticipated to provide a long-term, cumulative benefit to the water quality in the vicinity of the MCR.

Future development, construction activities, and other foreseeable future projects, in combination with population growth, would produce changes in the amount of impervious surfaces and associated runoff in the vicinity of the MCR. However, all projects are required to adhere to local, state, and federal stormwater control regulations and best management practices that are designed to limit surface water inputs.

Biological resources include fish and wildlife, vegetation, wetlands, federal threatened and endangered species, other protected species, and natural resources management. While historic development in the vicinity of the MCR has caused losses of aquatic and riparian habitats, especially in the lower Columbia River and estuary with resulting adverse impacts to fish and wildlife resources, these actions occurred in a regulatory landscape that is very different from that which exists today. While future development will likely have localized impacts on these resources, under the current regulatory regime these resources are unlikely to suffer significant losses. Moreover, initiatives by federal, state, and local agencies and groups would operate to mitigate the unavoidable environmental impacts of any future development. In addition, there are a number of actions that are ongoing or planned that would provide a cumulative, long-term improvement to aquatic resources and habitat, especially for ESA-listed salmonid species, including the implementation of the Conservation Recommendations and Reasonable and Prudent Alternatives specified in the 2008 NMFS Federal Columbia River Power System Biological Opinion and more stringent non-point source pollution standards. Any future federal actions would require additional evaluation under the National Environmental Policy Act at the time of their development.

In the long term, mitigation associated with the proposed action would provide the benefits previously described, including an increase in the overall square footage of wetlands and improve uplands, potentially also improving wetland-stream hydrologic functions in the Columbia River estuary.

A long-term reduction in the levels of recreational activities near the MCR jetties would occur during the proposed action and future activities. This reduction in recreation activity could also affect the local economy of the Long Beach peninsula and the Warrenton/Hammond area, which are highly dependent on tourism. These recreation and local economy impacts are not expected to be significant. The proposed action and future activities are not expected to cause a cumulative, adverse change to population or other indicators of social well being, and should not result in a disproportionately high or adverse effect on minority populations or low-income populations. No cultural and historic resources are expected to be impacted by the proposed action. Reasonably foreseeable future actions will be subject to review and approval by State Historic Preservation Officer.

The proposed action would facilitate effective maintenance of the Columbia River navigation channel, as it would improve and restore the function of the MCR jetty system. The jetty system helps reduce shoaling in the main channel and directs and concentrates currents in order to preserve sufficient depths in the main channel. While operations and maintenance dredging would continue at the MCR, the proposed action is intended to reduce the migration of littoral drift into the channel; upon completion, this may reduce the volumes and frequency of future operation and maintenance dredging at the MCR. Another benefit of reducing littoral drift into the MCR is the preservation of Benson Beach and Clatsop Spit. The dredge disposal at Benson Beach and the other existing SWS, North Jetty 404 site, and proposed North Head beneficial use sites may complement the proposed infill actions that are intended to protect the North Jetty root. Similarly, this may also be the case if new disposal sites are implemented at both the South Jetty Nearshore and Intertidal sites near the South Jetty trunk, root, and dune augmentation areas.

Shoreline preservation could be complemented by the infill activities, dredge disposal, and further stabilization and augmentation efforts at the spit.

In conclusion, this cumulative effects analysis considered the effects of implementing the proposed action in association with past, present, and reasonably foreseeable future Corps' and other parties' actions in and near the MCR. The potential cumulative effects associated with the proposed action were evaluated with respect to each resource evaluation category and no cumulatively significant, adverse effects were identified. In addition, there are a number of actions that are ongoing or planned that would provide a cumulative, long-term improvement to aquatic and wildlife resources and habitat.

Coordination

The proposed work has been coordinated with the following agencies:

Federal
U.S. Environmental Protection Agency
U.S. Fish and Wildlife
National Oceanic and Atmospheric Administration

State of Oregon
Oregon Department of Fish and Wildlife
Oregon Department of State Lands
Oregon Department of Environmental Quality
Oregon Parks and Recreation Department
Oregon Department of Land Conservation and Development
Washington Department of Fish and Wildlife
Washington Parks and Recreation Department
Washington Department of Ecology

An agency coordination meeting was held on May 25, 2006 for the purpose of introducing the project to several agencies that will be involved with review of environmental documents. Staff from the USACE Portland District presented the current state of environmental review and engineering modeling to the NMFS, USFWS, WDOE, ODEQ, and Oregon Department of Land Conservation and Development.

On April 13, 2007 the USACE met with the U.S. Geological Survey (USGS) and Portland State University regarding numerical modeling in support of the MCR rehabilitation project. Also in 2007, four resource agency meetings and presentations were held regarding the MCR project on April 27, May 30, July 11, and September 5. A public information meeting was held in Astoria, Oregon on July 31, 2006. After a presentation about the MCR jetty rehabilitation project, the public was invited to ask questions and talk to USACE staff about the project. In addition, the USACE Portland District established a web site to keep the public informed about the repair/rehabilitation of the MCR jetties located at https://www.nwp.usace.army.mil/issues/jetty/home.asp.

An initial draft EA was distributed for a 30-day public review in June 2006. Due to changes in the project description, a revised draft EA was prepared. The revised 2010 draft EA (*Revised Draft Environmental Assessment Columbia River at the Mouth, Oregon and Washington Rehabilitation of the Jetty System at the Mouth of the Columbia River, January 2010*) was informed by and revised to reflect and address comments received, as appropriate. The revised draft EA was issued for a 30-day public review period in January 2010. The revised draft EA was provided to federal and state agencies, organizations and groups, and various property owners and interested publics. In addition, a public information meeting was held in Astoria, Oregon on February 3, 2010. After a presentation by the Corps about the MCR jetty rehabilitation project, the public was invited to ask questions and talk to USACE staff about the project. Another public information meeting to describe likely construction techniques was also held on June, 4, 2010, at Fort Vancouver, WA to solicit input from potential construction contractors and to provide additional information regarding the feasibility of the Major Rehabilitation and Repair approach. The original EA was finalized and posted on the Corps website along with the 404 (b) (1) evaluation in May 2011.

After additional project developments, the 2012 revised final EA updates and corrects the 2011 final EA by updating the alternative plans considered and the Preferred Alternative actions proposed for the North Jetty, South Jetty and Jetty A. The 2011 and 2012 EAs were also informed by and revised to reflect and address the above public notice comments, as appropriate. After the previous 30-day public review period and receipt of comments from federal and state agencies, organizations and groups, and various property owners and interested publics, public concerns identified in comments were addressed.

Besides these official public information meetings and distribution of the EA, the Corps has also had multiple meetings with various regulatory agencies to ensure regular coordination throughout project development. Also as mentioned, the Corps has proposed formation of a modified interagency Adaptive Management Team to keep resource agency partners apprised of any potential project changes or challenges that arise during implementation.

V. Findings of Compliance (40 CFR § 230.12)

a. Adaptations: No significant adaptations of the guidelines were made relative to this evaluation.

b. Alternatives: The No Action alternative was considered and subsequently rejected. Breaching and deterioration of the jetties would cause severe ecological and economic damage to the region. Multiple other options and alternatives were also evaluated resulting in the Preferred Alternative described in the 2012 *Revised Final Environmental Assessment Columbia River at the Mouth, Oregon and Washington Rehabilitation of the Jetty System at the Mouth of the Columbia River* incorporated herein.

c. Water Quality Standards [40 CFR § 230.10(b) (1)]. Water quality certification from both the States of Washington and Oregon will be requested. The Corps does not anticipate its actions will degrade any of the water quality parameters, including those listed for the Columbia.

d. Toxic Effluent Standards [40 CFR § 230.10(b) (2)]. The proposed action would not violate the toxic effluent standards of Section 307 of the Clean Water Act.

e. Endangered Species [40 CFR § 230.10(b) (3)]. The dredging of materials and placement of fill would not harm any endangered species or their habitat as discussed under the Endangered Species Act of 1973. This is further demonstrated in the associated Biological Assessments and Biological Opinion and Letter of Concurrence from the Services.

f. Marine Sanctuaries [40 CFR § 230.10(b) (4)]. No marine sanctuary designated under Title III of the Marine Protection, Research, and Sanctuaries Act of 1972 will be affected by the proposed action.

g. No Significant Degradation [40 CFR § 230.10(c)].

   1) The proposed action would not result in significant adverse effects on human health or welfare, including municipal water supplies, plankton, fish, shellfish, or wildlife.

   2) Significant adverse effects on life stages of aquatic life and other wildlife dependent on the aquatic ecosystem, on ecosystem diversity, productivity, or stability, or on recreational, esthetic, or economic values would not occur.

   3) No significant adverse effects on aquatic ecosystem diversity, productivity and stability are expected due to avoidance, impact minimization, and implementation of best management practices, mitigation, and monitoring actions, to assess project-related impacts throughout the project life.

   4) No significant adverse effects of the fill material are expected on recreational, aesthetic and economic values.

h. Minimization of Impacts [40 CFR § 230.10(d)]. Appropriate actions to minimize potential adverse impacts would be specified in the construction contract.

   1) Other alternatives were considered including the "no action" alternative for the project. These alternatives were dismissed for reasons detailed in Section III above and for reasons further described in the Revised 2012 EA.

   2) The proposed action is in compliance with applicable State water quality standards. . The Corp will obtain State 401 Water Quality Certifications prior to any inwater work or wetland fill. In addition, a National Pollutant Discharge Elimination System permit will be required from the USEPA and obtained prior to disturbance and work performed on federal lands in Washington, and the Corps intends to use the Construction General Permit (CGP) after development of an appropriate Stormwater Pollution Prevention Plan (SWPPP). The Corps has a general 1200-CA permit (#14926) through the ODEQ that, though expired, has been administratively extended indefinitely by ODEQ and remains in effect. The Corps intends to maintain compliance with its terms and conditions,

including development of an Erosion and Sediment Control Plan prior to disturbance and work performed on federal, state, and local lands in the Oregon State.

3) The proposed action would not violate the toxic effluent standards of Section 307 of the Clean Water Act. State water quality certification has been requested for the project.

4) Information on federally listed species and designated critical habitat was presented in the EA. Biological Assessments (BAs) were also prepared for the proposed action to address federally listed species under the jurisdiction of the NMFS and USFWS. The BAs were provided to the respective agencies for review and consultation.

   On March 18, 2011, The Corps received a Biological Opinion from NMFS indicating that the Corps' proposed actions were not likely to adversely affect any listed species, with the exception of eulachon, humpback whales, and Stellar sea lions (2010/06104). For these species, NMFS determined that Corps actions were not likely to jeopardize the existence of the species. NMFS also concluded that Corps actions were not likely to adversely affect any of the current or proposed critical habitats. There was a Conservation Recommendation to carry out actions to reverse threats to species survival identified in the Columbia River Estuary ESA Recovery Plan Module for Salmon and Steelhead.

   On February 23, 2011 the Corps received a Letter of Concurrence from USFW regarding potential effects to species under their jurisdiction (13420-2011-I-0082). The Corps' determined its actions would have no effect on listed species, with the exception of bull trout, marbled murrelets, and snowy plover. The Corps concluded that its actions were not likely to adversely affect these species or their critical habitat. The USFW concurred with the Corps' determination. USFW also included four Conservation Recommendations to protect and improve snowy plover habitat and manage attractant waste derived from construction actions.

5) The proposed project would not result in significant adverse effects on human health and welfare, including municipal and private water supplies, recreational and commercial fishing, plankton, fish, shellfish, and wildlife. Significant adverse effects on aquatic ecosystem diversity, productivity, and stability, and recreational, esthetic, and economic values would not occur. Any unavoidable wetland or 404 waters impacts will be appropriately mitigated.

6) Appropriate steps to minimize potential adverse impacts have been further detailed in the EA and will be specified in the Environmental Protection standards prepared for the project.

With the inclusion of appropriate and practical measures to minimize adverse effects to the aquatic ecosystem, the proposed action is determined to be in compliance with the requirements of the Section 404(b) (1) guidelines.

VI. Conclusions

On the basis of the factual determinations and findings made above, the proposed fill materials comply with the Guidelines at 40 CFR Part 230 and with the requirements of Executive Order 11990 (Protection of Wetlands) and based on the factual determinations and findings made above that the proposed fill material associated with this project is in the overall public interest.

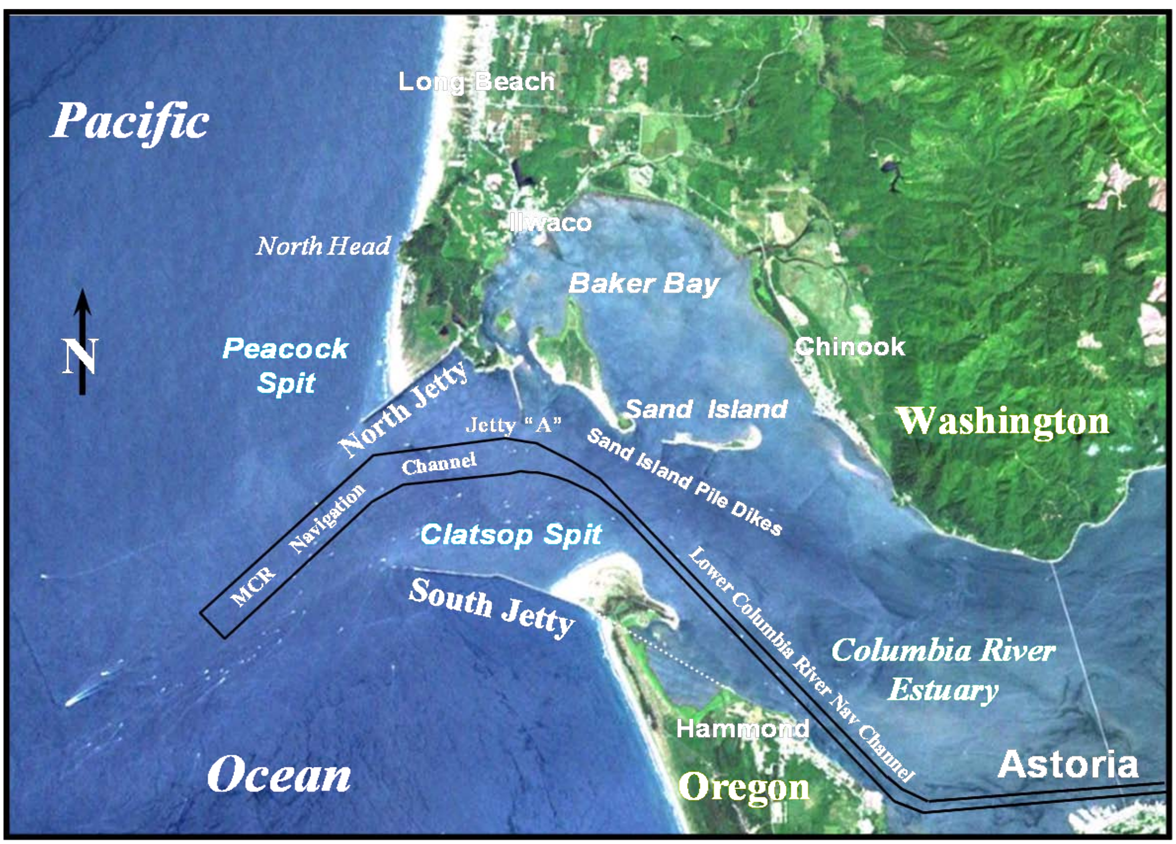
INTRODUCTION

The U.S. Army Corps of Engineers (Corps) prepared and is submitting this Biological Assessment (BA) to the National Marine Fisheries Service (NMFS) in compliance with the requirements of Section 7(c) of the Endangered Species Act of 1973, as amended. This BA evaluates effects to species listed on the Endangered Species Act (ESA) and their designated and proposed critical habitat, as well as an Essential Fish Habitat (EFH) analysis, in accordance with the Magnuson-Stevens Fishery Conservation and Management Act (MSA) for the Major Rehabilitation of the Jetty System at the mouth of the Columbia River (MCR). Federally listed marine and anadromous fish, mammal, and turtle species are present in the vicinity of the proposed action, as well as EFH species including five coastal pelagic species, numerous Pacific Coast groundfish species, and coho and Chinook salmon. The Corps also requests a Conference Opinion regarding effects to proposed critical habitat for leatherback turtles. Additionally, prior to construction activities, an incidental harassment authorization (IHA) for marine mammals at the South Jetty will be obtained. The Corps did not request a species list from NMFS. The Corps maintains this jetty system and navigational channels as appropriate based on necessity and appropriations. The Corps is currently proposing major repair and rehabilitation for the North Jetty, South Jetty, and Jetty A located at the MCR (Figure 1).

Figure 1. Location of the Jetty System at the MCR



PROJECT AUTHORITY

For the authorization for the actual construction of the MCR jetties, the present navigation channel and configuration of the inlet at the mouth of the Columbia River are the result of continuous improvement and maintenance efforts have been undertaken by the Corps Portland District since 1885. Congress has authorized the improvement of the MCR for navigation through the following legislation. Senate Executive Document 13, 47th Congress, 2nd Session (5 July 1884) authorized the Corps to construct the South Jetty (first 4.5 miles) for the purpose of attaining a 30-foot channel across the bar at the MCR. House Document 94, 56th Congress, 1st Session (3 March 1905) authorized the Corps to extend the South Jetty (to 6.62 miles) and construct a North Jetty (2.35 miles long) for the purpose of attaining a 40-foot channel (0.5 mile wide) across the bar at the MCR. House Document 249, 83rd Congress, 2nd Session (3 September 1954) authorized a bar channel of 48 feet in depth and a spur jetty ("B") on the north shore of the inlet. Funds for Jetty "B" construction were not appropriated. Public Law 98-63 (30 July 1983) authorized the deepening of the northern most 2,000 feet of the MCR channel to a depth of 55 feet below mean lower low water (MLLW). The MCR federal navigation project was originally authorized (in 1884) before formulation of local sponsor cost sharing agreements; therefore, all navigation maintenance and improvements at MCR are borne by the Federal Government.

The authority for maintenance of the MCR jetties comes from the original authority for construction of the project and then with Corps' policies for the operations, maintenance, and management of a Corps' project (Chapter 11 of EP 1165-2-1). For navigation, completed projects like the MCR have established that operations and maintenance (O&M) is solely a federal responsibility to be accomplished at federal cost.

When maintaining a Corps' project, there is regular O&M, major maintenance, and major rehabilitation. Major rehabilitation consists of either one or both of two mutually exclusive categories, reliability or efficiency improvements.

- <u>Reliability</u>. Rehabilitation of a major project feature that consists of structural work on a Corps operated and maintained facility to improve reliability of an existing structure, the result of which will be a deferral of capital expenditures to replace the structure. Rehabilitation will be considered as an alternative when it can significantly extend the physical life of the feature (such as a jetty) and can be economically justified by a benefit/cost relationship. Each year the budget EC delineates the dollar limits and construction seasons (usually two construction seasons).
- <u>Efficiency Improvements</u>. This category will enhance operational efficiency of major project components. Operational efficiency will increase outputs beyond the original project design.

Thus, the authority for maintenance of the MCR jetties comes from the authorization documents for the project and/or the authority to operate and maintain the structures.

CONSULTATION HISTORY

As the project's preferred alternative has evolved, the Corps has been coordinating with NMFS since 2005. On November 5, 2007, the Corps submitted an earlier version of this Biological Assessment (BA) proposing a larger jetty rebuilds. On January 11, 2008, the Corps provided a memo responding to inquiries NMFS had made regarding the BA. Subsequently, the BA was withdrawn later in January of 2008 due to significant changes in the project description.

Regular coordination with NMFS and was reinstituted in the spring of 2010 after publication of the revised Draft Environmental Assessment in which a new proposed action with a smaller project footprint was determined to be the preferred alternative with which the Corps of Engineers would be moving forward. In August of 2010, a site visit to view construction activities on the Tillamook North Jetty was conducted with NMFS and Corps representatives in order to observe and to compare construction activities and design elements associated with a similar, smaller-scale jetty rehabilitation project. To ensure development of the updated Biological Assessment fully addressed ESA Consultation requirements and expectations, since July 2010 the Corps also has been meeting on a nearly weekly basis with NMFS to further discuss and describe proposed actions, related studies, and jetty design model runs.

The Corps has determined that the proposed action will have **no effect** on the following species of marine turtles: loggerhead sea turtles (*Caretta caretta*), green sea turtles (*Chelonia mydas*), and olive ridley sea turtles (*Lepidochelys olivacea*). The Corps is also seeking a Conference Opinion regarding proposed critical habitat for leatherback sea turtles, and has determined the proposed actions may affect but are **not likely to adversely affect** (NLAA) leatherback sea turtles. The Corps has determined that the proposed action is **not likely to adversely affect** (NLAA) the following marine mammal species: blue whales (*Balaenoptera musculus*), fin whales (*B. physalus*), humpback whales (*Megaptera novaeangliae*), sperm whales (*Physeter macrocephalus*), killer whales (*Orcinus orca*) and sei whales (*B. borealis*). Previously, for interim repairs on the South Jetty, the Corps obtained an IHA permit as it was believed that sea lions would be disturbed during construction (Corps 2007). The Corps has determined that the proposed action is **likely to adversely affect** Stellar sea lions (*Eumotopias jubatus*) and will again obtain an IHA permit from NMFS for incidental harassment of Steller sea lions during construction, as well as non-federally listed California sea lions and harbor seals. Through this Biological Analysis the Corps has further determined that the proposed action may affect and is **likely to adversely affect** eulachon (*Thaleichthys pacificus*). The Corps has also determined that the proposed action is **likely to adversely affect** green sturgeon (*Acipenser medirosris*). Finally, the Corps has determined that the proposed action may affect and is **likely to adversely** affect all runs of listed salmonids and steelhead discussed further in this BA.

BACKGROUND

The MCR project consists of a 0.5-mile wide navigation channel extending for about 6 miles (3 miles seaward and shoreward of the tip of the North Jetty) through a jettied entrance between the Columbia River and the Pacific Ocean on the border between Washington and Oregon. Figure 1 shows the navigation project and the three primary navigation structures, the North Jetty, South Jetty, and Jetty A. Those structures are shown in more detail in Figure 2. The North Jetty and Jetty A are located in Pacific County, Washington, near Ilwaco and Long Beach on the Long

Beach Peninsula. The South Jetty is located in Clatsop County, Oregon near Warrenton/Hammond and Astoria.

Figure 2. Rubble-mound Jetties at the MCR

Top left photo shows the South Jetty looking east. The remnant feature shown disconnected from the primary structure is the concrete monolith that was constructed in 1941. The top right photo shows Jetty A. The bottom photo illustrates the North Jetty and the shoreline north of the MCR.

South Jetty

Jetty A

North Jetty

From 1885 to 1939, three rubble-mound jetties with a total length of 9.7 miles were constructed at the MCR on massive tidal shoals. The jetties were constructed to accelerate the flow of the river, which helps maintain the depth and orientation of the navigation channel, and to provide protection for ships of all sizes (both commercial and recreational) entering and leaving the Columbia River. The intention was to secure a consistent navigation channel through the coastal inlet, though morphology of the inlet currently remains in a dynamic, high-energy state. Under such conditions, the jetties have experienced significant deterioration since construction, mainly due to extreme wave attack and foundation instability associated with erosion of the tidal shoals on which the jetties were built.

The initial 4.5-mile section of the South Jetty was completed in 1895-1896. The Rivers and Harbor Act of 3 March 1905 authorized the extension of the South Jetty to 6.6 miles, with the 2.4-mile extension completed in 1913. Historical records show that six spur groins were constructed along the channel side of the South Jetty. Four of the groins were subsequently buried by accreted shoreline or sand shoal. Nine repairs to the South Jetty have been completed with the latest one in 2007. To date, jetty rock placement at the South Jetty totals approximately 8.8 million tons. In spite of these repairs and structural features, over 6,100 feet of head loss has occurred at the South Jetty.

The North Jetty was completed in 1917. Three repairs to the North Jetty have been made with the last one completed in 2005. To date, jetty rock placement totals approximately 3.4 million tons. Since initial construction, about 0.4 miles of the North Jetty head has eroded and is no longer functional.

Jetty A was constructed in 1939 to 1.1 miles in length in connection with rehabilitation of the North Jetty for the purpose of channel stabilization. Its purpose was to assist in controlling the location and direction of the ebb tidal flow through the navigation entrance. Improvements made from 1930 to 1942 (including addition of Jetty A and Sand Island pile dikes) produced the present entrance configuration.

The construction and repair history of the MCR jetties is summarized in Table 1.

The Corps' dredging and in-water disposal of dredged sediments to maintain the above referenced authorized navigation channel is conducted under the provisions of sections 102 and 103 of the Marine Protection Reserve and Sanctuaries Act of 1972, sections 401 and 404 of the Clean Water Act of 1977, and in accordance with Regulations 33 CFR parts 335-338.

Table 1. Construction and Repair History for the MCR Jetties

1881: Proposed project to build a strong pile-dike, 3 feet high about at low tide, 8,000 feet long and 20 feet wide along a line previously established on the south side. The structure to start near the northeast corner of Fort Stevens, following the 12-foot curve, dike will be directed a little westward of the outer part of headland of Cape Hancock. It was stated that work commence soon (during summer and autumn) because channel maintenance is dependent upon building up Clatsop Spit.

1883: A jetty plan approved by the Board of Engineers from the south cape of the entrance on the spit. A survey was conducted in October-November of the south cape, Point Adams, to extreme low water. The jetty extends from Point Adams and makes the distance between the outer end of the jetty and Cape Disappointment the same as the distance between Chinook Point and Point Adams. The Board stated that any structures placed in-river should not harm the river and should keep the channel open using the tide; therefore, the jetty should not obstruct the entry of the flood tide. The jetty design called for a crest elevation at low water level. Estimated depths of various jetty sections from the landward end are: 5,000 feet - less than +6 feet; 7,500 feet – +6 to +11 feet; 4,000 feet – +11 to +16 feet; and 7,500 feet – +16 to +21 feet. Jetty crest elevation was designed to be at low water level because of wave violence that could harm a higher jetty. The logic was that a higher jetty could be built, if needed later, by placing more stone on the existing jetty. A jetty height to mid-tide level was suggested but not recommended because the lower jetty would be quite effective in directing the ebb tide and would interfere less with the flood tide. A higher jetty would result in higher maintenance costs due to the jetty being more exposed to wave action.

1884: The improvement plan for MCR was approved by the Rivers and Harbors Act of July 5, 1884 to maintain a channel 30 feet deep at mean low tide by constructing a low-tide jetty, about 4.5 miles long, from near Fort Stevens on the South Cape to a point about 3 miles south of Cape Disappointment.

1886-1896: Original construction South Jetty from Fort Stevens (station 25+80) across Trestle Bay and Clatsop Spit to station 250+20. Rock placed with a natural slope to an elevation from 4 to 12 feet, crest width roughly 10 feet. "The jetty, of a brush-mattress and stone ballast, was built for 1,020 feet from ordinary highest tide-line, and minor constructions added." Material has filled along the jetty's south side, moving the shoreline seaward. Highest tide-line is located at tramway station 30+50. A 115 feet long spur was built landward of the jetty for shore protection. A 510 feet long sand-catch, consisting of heavy beach drift and loose brush, was built on the south side of landward end of the jetty to continue filling the old outlet of a lagoon at extreme end of Point Adams. Jetty stone was originally dumped in ridges, but waves flattened and compacted the rocks to a width of 50 feet. The report indicated urgency to extend the jetty to prevent further deterioration of the bar channel.

1889: The South Jetty now under construction for 1.5 miles. Clatsop Spit has more material visible at low water and the river channel has a tendency towards a straight course out to sea. Tillamook Chute being closed. Sand building up south of the jetty adjacent to and in front of the mattresses as they are constructed.

1890: South Jetty construction is 3.25 miles underway. Jetty elevation at MLLW for about 3 miles. 1.25 miles of tramway to be constructed. Clatsop Spit building up, the outflowing waters being concentrated over the channel bar. Station 25+80 considered the beginning of the jetty. The jetty mattress has advanced from stations 99+04 to 194+08. The jetty elevation is at MLLW to station 170+00. From Station 170+00 to the end of mattress work, there is about 9 feet of rock on top of the mattress. At station 65+00, there were signs of sinking and a large amount of rock was dumped in place.

1903-1913: Extension of South Jetty. Crest elevation of jetty raised to 10 feet MLLW from stations 210+35 to 250+20, and rock placed from stations 250+20 to 375+52, elevation increasing in steps to 24 feet MLLW. Crest width is 25 feet and side slopes are natural slope of rock. Seaward bend in the jetty is added and called the "knuckle."

1913-1917: Original construction of North Jetty from stations 0+00 to 122+00. Side slopes are 1 vertical by 1.5 horizontal (1:1.5) and crest width is 25 feet. Crest elevation varies from 15 to 32 feet.

1931-1932: Repair South Jetty from stations 175+00 to 257+68.7 (shoreline to knuckle), side slopes 1:1.5, crest elevation 24 feet MLLW, and crest width 24 feet. This is first maintenance for South Jetty. The jetty had been flattened to about low water level. 2.2 million tons of stone placed in super-structure. The work completed in 1936. The end of jetty would unravel 300 feet or more, so a solid concrete terminal was constructed above low water level. The terminal was located 3,900 feet shoreward of the original jetty end that was completed in 1913.

1933-1934: Repair of South Jetty from stations 257+68.7 to 305+05 (knuckle to middle of outer segment). Two level cross section with crest elevations of 17 and 26 feet. Crest width of each level is 24 feet. Side slopes are 1:1.5 on channel side and vary from 1:1 to 1:1.75 to 1:2 on ocean side.

1935-1936: Repair South Jetty from stations 305+05 to 353+05 (middle of outer segment to existing end). Similar design to 1933-1934 repair.

Table 1 (continued). Construction and Repair History for the MCR Jetties

1936: Stone/asphalt cone-shaped terminal constructed on South Jetty from stations 340+30 to 344+30. Crest width of approximately 50 feet and elevation varied from 23 to 26 feet. Side slopes are 1:2.

1937-1939: Repair of North Jetty from stations 68+35 to 110+35. Crest elevation 26 feet and crest width 30 feet. Side slope 1:1.25 on ocean side and 1:1.5 on channel side.

1939: Original construction of Jetty A from stations 40+93.89 to 96+83. Crest width is 10 feet from beginning to station 53+00, 30 feet in width, and elevation at 20 feet from this point on. Four pile dikes completed at Sand Island.

1940: Repair of South Jetty with replacement rock in locations as needed.

1940-1942: South Jetty repair from stations 332+00 to 343+30. Concrete terminal/stone foundation added. Crest elevation from 8-20 feet and crest width from 50-75 feet, 10 inches. Side slopes determined by concrete terminal shape.

1945-1947: Repair Jetty A from stations 78+00 to 96+00. Crest elevation to 20 feet with crest width of 40 feet.

1948-1949: Repair 300 feet of Jetty A from stations 92+35 to 95+35 with a crest elevation of 20 feet, a crest width of 30 feet, and side slopes of 1:1.25.

1951: Repair Jetty A from stations 91+50 to 93+00 with a crest elevation of 20 feet MLLW, a crest width of 30 feet, and side slopes of 1:1.5.

1952: Repair of Jetty A from stations 90+00 to 94+00 with a crest elevation of 20 feet, a crest width of 30 feet, and side slopes of 1:1.5.

1958: Repair of Jetty A from Stations 41+00 to 79+00. Crest elevation raised to 20 feet and a crest width of 20 feet from Stations 41+00 to 56+00. Crest width is 30 feet from Stations 61+00 to 79+00.

1961-1962: Repair Jetty A from stations 50+00 to 90+50, with no repairs from Stations 68+00 to 76+50. Crest elevation built with a 10% grade from 20 feet to 24 feet from stations 50+00 to 68+00. The crest elevation was raised to 24 feet from stations 76+50 to 90+50.

1961: South Jetty repair from stations 194+00 to 249+00 (before knuckle, current stationing). Crest elevation varies from 24 to 28 feet and crest width is 30 feet. Channel side slope 1:1.25 and ocean side slope 1:1.5. Repairs from stations 38+00 to 93+00 (old stationing). Elevation at station 38+00 is +24 feet and then increased with a 0.5% grade up to +28 feet for the remainder of repair section. The repair centerline is located 13 feet north of the centerline of the original jetty design. The design crest width is 30 feet. North slope is 1:1.25 and south slope is 1:1.5.

1962-1965: South Jetty repair from stations 249+00 to 314+05 (beyond knuckle). Crest elevation begins at 28 feet and transitions to 25 feet for most of section. Side slopes vary from 1:1.5 to 1:2 and crest width is 40 feet (this appears to be the furthest seaward intact portion of current jetty). Repairs made from stations 93+00 to 157+50 (old stationing). The crest elevation is +28 feet at station 93+00, then decreases to +25 feet at station 95+00, and then continues with this elevation to end of the repairs. The crest width is 40 feet and has a slope of 1:1.5 from stations 93+00 to 152+00. Slope then transitions to 1:2 from stations 152+00 to 154+00. The centerline of the repair is 15 feet south of the trestle centerline.

1965: Repair North Jetty from stations 89+47 to 109+67 with a crest elevation of 24 feet and crest width is 30 feet. Side slopes vary from 1:1.5 to 1:2.

1982: Repair South Jetty from stations 194+00 to 249+00 (segment before knuckle). Crest elevation varies from 22 to 25 feet MLLW. Crest width varies from 25-30 feet and side slopes 1:1.5. Crest elevation varies from +22 feet at station 38+00 to +25 feet at station 80+35 (old stationing). From stations 44+50 to 80+35, crest width is 30 feet and slope is 1:1.5. Centerline of repairs has 10 feet maximum variance to the north for the South Jetty control line. From stations 80+35 to 93+00, centerline of repairs is the same as South Jetty control. Crest elevation +25 feet, width varies from 25-30 feet, side slope is 1:1.5.

2005: Interim repair of North Jetty (stations 55+00 to 86+00). Crest elevation +25 feet with side slope of 1:1.5.

2006: Interim repair of South Jetty (stations 223+00 to 245+00). Crest elevation +25 feet with side slope of 1:2.

2007: Interim repair of South Jetty (stations 255+00 to 285+00). Crest elevation +25 feet with side slope of 1:2.

DESCRIPTION OF THE PROPOSED ACTION

OVERVIEW

The Corps proposes to perform modifications and repairs to the North and South Jetties and Jetty A at the MCR that would strengthen the jetty structures, extend their functional life, and maintain deep-draft navigation.

Proposed actions are generally comprised of four categories applicable to each jetty: (1) engineered designs elements and features of the physical structures; (2) construction measures and implementation activities; (3) proposed 7(a)(1) habitat improvement measures and wetland mitigation actions to improve habitat for the benefit of listed species and to offset wetland fill, and (4) proposed establishment of and coordination with an Adaptive Management Team (AMT) comprised of Corps' staff and representatives from appropriate Federal and State agencies.

It is notable that the duration of the construction schedules is 20 years, with a 50-year operational lifetime for the MCR jetty system. Therefore, an inherent level of uncertainty exists regarding dynamic environmental conditions and actual conditions of and at each of the jetties. For this reason, in all cases where areas, weights, and volumes (tons, acres, cubic yards, etc.) or other metrics are indicated, these are best professional estimates and may vary by greater or lesser amounts within a 20% range when final designs are completed. These amounts represent Corps' and staff's best professional judgments of what the range of variability could entail as the design is further developed and as on-the-ground conditions evolve over the 20-year construction schedule. The Corps maintains an active jetty monitoring and surveying program that will further inform the timing and design of the proposed action in order to facilitate efficient completion of the project and whenever possible to avoid emergency repair scenarios.

(1) Design elements and structural features specific to each jetty include the following:

- North Jetty – Scheduled repairs addressing the existing loss of cross section and the addition of engineering features designed to minimize future cross section instability are planned. The cross section repairs are primarily above MLLW, with a majority of stone placement not likely to extend beyond -5 ft below MLLW. In order to address the structural instability of the jetty cross-section, four spur groins will be added and the jetty head (western-most section) will be capped with large stone. Groins will be constructed primarily on existing relic stone and the head capping will be placed on relic as well as jetty stone that is above MLLW. The shore-side improvements that have been identified are culvert replacement and lagoon fill. These actions are designed to stop the current ongoing erosion of the jetty root.

- South Jetty – Scheduled repairs addressing the existing loss of cross section and the addition of engineering features designed to minimize future cross section instability are planned. The cross section repairs are primarily above MLLW, with a majority of stone placement not likely to extend beyond -5 ft below MLLW. In order to address the structural instability of the jetty cross-section, five spur groins will be added and the jetty head (western-most section) will be capped with large stone. Groins will be constructed primarily on existing relic stone and the head capping will be placed on relic as well as jetty stone that is above MLLW. Augmentation of the dune at the western shoreline extending south from the jetty root has been included in the repair plan. This action is intended to prevent the degradation of the jetty root and prevent the potential breaching of the fore dune.

- Jetty A – Scheduled rehabilitation addressing the existing loss of cross section and the addition of engineering features designed to minimize future cross section instability are planned for Jetty A. The cross section repairs are primarily above MLLW, with a majority of stone placement not likely to extend beyond -5 ft below MLLW. In order to address the structural instability of the jetty cross-section, two spur groins will be added and the jetty head (southern most section) will be capped with large stone. The groins will be constructed primarily on existing relic stone and the head capping will be placed on relic as well as jetty stone that is above MLLW. Immediate rehabilitation with small cross section, two spur groins, and head capping.

(2.) Construction measures and implementation activities for all three jetties include the following:

- Storage and staging areas for rock stockpiles and all associated construction and placement activities such as: roadways, parking areas, turn-outs, haul roads, weigh stations, yard area for sorting and staging actions, etc.
- Stone delivery from identified quarries either by barge or by truck. Possible transit routes have been identified. This also includes the construction and use of permanent barge offloading facilities and causeways with installation and removal of associated piles and dolphins.
- Stone placement either from land or water, which includes the construction, repair, and maintenance of a haul road on the jetty itself, crane set-up pads, and turnouts on jetty road. Placement by water could occur via the use of a jack-up barge on South Jetty, but will not occur by other means or on North Jetty to avoid impacts to crab and juvenile salmon migration.
- Regular dredging and disposal of infill at offloading facilities with frequency dependent on a combination of the evolving conditions at the site and expected construction scheduling and delivery. Disposal will occur at existing approved in-water sites.

(3.) A suite of potential projects to provide 7(a) (1) habitat improvement and wetland mitigation actions have been identified as beneficial to listed species. Depending on further development of alternatives within this list, a specific project or combination of projects will be selected and constructed concurrently to provide environmental benefits as portions of the proposed action are completed over time. Estimates for wetland impacts are preliminary and may be reduced when final delineations are completed; therefore wetland restoration may be less than approximations noted, but will be commensurate with impacts from construction activities. These restoration and habitat improvement measures will therefore require additional consultations, and it is anticipated that the proposed AMT will be of assistance in this process. It is anticipated that a programmatic opinion similar to SLOPES Restoration or Limit 8 may be useful to fulfill clearance requirements. Possible restoration measures could include an individual project or a combination of projects and actions such as:

- Excavation and creation of wetlands to restore and improve wetland functions including water quality, flood storage, and salmonid refugia.
- Culvert and tide gate replacements or retrofits to restore or improve fish passage and access to significant spawning, rearing, and resting habitat.
- Dike breaches to restore estuarine brackish intertidal shallow-water habitat for fish benefits.
- Beneficial uses of dredged material from MCR hopper dredge to replenish littoral cells.
- Invasive species removal and control and revegetation of native plants to restore ecological and food web functions that benefit fisheries.

(4.) Due to the long duration of the MCR Jetty Rehabilitation schedule, the Corps proposes formation of a modified Adaptive Management Team (AMT). The Corps suggests annual meetings to discuss relevant design and construction challenges and modifications, technical data, and adaptive management practices as needed. The primary purpose of the proposed AMT and its implementation is to ensure construction, operation, and maintenance actions have no greater impacts than those described in the Biological Assessment, and that terms and conditions of the Biological Opinion are being met. This will also allow confirmation that any necessary construction or design refinements remain within the range and scope of effects described during Consultations. This forum will facilitate continued coordination and updating and allow the Corps to inform agency partners when unforeseen changes arise. Results regarding marine mammal and fish monitoring, wetland mitigation and habitat improvement monitoring, as well as water quality monitoring will also be made available to the AMT in order to fulfill reporting requirements and to address any unexpected field observations. Results of jetty monitoring surveys will also inform the AMT of the repair schedule and design refinements that become necessary as the system evolves over time. This venue will also provide greater transparency and allow opportunities for additional agency input. Final selection and design of the habitat improvement and wetland mitigation proposal will also be vetted through this forum to facilitate obtaining final environmental clearance documents for this component of the MCR proposed action. Potential principal partners include federal (National Marine Fisheries Service, U.S. Fish and Wildlife Service) and State (Washington, Oregon) resource management agencies. The strategy is designed to be consistent with the guidance provided in 65 Federal Register (FR) 35242.

GENERAL TERMS AND FEATURES

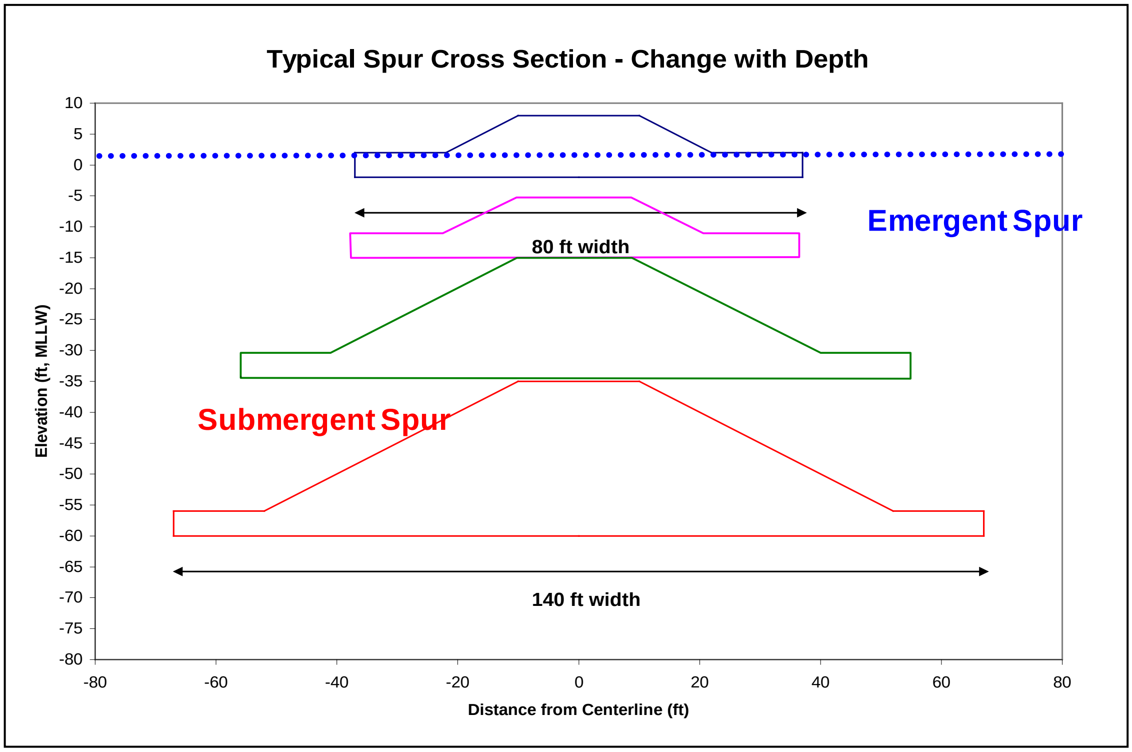
Previously during earlier design phases of the proposed action, the U.S. Geological Survey (USGS) in Menlo Park, California assisted the Corps with evaluating potential improvements and impacts of rebuilding and repairing the lengths of the MCR jetties. The USGS efforts focused on using the Delft-3D model of the Columbia River estuary and adjacent coast (Delft3D 2006) to identify potential changes in circulation, salinity and sediment transport that could result from the offshore re-build of the three jetties. Increased jetty lengths were investigated to determine if they could provide a more sustainable jetty system over the long term. Although rebuild of the jetties is no longer proposed, Corps' engineering staff has also indicated modeling results remain relevant and valid for evaluating jetty performance in the current proposed action, which caps jetty lengths in their current locations (Moritz 2010).

The Corps' Engineering Research and Development Center (ERDC) in Vicksburg, Mississippi was also contracted to conduct a physical model of the jetty cross-section design. The range of structural repair types addressed in the model included crest elevation and crest widths variations, side-slope variations, underwater berms, armor stone, and concrete armor unit options. Both the North Jetty and South Jetty were tested under low and high water conditions. Physical modeling results showed that the primary failure modes for the North and South jetties were high water wave attack and overtopping. These results were used to determine cross-section design options for the jetties that achieve varying levels of structure reliability. The following design components are a result of a combination of these models and other modeling and engineering staff efforts (Moritz and Moritz 2010).

Each MCR jetty consists of three parts. The head is the seaward terminus and is exposed to the most severe wave action. Jetty head design is much more substantial than a typical jetty trunk section due to its increased exposure to wave attack and its critical protective function for the rest of the structure. The trunk forms the connection from jetty head to shore, retains sub-tidal shoals, and confines circulation in the navigation inlet. The root forms the connection from the jetty trunk to shore and prevents accreted landforms from migrating into the navigation channel.

A spur groin is a relatively short structure (in comparison to jetty length) usually extending perpendicular from the main axis of a jetty. Spur groins are constructed: (1) on the ocean or beach side of a jetty to deflect the long-shore (rip) current and related littoral sediment away from the jetty and prevent littoral sediment from entering the navigation channel; and (2) on the channel side of a jetty to divert the tidal or river current away from the channel side toe of the jetty. Spur groins also act to reduce the scour affecting the foundation while increasing the current in the navigation channel, thus reducing the deposition in the channel. In areas where foundation scour threatens the overall stability of the MCR jetties, spur groins constructed perpendicular to the structure facilitate stabilization by the accumulation of sediment along the jetty's foundation. Each spur groin will have a crest width of about 20 feet, and will be constructed using a bedding layer (mixture of gravel and rock) that will be covered with large stone sized for the location and exposure. Submergent spur groins that located at greater depths also typically have wider bases than shallower, emergent groins (Figure 3).

Figure 3. Typical Spur Cross Section - Change with Depth



The ERDC analyzed the hydrodynamics and circulation patterns in the MCR entrance, as well as the potential impacts and effectiveness of placing spur groins on the jetties. This analysis was conducted with the coastal modeling system and other models to select the type, depth, and length of spur groins necessary to protect the each jetty from the processes causing increased scour (e.g., rip currents, eddies). Although the models were also evaluating a potential restoration of the jetties' former lengths, proposed construction of spur groins at each jetty has not changed since modeling was completed. Therefore, Corps' engineering staff has indicated that modeling results remain relevant and valid in their assessment of spur groin performance.

Two potential construction methods could be used for spur groins, either land-based or marine-based depending on location. Barges or similar equipment could be used to dump the bedding layer rock into place and a clamshell would be used to place larger stone on top of the bedding rock layer in locations with sufficient water depth. This type of marine placement activity will not require installation of additional piles or dolphins. Material could also be placed using land-based equipment from on top of the jetty. Land-based construction may require a wide turnout crane placement with over-excavation down to grade as the crane walks back onto the main jetty axis. In addition, the emergent spur groins may be used as turnouts for construction equipment. The land-based construction method could be used for all but the deepest spur groins.

Head capping involves placing much larger armor stone at the terminus of the jetty where the highest degree of enforcement is necessary to withstand conditions. Enforcement could also include the use of concrete armor units (CAU). These will be fabricated off-site and then transported to the head via truck or barge. The armor stone at the head helps avoid recession and loss of length and by protecting the rest of the jetty from unraveling back towards the root.

Repair and rehabilitation are two proposed approaches that specifically describe construction and stone placement actions for the cross-sections and engineered features along the trunks and roots of the jetties. The economics and design model used to select Schedule Repair as the proposed action at the North and South jetties predicts a certain number of repair actions that will be needed to avoid a breaching scenario during the 20-year construction schedule and 50-year operational lifetime of the jetties.

Along certain sections of each jetty, wave cast and erosional forces have in some cases flattened the jetty prism and left a bedding of relic stone with little or only a partially complete jetty prism remaining. The Scheduled Repair approach prioritizes work on specific portions of the jetty so that sections in a greater degree of deterioration will be repaired with rock according to a programmed sequence developed as a result of regular jetty monitoring and inspections. Proposed repair alternatives involve adding limited amounts of stone to trunk, head, and root features in order to restore the damaged cross-sections back to a standard repair template. A repair action is generally triggered when the upper cross-sectional area falls below 30%-40% of its standard jetty template profile (only 30% or 40% of the current jetty structure remains; 60%-70% of the previously existing prism is gone). Then a standard repair template is implemented. For each repair action, a majority of stone placement will occur above MLLW. However, depending on conditions at specific jetty cross-sections, stone could extend deeper than -5 ft below MLLW in order to restore the reach back to the standard repair template. Therefore, repair actions could be slightly greater or smaller depending on the condition of the cross-section being repaired. Stone placement will remain mostly within the prism of the existing jetty and relic stone structures; though it is possible that wave actions and slope angles could result in a small percentage of further rock slipping off the relic slope.

Proposed rehabilitation alternatives generally incorporate engineering components and rock placement along the cross-section of the entire root and trunk. The construction and placement sequence for Immediate Rehabilitation at Jetty A means stone placement activities are initiated at one end of the jetty and are completed continuously in succession without prioritization based on conditions at any particular jetty section. The proposed rehabilitation action on Jetty A is more robust than a repair action and includes a small cross section along the entire length of the jetty. Sections in a greater state of deterioration may receive a relatively larger amount of rock compared to sections with less damage. The rehabilitation cross-section template is expanded slightly beyond the existing prism template. This generally involves stone placement that primarily fits within the existing footprint of the jetty structure or relic stone, but may extend slightly beyond the existing prism. It also generally involves the bulk of the rock placement above MLLW, though it could extend below in some sections, again depending conditions in each reach.
